THE

ENGLISH CYCLOPÆDIA.

NATURAL HISTORY.

CLIVI'NA, a genus of Coleopterous Insects of the family *Scaritidæ*, and section *Geodephaga*. It has the following characters:—Body elongate, somewhat cylindrical; antennæ moniliform, the basal joints rather long (the first longest), the remaining joints short and rounded; palpi with the terminal joint long and pointed; mentum trilobate; thorax nearly square; anterior tibiæ broad and compressed, with two notches externally, leaving three long pointed tooth-like processes; the intermediate pair of legs with one of these external processes on the tibia.

Dejean incorporates with this genus that of *Dyschirius*, but we think without sufficient reason.

These insects are of small size, and live under stones in damp situations, particularly on the margins of rivers, lakes, &c. Their dentated anterior tibiæ enable them to burrow like the Lamellicorn Beetles.

Of the genus *Clivina* but few species are known. In England there are two; the more common is *C. fossor* (or *C. arenaria* of some authors). This species is rather more than $\frac{3}{10}$ths of an inch in length, and of a black or brown colour; the legs, antennæ, and palpi, are reddish. *C. collaris*, the other British species, is rather less than the one just described. It is black, and has chestnut-red elytra, sometimes with a black dash on the suture.

The species of the genus *Dyschirius* are distinguished from those of *Clivina* principally by their having the thorax globular, the terminal joint of the palpi thicker in proportion, and somewhat securiform. The body is generally shorter in proportion, and more convex, or less cylindrical; they are almost always of a brassy metallic colour, whereas the species of *Clivina* are black or brown, and without any metallic hue.

Of the genus *Dyschirius* between twenty and thirty species are known. Their habits are much like those of the genus *Clivina*, but they are less frequently found under stones, and often make cylindrical burrows in the ground in banks at the margin of rivers or other pieces of water. Upwards of twelve species inhabit this country, the largest of which is scarcely more than one-eighth of an inch in length.

CLOANTHITE. [NICKEL.]

CLOT. [BLOOD.]

CLOTHO, a genus of Fossil Bivalve Shells, established by Faujas de Saint Fond. Shell oval, subregular, striated longitudinally, equivalve, subequilateral. Hinge formed by a bifid tooth, curved into a hook, a little larger in one valve than in the other. Ligament external.

CLOTHONIA. [BOIDÆ.]

CLOUDBERRY, a dwarf kind of Bramble, with herbaceous stems, and orange-yellow fruit, found in turfy alpine bogs; it is the *Rubus chamæmorus* of botanists. Its fruit is excellently well flavoured when newly gathered. [RUBUS.]

CLOVE-PINK, a species of *Dianthus*, so called from a supposed resemblance in odour between its flowers and the cloves of the shops. [DIANTHUS.]

CLOVER. [TRIFOLIUM.]

CLOVES. [CARYOPHYLLUS.]

CLUB-MOSS, or SNAKE-MOSS, is a prostrate moss-like plant, with small scaly imbricated leaves, found in alpine or damp situations in most parts of the world. Its fructification consists of little two-valved cases, containing powdery matter. All the species belong to the genus *Lycopodium*; that to which the name is most commonly applied is *L. clavatum*. [LYCOPODIUM.]

CLUNCH, a name given to the lower and harder beds of the Cretaceous Rocks. They are occasionally used for building purposes, and have been especially employed for internal work in cathedrals and other large public buildings. This material stands well if not exposed to accidents from mechanical violence. (Ansted, *Elementary Geology*.)

CLUPE'IDÆ, a family of Fishes of the section *Abdominales*. The *Clupeidæ* are placed by Cuvier between the *Salmonidæ* and the *Gadidæ*: in fact they form the fifth and last division of his section 'Malacopterygiens Abdominaux.' The fishes of this division may be distinguished by their wanting the adipose fin, by having the upper jaw composed of the intermaxillary bones in the middle, and the maxillaries at the sides, and by the body being always covered with scales. Some of the species ascend rivers.

The genus *Clupea*, as now restricted by Cuvier, may be thus characterised:—Maxillaries arched in front; opening of the mouth moderate; upper jaw entire; body compressed and covered with large scales; teeth minute or wanting. To this genus belong the Herring, Sprat, Whitebait, Pilchard, &c.

C. Harengus, Linn., the Herring (French, Le Hareng Commun), is a fish well known. Its characters however will be useful to distinguish it from some allied species; they are as follows:—

Small teeth in both jaws; suboperculum rounded; veins on the infra-orbitals and gill-covers; dorsal fin behind the centre of gravity; this fin commences about half way between the point of the upper jaw and the end of the fleshy portion of the tail; ventrals placed beneath the middle of the dorsal fin; tail forked; length of the head one-fifth of that of the body; the greatest depth of the body one-fifth of the whole length. The upper part of the fish is blue or green, according to the light; the sides, belly, and gill-covers are silvery-white; ordinary length, ten to twelve inches.

The term Herring is the same as the German Häring, which, according to some, is derived from Heer, an army, and is applied to these fishes from their visiting the coasts in such immense numbers.

"The Herring inhabits the deep waters all round the British coasts, and approaches the shores in the months of August and September for the purpose of depositing its spawn, which takes place in October, or the beginning of November. It is during these months that the great fishing is carried on, for after the spawning is over it returns to deep water. The mode of fishing for herrings is by drift-nets, very similar to those employed for taking mackerel and pilchard, with a slight difference in the size of the mesh. The net is suspended by its upper edge from the drift-rope by various shorter and smaller ropes, called buoy-ropes; and considerable practical skill is required in the arrangement, that the net may hang with the meshes square, smooth and even, in the water, and at the proper depth; for according to the wind, tide, situation of their food, and other causes, the herrings swim at various distances below the surface.

"The size of the boat used depends on the distance from shore at which the fishery is carried on, but whether in deep or in shallow water, the nets are only in actual use during the night. It is found that the fish strike the nets in much greater numbers when it is dark than when it is light: the darkest nights therefore and those in which the surface of the water is ruffled by a breeze are considered the most favourable. It is supposed that nets stretched in the daytime alarm the fish, and cause them to quit the places where that practice is followed; it is therefore strictly forbidden." (Yarrell.)

The young are found on our coast during the summer months in great abundance, and are often taken in small-meshed nets used for catching other fishes.

The food of the Herring consists principally of small *Crustacea*, but they have been known to devour the fry of their own species.

C. Leachii, Leach's Herring. This second species of herring was discovered by Mr. Yarrell, and described in the 'Proceedings of the Zoological Society' for 1831, p. 34. An account by the same gentleman is also given in the 'Zoological Journal,' vol. v., where a figure of the species will be found, as well as in his 'History of British Fishes.' The following is Mr. Yarrell's description:—

"The length of the head, compared to that of the body alone, without the head or caudal rays, is as one to three; the depth of the body greater than the length of the head, and, compared to the length of the head and body together, is as one to three and a half; it is therefore much deeper in proportion to its length than our common herring, and has both the dorsal and abdominal lines much more convex; the under jaw longer than the upper, and provided with three or four prominent teeth just within the angle formed by the symphasis; the superior maxillary bones have their edges slightly crenated; the eye is large, in breadth full one-fourth of the length of the whole head; irides pale yellow; the dorsal fin is placed behind the centre of gravity, but not so much so as in the common herring; the scales are smaller; the sides without any distinct lateral line; the edge of the belly carinated, but not serrated; the fins small. The fin-rays in number are—dorsal, 18; pectoral, 17; ventral, 9; anal, 16; and caudal, 20. Vertebræ, 54.

"The back and upper part of the sides are deep blue, with green reflections, passing into silvery-white beneath. The flesh of this species differs from that of the common herring in flavour, and is much more mild."

Mr. Yarrell first discovered this species when examining the various kinds of fishes caught by the fishermen engaged in taking sprats.

C. Sprattus, the Sprat, called in France Le Melet, Esprot, or Harenguet. This fish has by many authors been confounded with the young of the herring. It is however distinct, and its characters were first pointed out by Pennant; they are as follows:—proportions nearly the same as those of the herring, but the depth of the body is greater in proportion than in the young of that species; the gill-covers are not veined; the teeth of the lower jaw are so minute as to be scarcely visible to the touch. The dorsal fin is placed farther back, and the keel to the abdomen is more acutely serrated than in the herring.

Sprat-fishing commences in the early part of November; hence in season they immediately follow herrings, and the markets continue to be supplied with them during the winter months. Like the herrings these fishes inhabit the deep water during the summer: they are so plentiful as to be frequently used for manuring the land, and are often sold as low as 6*d.* per bushel.

C. alba (Yarrell), the White-Bait; French, Blanquette; German, Breitling. This fish has been supposed to be the young of the Shad. Mr. Yarrell however, upon a careful investigation of the subject, ascertained it to be a distinct species. Its distinguishing characters are:—Length of the head compared with that of the body, and not including the tail, as two to five; depth, as compared to the whole length of the fish, as one to five; keel of the abdomen distinctly serrated, but not so sharp as in the Shad. The dorsal fin commences half way between the tip of the muzzle and the end of the tail; the upper jaw is slightly crenated, the lower jaw is the longer, and is smooth. Its colour is silvery-white, growing greenish on the back; the body is more compressed than in the herring, and the keel to the abdomen is more sharply serrated than in either that fish or the sprat.

The White-Bait is caught in great abundance in the Thames as high up as Woolwich and Blackwall. The fishing commences about the beginning of April, and is continued to September. "When fishing as high as Woolwich," says Mr. Yarrell, "the tide must have flowed from three to four hours, and the water become sensibly brackish to the taste, before the White-Bait will be found to make their appearance. They return down the river with the first ebb-tide; and various attempts to preserve them in well-boats in pure fresh water have uniformly failed." The food of the White-Bait consists of small *Crustacea*. Dr. Parnell states that he has taken White-Bait in the Frith of Forth in considerable numbers during the summer months. It is also taken in the Ex and other rivers of England. When fried with flour it is a favourite dish with all classes of the community; and amongst the English few entertainments are more popular than White-Bait dinners. It is the young of the season that are taken in such large numbers in the Thames. The adult White-Bait are taken on the Kentish and Essex coasts throughout the winter.

C. Pilchardus, the Pilchard, Le Celan of the French. In size this fish resembles the herring; it is also nearly of the same form, but rather thicker, and of greater proportionate depth; the scales are larger, the head is shorter, the suboperculum is square, and the dorsal fin is more forward in position; the gill-covers are distinctly veined.

This fish is caught off the coast of Cornwall in great abundance; the fishing commences in July. The food of the Pilchard consists of small shrimps and other crustaceous animals.

C. alosa, Linnæus (*Alosa finta*, Cuvier), the Shad, is another fish belonging to this group. Cuvier separated this, together with several other species, from the true *Clupeæ*, from the circumstance of their having the upper jaw deeply notched in the middle.

Two species of Shad are found off the British coast; the first, the Twaite Shad of Yarrell, known generally by the name of Shad (*Alosa finta*), is about 14 inches in length; its colour is brownish-green on the back, or inclining to blue in certain lights; the rest of the body is silvery; five or six dusky spots are observed on each side, and are disposed longitudinally, the first close to the head, and the others at short intervals; the length of the head, as compared with the body, is as one to five; the body rather exceeds this measurement in depth; the jaws are furnished with distinct teeth, and the tail is deeply forked.

This fish is found in the Severn and Thames in tolerable abundance. The principal fishing season for the Shad in the Thames is about the second week of July. They begin to ascend the river about May for the purpose of depositing their spawn, and this being done they return to the sea about the end of July.

In former times the Shad was caught as high up the river as Putney; it now rarely passes London Bridge, and is caught in the greatest abundance a little below Greenwich. Its flesh is dry, and therefore not much esteemed for the table.

The second species of Shad, the Allice, or Allice Shad of Yarrell (*Alosa communis*), is considerably larger than the one just described, being from two to three feet in length: it may moreover be distinguished by its having only one spot on the side of the body, near the head, and that is sometimes scarcely visible: the jaws have no distinct teeth, and the scales of the body are rather smaller in proportion, though they are large in both species.

The Allice Shad is plentiful in the Severn, but of rather rare occurrence in the Thames.

C. encrasicolus (Linnæus), the Anchovy (*Engraulis encrasicolus*, Fleming; *Engraulis vulgaris*, Cuvier). This fish, which is a favourite condiment, is a native of the British seas. It has been taken in the river Dart; and Mr. Couch, in his 'Cornish Fauna,' says, "This fish abounds towards the end of summer, and if attention were paid to the fishery enough might be caught to supply the consumption of the British Islands. It is abundant on the coast of Wales:" and Mr. Yarrell says, "The Anchovy is reported to be at this time an inhabitant of the large piece of water below Blackwall called Dagenham Breach; and in May 1838 I received one that was caught in the Thames, where however this species is so little known that the specimen referred to was sent to me with a request to know what fish it was." [ANCHOVY.]

CLU'SIA, a genus of Plants belonging to the natural order *Clusiaceæ* or *Guttiferæ*, named after Charles de l'Ecluse, or Clusius, one of the most celebrated botanists of the 16th century. [CLUSIUS, CAROLUS, in BIOG. DIV.] It has a calyx of four imbricate coloured permanent sepals, the outer ones smallest, usually doubly bracteate at the base; the corolla of 4-6 deciduous petals; the stamens numerous and free in the male flowers; few, sterile, and connected in the female flowers; the style absent; the stigmas 5-12, radiately peltate, sessile, permanent; the flowers usually polygamous; the ovary surrounded by a short staminiferous nectary; the capsule fleshy, 5-12-celled, opening by valves from the top to the base, with a dissepiment in the middle of each valve; the placenta thick, triangular, central; the seeds egg-shaped, surrounded by pulp, suspended from the inner angle of the cells; the embryo straight, inverted; the cotyledons separable. This definition includes the genus *Quapoya* of Aublet. The species are trees and shrubs, usually parasitical, and yielding a vield resinous juice, of a balsamic flavour; hence they are called in England Balsam-Trees.

C. rosea, Rose-Flowered Balsam-Tree, has polygamous flowers, a rose-coloured 5-6-sepaled calyx; the tops of the dense nectaries awl-shaped; 8-12 stigmas; the leaves obovate, obtuse, veinless, sometimes emarginate, on short striated petioles. It is a native of the Carolinas and St. Domingo, and other parts of tropical America. The fruit is green, and of the size of an apple, with eight lines running like the meridians of a globe: when it ripens it opens at these lines, disclosing its scarlet seeds lying in the midst of a pulpy mucilaginous matter, similar to the pomegranate. The whole tree is very handsome, but few fruits offer so beautiful a piece of mechanism. "It grows on rocks, and frequently on the trunks and limbs of trees, occasioned by birds scattering or voiding the seeds, which being glutinous, like those of the mistletoe, take root in the same manner; but the roots not finding sufficient nutriment spread on the surface of the tree till they find a decayed hole or other lodgment wherein is some small portion of soil: the fertility of this being exhausted a root is discharged out of the hole till it reaches the ground, where it fixes itself, and the stem becomes a large tree." (Loudon.) The resin collected from this plant is used as an external application in veterinary medicine, and also is employed for covering boats instead of tallow and pitch.

C. alba has hermaphrodite flowers, a many-leaved calyx; corolla with 5-8 petals; tops of nectaries retuse, or with 5-10 short stamens;

Rose-Flowered Balsam-Tree (*Clusia rosea*).

1, an expanded flower; 2, a calyx seen from below; 3, the ovary, with a part of the calyx cut away; 4, a transverse section of a fruit.

stigmas 5-6; leaves like the preceding, but not emarginate. An elegant tree, native of South America, and epiphytical on larger trees. The trunk is frequently a foot in diameter. It abounds in a balsamic juice of a green colour, which becomes brown on being exposed to the air. The fruit is scarlet, and contains its seeds embedded in a scarlet pulp. Birds are very fond of the seeds, and pluck them out of the fruit while hanging on the tree. The Caribbees use the juice for painting the outside of their boats. The flowers are white, but not handsome.

C. Quapoya has stalked diœcious flowers; the calyx of 5 or 6 sepals; the corolla of 5 or 6 yellow petals; the nectary short, 4-5-lobed; stigmas 5; fruit globose; leaves obovate, acute. It is a native of the woods of Guyana, where it is called Quapoy. It is a climbing shrub with yellow flowers, and when cut into yields a white transparent juice. *C. panapanari* is a similar plant, yielding a yellow juice. *C. flava* is a tree closely resembling *C. alba*. *C. flava* is said by Endlicher to yield the Hog-Gum of Jamaica. The flowers of *C. insignis* weep a considerable quantity of resin from the disc and stamens. Von Martius says he obtained an ounce from two flowers.

All the species grow well in a light sandy loam, and cuttings root freely in sand under a hand-glass in heat. The pots in which the plants are grown require to be well drained with potsherds.

(Don, *Dichlamydeous Plants*; Loudon, *Encyclopædia of Plants*.)

CLUSIA'CEÆ, or GUTTIFERÆ, *Guttifers*, a small natural order of Exogenous Plants, inhabiting the hotter parts of tropical countries in both the Old and New World. They are readily known by their coriaceous opposite leaves, with very fine veins running parallel with each other in a gentle curve from the midrib to the margin; by the absence of stipules; their calyx composed of several sepals regularly overlapping each other, and bearing a definite proportion to the petals; their numerous stamens; and their superior ovary, which is in most cases many-celled and many-seeded, with a peltate radiant stigma. Their fruit is succulent, juicy, and in many cases resembling a large apple or orange. The Mangosteen (*Garcinia Mangostana*) is probably the most delicious of any known; but it has never been seen in a fresh state in Europe, for the tree will hardly exist out of its native humid heated atmosphere in the Indian Archipelago. The most remarkable product of this order is an acrid, purgative, yellow gum-resin. In one of its forms this is the Camboge or Gamboge of commerce. This substance is well known as a yellow pigment, as also a purgative medicine. The plant which yields the Gamboge of commerce is still unknown. The London College of Physicians in their 'Pharmacopœia' refer it to some species of *Garcinia*, others refer it to species of *Cambogia*, *Xanthochymus*, *Hebradendron*, and *Stalagmitis*. The East Indian Tacamahaca is yielded by a species of *Calophyllum*. [CALOPHYLLUM.] The Butter or Tallow-Tree of Sierra Leone is the *Pentadesma butyracea*. The fruits of many species are esteemed, besides the Mangosteen. The Mammee Apple, or Wild Apricot of South America, is said to be very delicious. Its seeds are anthelmintic; its flowers yield on distillation a spirit known as Eau de Creole, and wine is obtained by fermenting its sap. The large berries of the Pacouryuva (*Platonia insignis*) of Brazil are highly prized on account of their delicious flavour. The fruits of several species of *Garcinia* [GARCINIA], besides the Mangosteen, are brought to table in the countries where they grow, but they are regarded as very inferior. The blossoms of *Mesua ferrea* are remarkable for their fragrance, and are sold in the bazaars of India under the name of Nagkesur.

The affinities of the order *Clusiaceæ* are with *Hypericaceæ*, *Ternströmiaceæ*, and *Ebenaceæ*. The order contains 30 genera and 150 species.

(Lindley, *Vegetable Kingdom*.)

CLUTHALITE, a Mineral occurring in large nodules in amygdaloid, constituting a congeries of imperfect crystals with rough surfaces. Colour flesh-red. Hardness 3·5. Brittle. Lustre vitreous. Opaque or translucent on the edges only. Specific gravity 2·166. Found in the Kilpatrick Hills, near Dumbarton. An analysis by Dr. Thomson gives—

Silica	51·266
Alumina	23·560
Peroxide of Iron	7·306
Soda	5·130
Magnesia	1·233
Water	10·553

CLYMENIA. [CLYMENIDÆ.]

CLYMENIDÆ, a family of Fossil *Mollusca* belonging to D'Orbigny's order *Tentaculifera* of the class *Cephalopoda*. It embraces several genera, which are divided into groups according as their partitions are without or possess a single lateral lobe. To the first division, or those without lateral or dorsal lobes, belong the genera *Melia*, *Cameroceras*, *Campulites*, and *Trochilites*. To the second division, or those in which the partitions have one lateral lobe but no dorsal lobe, the genera *Clymenia* and *Megasiphonia* are referred.

The genus *Clymenia*, the type of this family, was first separated from the *Goniatites*, to which it has a strong resemblance, by Count Munster. The species of *Clymenia* have the variations of form and surface seen in *Goniatites*. [GONIATITES.] By some writers the *Clymenidæ* are referred to the *Nautilidæ*, with which they have no doubt a stronger affinity than with *Ammonitidæ*, the family to which *Goniatites* must be referred.

The genus *Clymenia* has a discoidal shell with slightly lobed septa, and an internal siphuncle. Several species were described by Count Munster from some calcareous bands in the Palæozoic strata of the Fichtelgeberge. Some of these, with others, occur in the strata of Devon and Cornwall, and also in North America.

CLYPEASTER. [ECHINIDÆ.]

CLY'PEUS, the generic name given by Klein and Leske to a group of Fossil *Echinidæ*, frequent in the Oolitic Formations. *C. sinuatus* of Leske is the largest British species. *C. clunicularis* of Smith is now ranked as a *Nucleolites*.

CLY'THRA, a genus of Coleopterous Insects of the family *Chrysomelidæ*. The insects of this genus generally have the body more or less cylindrical; the antennæ short, with the basal joint thick, the two following joints short, and the remaining (with the exception of the apical joint) serrated, that is, produced internally, so as to resemble the teeth of a saw. The head is placed vertically, and inserted into the thorax, so as to be scarcely visible from above; often larger in the male than the female. The legs are moderately long, rather thick; in the males the anterior pair are often considerably larger than the two posterior pairs; the penultimate joint of the tarsi is bilobed.

The larvæ of these insects (at least those that are known) inhabit a coriaceous tube, which they drag about with them.

The *Clythræ* reside on trees and shrubs, and those found in this country appear in the beginning of the summer. The species are very abundant, and seldom adorned with metallic colours. In England we have five species, the most common of which is *C. quadripunctata*. This is not quite half an inch in length, and black; the elytra ochre-coloured, with four black spots, two near the base, and two near the middle. The next species which is not uncommonly met with is *C. tridentata*. This beetle is rather less than the last, and of a blue-green colour, thickly and finely punctured above; the elytra are pale-yellow and immaculate; the anterior pair of legs in the male are elongated.

CLY'TUS, a genus of Coleopterous Insects of the section *Longicornes* and family *Cerambycidæ*.

The species of the genus *Clytus* (a genus established by Fabricius) form a well-marked group among the *Cerambycidæ*, and are chiefly distinguished by their having the palpi short and nearly equal, the terminal joint thicker than the others, and truncated at the apex; the head narrower than the thorax, and the latter nearly globular or approaching to a cylinder. The body is elongate, and nearly cylindrical; the antennæ are shorter than the body, and filiform; the basal joint is rather thick, and the terminal joints are sometimes incrassated; the legs are moderately long.

These insects are generally of moderate size, and have the elytra adorned with arcuated fasciæ; their ground colour is usually black or brown, and the markings yellow.

About 90 species of this genus have been discovered, and they appear to inhabit every quarter of the globe; 5 are recorded as British, of which the more common are *C. mysticus*, *C. Arietis*, and *C. arcuatus*. *C. mysticus* is about half an inch in length; colour black; the base of the elytra red-brown; three bent white fasciæ are situated near the middle of the elytra; and there is a white patch at the apex. This species is common in the neighbourhood of London. We have frequently found its larva in the rotten wood of old blackthorns.

C. Arietis is about the same size as the last; its colour is black; legs and base of the antennæ reddish; the former with the thighs of the two anterior pairs blackish; thorax with a yellow band on the anterior part, and another on the posterior; scutellum yellow; elytra with four yellow bands.

This insect is frequently met with in gardens and woods in the neighbourhood of London and elsewhere. When handled it makes a peculiar noise, which seems to be produced by the friction of the thorax against the smooth part of the abdomen which is inserted in that part. Many of the *Cerambycidæ* have this power.

C. arcuatus is less common than either of the preceding species; it somewhat resembles the *C. Arietis*, but is considerably larger and broader in proportion. The antennæ are entirely of a reddish-yellow colour, the legs are coloured as in the last-mentioned species; the thorax has a yellow band on the fore part, and an interrupted band in the middle; the elytra have three yellow bands, and towards the base three spots of the same colour; the scutellum is also yellow.

CNEMIDIUM, a genus of *Spongiadæ*, proposed by Goldfuss for some fossils usually ranked as *Mantellia* and *Siphonia*.

COAGULATION. [BLOOD.]

COAITA, or QUATA. [ATELES.]

COAITIMONDI. [VIVERRIDÆ.]

COAL, an opaque combustible mineral substance of a black or brown colour, and in all cases giving indications of having been derived from a vegetable source. Such is a definition that would probably include all those substances which are used in domestic economy and the arts for the purposes of combustion, and popularly called Coal. At the same time it should be stated that the term has at present no special scientific application that is universally admitted, and each investigator thinks himself at liberty to apply the term in accordance with his own views. As the knowledge of chemical principles and methods of investigation have advanced, substances which at one time were regarded as identical have been shown to have a very different chemical composition as well as microscopic structure. This has led in some instances to the discussion of the question, What is Coal?

For instance, in our courts of law, one of the most recent cases—that of Gillespie *v.* Russell—was tried in Edinburgh during the present year (1853). In this case, by an agreement for a lease entered into between the plaintiffs and defendants, the former agreed to grant to the latter a lease of "the whole coal, ironstone, iron-ore, limestone, and fire-clay, but not to comprehend copper or any other mineral whatsoever." It was alleged by the plaintiffs that, although the defendants had in the course of their operations come upon iron-ore and ironstone, coal, and fire clay of workable value, they had neglected these, and had chiefly worked a certain mineral substance which the plaintiffs contended was not let to the defendants, not being one of the mineral substances specified in the agreement. This mineral was of much greater value, it was stated, than any which the defendants were permitted to work. Although used as a combustible material, it was alleged that this substance was not coal, and that its chemical, microscopical, and mineralogical characters were not those of coal. On the other hand, it was asserted by the defendants that the mineral in question was coal; that they had been led to seek a lease of the Torbane-Hill estate from the fact that on the adjoining lands of Boghead this mineral existed, and was worked and sold as coal, being known in the markets by the name of the 'Boghead Gas Coal.' This mineral, they contended, was true coal belonging to the variety known as Cannel or Parrot Coal. This trial was interesting on account of the large number of chemists, mineralogists, geologists, and microscopists examined, who appeared in about equal numbers on either side; one set of them contending that the mineral was coal, whilst the others contended it was not. A large amount of interesting facts on the nature of coal and the substances with which it is found associated was laid before the jury, who came to the conclusion that, whatever might be the result of scientific investigation in more rigorously defining the nature of coal and limiting the use of that term, both plaintiffs and defendants called this mineral coal when the lease was drawn up, and therefore gave a verdict in favour of the defendants.

The same question which has thus been debated in Scotland has also come before the law courts of Germany and of the United States of America with the same differences of opinion; and we refer to these cases to show the difficulty of defining accurately this well-known substance. It may be regarded in the present state of our knowledge as one of those instances in which the typical form is lost by irregular combination with other and different substances.

That Coal is and must be of vegetable origin seems to be agreed upon by all inquirers, but the question of how to determine that origin in particular cases is the difficulty. Again, it is well known that coal after it is deposited undergoes certain chemical changes by which substances with a very definite chemical character are produced, such as bitumen, paraffine, &c. These, mixed with the coal itself and the earthy matters around, may form compound substances about whose nature there may be considerable difference of opinion. This is not improbably the case with the Torbane-Hill mineral, and will account for the peculiarity of both its chemical and microscopical characters.

Coal presents itself ordinarily in a massive form, and is brittle or sectile. It has a hardness of 2·5, and a specific gravity of 1·2 to 1·75. It is opaque, and has a black or brown colour. Its chemical composition is distinguished by the presence of carbon; in addition, it also yields, on ultimate analysis, hydrogen, oxygen, and nitrogen. On burning it leaves an ash which consists of varying quantities of silica, alumina, and oxide of iron. The carbon and hydrogen are often found chemically united to form bituminous compounds which are mixed with the coal. It is the presence of these compounds which causes coals to burn with a bright flame; at the same time they give off a bituminous odour. Those destitute of bituminous compounds burn with a pale blue flame, due to carbonic oxide, which is formed in these cases through the decomposition of the water present.

The following table, founded on Mr. Mushet's Analysis of Coal, is taken from Professor Ansted's 'Elementary Course of Geology, Mineralogy, and Physical Geography:'—

Analyses of various Kinds of Coal.

Locality.	Description of Coal.	Specific Gravity.	Carbon.	Bitumen Volatile Matter. Water.	Ash.
1. Newcastle-upon-Tyne	Bituminous	1·257	57·00	37·60	5·40
2. Lancashire	Ditto	1·260	54·90	40·48	4·62
3. Ditto	Cannel	—	56·40	41·00	2·60
4. North Wales	Bituminous	—	02·72	36·00	1·28
5. Staffordshire Potteries	Ditto	—	02·40	34·10	3·50

36. America, Nova Scotia	Bituminous	1·321	58 80	28·20	12·95
37. America, Pennsylvania	Anthracite	—	92·60	2·25	2·25

The following analyses of the Torbane-Hill Mineral and Cannel Coal were presented by Dr. Fyfe at the trial in Edinburgh:—

	Carb.	Hyd.	Oxy.	Nit.	Sulp.	Ash.
Torbane-Hill Mineral	60·25	8·8	3·6	1·5	9·3	25·6
Capeldrae Cannel Coal	56·7	0·8	8·8	1·9	0·25	25·4

The Torbane mineral is only remarkable amongst other coals for the large quantity of sulphur it contains.

A large series of coals, more especially Welsh, has been submitted to chemical examination by order of the government; and the following table is taken from the 'Report on the Coals suited to the Steam Navy,' by Sir Henry De la Beche and Dr. Lyon Playfair, in the second volume of the 'Memoirs of the Geological Survey of Great Britain:'—

Locality, or name of Coal.	Specific Gravity of Coal.	Carbon.	Hydrogen.	Nitrogen.	Sulphur.	Oxygen.	Ash.	Per Centage of Coal left in each.

Coal differs considerably in its physical properties, and it has obtained various names in the markets. The mineralogist generally divides it into two varieties:—

First, Coal without Bitumen.

Second, Coal with Bitumen.

The first variety is known by the general name of *Anthracite.* It has however various local names. [ANTHRACITE.] It is sometimes very hard, and has a high lustre, and is often iridescent. Besides being used for fuel it is often made into inkstands, small boxes, and other articles of use. This is more especially the case with the Anthracite of America. It is the most common form of coal in the Welsh beds.

The Bituminous varieties of Coal present greater differences of structure and appearance, and have a larger number of names. By the above analyses it will be seen that the quantity of Bitumen, or substances resembling it [BITUMEN], differ very much in different specimens of coal. It is generally softer and less lustrous than Anthracite, although occasionally specimens exhibit a very brilliant fracture. Its specific gravity is less than that of Anthracite, seldom exceeding 1·5, whilst the specific gravity of Anthracite ranges from 1·3 to 1·75. The kinds of this coal are known by various names.

The following are analyses of the different kinds of Coal as they occur in the Newcastle beds:—

	Splint Coal.	Caking Coal. No. 1.	Caking Coal. No. 2.	Cherry Coal.
Density	1·302	1·274	1·280	1·266
Carbon	74·061	83·588	87·809	84·694
Hydrogen	8·254	5·150	5·159	5·054
Nitrogen and Oxygen . .	4·673	8·743	5·139	8·476
Ash	13·012	2·591	1·393	1·576
Relative heat by the same weight of Coal	110·840	114·080	122·560	116·630
Relative heat by the same volume of Coal	108·090	111·310	119·030	112·070

Pitching or *Caking Coal* is known by its velvet or grayish-black colour. When first thrown on a fire it breaks into small pieces, but on the continued application of heat the pieces again unite into a solid mass or cake. It burns readily with a yellow flame, but on account of its caking quality it is likely to clog the fire unless it is frequently stirred. The Newcastle beds mostly yield this form of coal.

Cherry Coal resembles in external appearance the pitch coal, and when exposed to heat it cracks and flies, but does not cake. It is very brittle, and on this account much loss is occasioned in mining it. It burns with a clear yellow flame. This kind of coal occurs in the Glasgow beds.

Splint Coal is a variety found in connection with the last, and is remarkable for its hardness; for which reason it is sometimes called Hard Coal. It is also found at Glasgow.

Cannel Coal has little lustre, is very compact and smooth in its texture, and breaks with a large conchoidal fracture. It burns very readily, giving out a clear yellow flame without melting. In consequence it has been employed for the making of candles—hence its name. It is often employed for making inkstands, snuff-boxes, and other articles of use. At the Great Exhibition of 1851 several models of public buildings, monuments, &c., were exhibited, formed of Cannel Coal.

The above coals are those most commonly burned. Their goodness for heating is tested by the quantity of water they evaporate. The following are the results of some recent experiments:—

	lb.	oz.
Common Scotch Bituminous Coal . . .	5	14
Carr's West Hartley Main (Newcastle) . .	7	5
Merthyr Bituminous Coal	8	0
Pure Welch Anthracite	10	8½

From which it will be seen that the heating power of anthracite nearly doubles that of some bituminous coals.

Brown Coal, Wood Coal, Lignite, are names given to less perfect varieties of coal than the last. Specimens of these coals have a brownish-black colour, and burn with an empyreumatic odour.

On placing sections of Lignite under the microscope, the structure of the wood of the plant forming it can be readily detected. This is not the case with the other kinds of coal, where, although the woody fibre can be frequently made out, it has evidently undergone considerable change. Professor Quekett, on this ground, proposes to confine the term Coal to those fossil or mineral substances alone which are evidently made up of the woody tissue of plants. He maintained that the Torbane mineral was not coal, on the ground that it was not composed of the debris or remains of vegetable woody tissue. Although woody and vascular tissue can be seen in the Torbane mineral, Professor Quekett maintains that this has been accidentally introduced, and that no true vascular or spiral tissue is found in coal.

The term *Brown Coal* is frequently applied to coal more recently deposited than that of the great coal-beds of the world, and this quite independent of its structure or any peculiarity in combustion. *Lignite* is also a term applied to the semi-carbonised forms of wood which are frequently found in deposits later than those of the coal deposits. Most of these varieties of coal contain a large quantity of water, and the quantity of matter given off at a moderate heat by distillation is at least equal to that of the carbon contained.

"*Dysodil* is a yellow or grayish highly laminated substance, often found with lignite, and burning vividly, and spreading an odour of assafœtida." (Ansted.)

Jet is another variety of coal belonging to the bituminous series. It sometimes occurs in elongated reiform masses, and sometimes in the form of branches with a woody structure. It is soft and brittle, with a conchoidal fracture. Its specific gravity is but little greater than that of water. It is opaque, of a velvet-black colour, and has a brilliant and resinous lustre. It is found in Saxony, and also in the Prussian amber-mines in detached fragments. It is sometimes washed up on the shores of Great Britain. The finer sorts are used in the manufacture of ornaments and trinkets of various kinds. The coarser sorts are burned as fuel. It gives out when burned a greenish flame and a strong bituminous smell, and leaves a yellowish ash. It contains about 37½ per cent of volatile matter.

For an account of the origin of Coal, and the beds of Coal on the surface of the earth, see COAL FORMATION and COAL PLANTS.

COAL FORMATION. That part of the Carboniferous System of Rocks which lies above the Limestone Shale and Mountain Limestone is called the Coal Formation. The deposits constituting this formation consist of a series of alternating beds of sandstone and shales, between which lie beds or seams of coal. These deposits generally lie upon a rock called the Millstone Grit. The following is a synopsis of the Carboniferous System as it is developed in two of the most typical coal districts in the British Isles. These two districts are South Wales and Derbyshire.

In South Wales we get, resting on the Old Red-Sandstone, a band of about a hundred feet in thickness, of black fossiliferous shale, called the Lower Limestone Shale, over which are beds of thick limestone, called the Mountain or Carboniferous Limestone. The following is a synopsis of the whole formation, taken from the published sections of the 'Geological Survey of Britain' (ascending order):—

1. Lower Limestone Shale, about 100 feet.
2. Carboniferous Limestone; limestone, with occasional partings of black shale; from 500 to 1500 feet.

3. Millstone Grit, or Farewell Rock; white quartzose sandstone and conglomerate, 300 to 600 feet.

4. Coal-Measures; a great series of alternations of sandstones and shales, with occasional beds of coal; from 8000 to 12,000 feet in total maximum thickness.

In the Derbyshire district we get the following groups or series:—

1. Mountain Limestone; the base of which is not exposed, consisting principally of thick limestone, occasionally interstratified with black shales, and exceeding 1200 feet.

2. Limestone Shale; black shales, with their interstratified limestones; in some places 400 to 650 feet.

3. Millstone Grit; strong sandstones, with occasional small conglomerate, interstratified with shales and a few small beds of coal; about 1700 feet.

4. Coal-Measures; alternations of sandstone and shale, with beds of coal and ironstone; total thickness, 2700 feet and more.

Proceeding from the Derbyshire district towards the north, a gradual change takes place in the Carboniferous Formation in such a way that it becomes more and more a series of Coal-Measures from top to bottom. The Millstone Grit is never anything more than the lower part of the Coal-Measures in which beds of strong sandstone occur. These as we proceed north become more and more split up and interstratified by beds of shale and occasional beds of coal. The Limestone Shale, too, of Derbyshire farther north becomes split up by beds of gritstone and limestone, and still farther north by beds of coal. Lastly, the Mountain Limestone itself becomes split up and interstratified first by beds of shale, then by beds of shale and sandstone, and lastly, on the borders of Scotland, by shales, sandstones, and coals.

In the midland counties of England—namely, in Leicestershire, Warwickshire, Staffordshire, and Shropshire—the Carboniferous Formation consists simply of the upper group of the formation of the Coal-Measures. Little patches of Mountain Limestone are found below them in one or two spots in the first and last named counties; but usually the Coal-Measures rest directly and unconformably on Silurian and still older rocks. In Staffordshire several beds of coal come together by the thinning out of the intermediate measures, and make a mass of coal which in some places is upwards of 30 feet thick, in from 10 to 13 beds.

In Scotland the Carboniferous Formation admits of no subdivisions into groups. Immediately above the Old Red-Sandstone are Coal-Measures containing beds of coal, over which are thick encrinital limestones interstratified with shales, so that no single mass of limestone is more than 40 feet thick. The whole series of Carboniferous rocks in Scotland is said to be upwards of 6000 feet thick, the whole being Coal-Measures with interstratified beds of limestone in the lower portion, representing the Mountain Limestone of England. The whole series is composed of materials in the following proportions:—

	Feet.
Sandstone	3300
Shale	2160
Limestone	306
Coal	180
Clay	132
	6078

These materials are so disposed that there never is an unbroken set of beds of more than the following thickness of each sort:—

	Feet.
Sandstone	200
Shale	130
Limestone	40
Coal	13
Clay	28

Small bands and nodules of clay-ironstone are found occasionally in all the shales and clays of the Carboniferous rocks of England, Scotland, and Ireland; but though of economical value, they are not of great geological importance.

In Ireland the Carboniferous rocks consist in the south and west of two subdivisions—Carboniferous Limestone and Coal-Measures. The Carboniferous Limestone, the maximum thickness of which is about 3000 feet, is locally again subdivided into three parts—A. Lower Limestone. B. Calp, a series of dark limestones, interstratified with black shale. C. Upper Limestone. The Coal-Measures consist of alternations of shale and sandstone, with a few thin beds of coal principally anthracite or culm, and have a thickness of more than 2000 feet in the Queen's County. In the north of Ireland the Carboniferous rocks seem to assume more of the type of those of Yorkshire and the north of England. The Coal-Measures are still confined to the upper portion; but the lower part seems to consist of alternations of shale and sandstone with various thick beds of limestone, so that it may be doubted whether the subdivisions of the Carboniferous Limestone of the centre of Ireland can be accurately traced into the north or north-west.

The Carboniferous Formation of Belgium admits of a three-fold subdivision (ascending order):—

1. Arenaceous Shales; gray shales, limestones and pisolitic iron-ore, over which are gray sandstones and anthracite.

2. Limestone Group; cunoidal, dolomitic, and productus limestones, with chert and anthracite.

3. Coal-Measures; shale and sandstone, with coal.

The formation is found also at St.-Etienne in central France, where it appears to consist of conglomerate and sandstone below, and shale and sandstone above, with beds of coal.

In Westphalia there are black shales below, passing up into black limestones, and those into lighter-coloured limestone, which are covered by black shales and sandstone in which beds of coal occur.

In Russia there are, according to Sir R. Murchison, two types of the formation. The northern type consists of (ascending order):—

1. Sands and Shales with coal.

2. Dark-Gray Productus Limestone, Yellow Magnesian Limestone, White Limestone of Moscow, shale and sandstone, and gray, white, and yellow limestone.

3. Limestones, calcareous grits, and flagstones capped by conglomerate.

In this type the coal is confined to the base of the formation.

The southern type consists of:—

1. Sands and Shales without coal.

2. Productus Limestone with shales, sandstones, and thin limestones, with many beds of coal.

3. Limestone, calcareous grits, and flagstones, with traces of coal, capped by sandstone containing coal plants.

In this type the most coal occurs about the centre of the formation.

The above remarks, taken from Mr. Jukes's admirable 'Introduction to Physical Geology,' will serve to show the relation of the deposits of Coal to the other rocks and substances with which it is found associated. The Coal-Measures above referred to occupy definite and limited areas of somewhat considerable extent in various parts of Europe, Asia, America, and the islands adjacent. The following is an estimate of the annual production of coals in various parts of the world as given by Professor Ansted:—

Countries.	Coal Area in Square Miles	Proportion to Area.	Total Yearly Production in Tons.
British Islands	12,000	1— 10	32,000,000
France	2,000	1—100	4,150,000
Belgium	520	1— 22	5,000,000
Spain	4,000	1— 52	550,000
Prussia	1,200	1— 90	3,500,000
Bohemia	1,000	1— 20	—
United States of America	113,000	1— 20	4,000,000
British North America	18,000	2— 9	(?)

Table of the Principal Coal-Fields of the British Islands. From Professor Ansted.

The following arrangement is that of Messrs. Conybeare and Phillips, and from its simplicity will serve as a plan for some general remarks on the coal-fields of Great Britain:—1. The great northern district, including all the coal-fields north of the Trent. 2. The central district, including Leicester, Warwick, Stafford, and Shropshire. 3. The western district, which may be subdivided into north-western, including North Wales; and south-western, including South Wales, Gloucester, and Somersetshire.

Coal-District North of the Trent.—This great coal formation encircles the whole Penine mountain chain on the east, south, and north; not however in one uninterrupted line, but in a series of detached coal-fields. 1. The Coal-Field of Northumberland and Durham. 2. Some small detached Coal-Fields in the North of Yorkshire. 3. The Coal-Field of South Yorkshire, Nottingham, and Derby. 4. The Coal-Field of North Stafford. 5. The South Lancashire Coal-Field. 6. The North Lancashire Coal-Field. 7. The Whitehaven Coal-Field.

1. The Coal-Field of Northumberland and Durham commences near the mouth of the river Coqnet on the north, and extends nearly to the Tees on the south. As far as Shields the sea is its boundary on the east; from that point it leaves a margin of a few miles between it and the sea, and extends about 10 miles west from Newcastle. Its greatest length is 58 miles, and its greatest breadth about 24 miles. The coal-measures of this field rest on the series of strata of the millstone grit and shale, and are in part under the magnesian limestone, the northernmost point of which is near the mouth of the Tyne. The beds of which this coal formation is composed dip towards the east and crop out towards the west, so that a section of them gives the idea of a form of a boat. In consequence of this disposition the beds of coal in some places appear at the surface, while in the middle of the basin they are at great depths. At Yarrow, about five miles from the mouth of the Tyne, one of the thickest beds, called the High Main, is 960 feet deep, and rises on all sides; the dip of the strata averages one inch in twenty, but this is not uniform throughout; and therefore that bed does not rise to the surface at equal distances around Yarrow. The beds of the coal-measures are 82 in number, and consist of alternating beds of coal, sandstone, and slate-clay; making an aggregate thickness of 1620 feet, which varies however in different parts. The irregularities of the surface do not affect the dip or inclination of the strata; so that when a valley intervenes they are found in the sides of the opposite hills at the same levels as if the respective strata had once been continuous. It is difficult to determine the exact number of beds of coal, in consequence of the different depths at which the same bed occurs, the numerous faults, and the varying thickness of the beds of coal and other strata. These strata occasionally enlarge and contract so much, that it is only by extensive observation that the identity of the seams can be ascertained. Dr. Thomson supposes the whole number of beds of coal in this field to be twenty-five; Messrs. Conybeare and Phillips state that forty beds of coal have been seen: a considerable number however of these are very thin. The two most important beds are those distinguished by the names of High Main and Low Main. The thickness of the first is 6 feet, and of the second 6 feet 6 inches. The Low Main is about 60 fathoms below the High Main. Eight other beds of coal occur between these: one called Bensham is 4 feet thick, and another called Coal-Yard is 3 feet thick. Seven beds of coal have been observed under the Low Main, some of which are of considerable thickness, but of an inferior quality. The aggregate thickness of the whole number of seams is about 44 feet; but there are eleven beds not workable, the thickness of some of them being only a few inches. Five others amount together to only 6 feet. Making proper deductions for these, it may be considered that the available beds amount to 30 feet in thickness.

The number of dykes or faults which traverse this field is very considerable. They appear to run in all directions. The most remarkable, called the Great Dyke, or 90-fathom dyke, has received the latter name because the beds on the north side of it have been thrown down 90 fathoms. Its direction is north-north-east and south-south-west. It enters the sea a little to the south of Hartley, or about three miles north of Shields, and running westward crosses the Tyne at Lemington, about four miles west of Newcastle Bridge. In some places it is only a few inches wide, but in Montagu colliery it is 22 yards wide, and is filled with hard and soft sandstone. From the southern side of this dyke two others branch off, one to the south-east and the other to the south-west. The latter, called from its breadth the 70-yard dyke, is also filled with hard and soft sandstone. This dyke intersects the upper or Beaumont seam of coal, but does not alter the level on either side. The thickness of the seam however decreases, beginning at the distance of 15 or 16 yards from the dyke: and the coal first becomes sooty, and at length assumes the appearance of coke. The south-eastern branch is only 20 yards in breadth. Another dyke, which passes through Coaley Hill, about four miles west of Newcastle, is about 24 feet wide. It is filled with basalt in detached masses, which are coated with yellow ochre; a thin layer of indurated clay is interposed between the sides of the fissure and the basalt. The upper seam of coal is here about 35 feet from the surface, and where it is in contact with the dyke is completely charred. Another dyke, which crosses the Tyne at Walker, and traverses the Walker colliery, does not alter the level of the strata, but on each side of it the coal is converted into coke, which on one side in some places was found to be 18 feet thick, and on the opposite side only about 9 feet. At Walbottle Dean, 5½ miles west of Newcastle, a double vein of basalt crosses the ravine in a diagonal direction, passing nearly due east and west; it underlies at an angle of 78 degrees, and cuts the coal strata without altering their dip, but the seam of coal is charred. A dyke, called the Cockfield Dyke, 17 feet wide, throws up the coal-measures on the south 18 feet. The Low Main coal, contiguous to the basalt, is only 9 inches thick, but enlarges to 6 feet at the distance of 150 feet from it; the coal contiguous to the dyke is reduced to a cinder. The dykes, if not large, are locally called *troubles*, *slips*, or *hitches*. These minor faults are numerous and extensive, and are a perpetual source of difficulty and expense to the coal-owner by disturbing the level of the strata and by the disengagement of carburetted hydrogen gas. They are not however without their use, being often filled with a tenacious water-proof clay, by which numerous springs are dammed up and brought to the surface. The faults which depress the strata have kept valuable seams within the basin, which would otherwise have cropped out and have been lost.

The coal-field of Northumberland and Durham supplies an enormous quantity of coal. Besides being consumed in its own district, London depends nearly altogether on it, as well as all the southern coast counties, with the exception of Cornwall. It is consumed along the eastern coast, including all the eastern counties as far west as Hull, Boston, Peterborough, Bedford, and Windsor. An inquiry as to the probable duration of this supply is one of no small interest. Dr. Thomson calculates that this coal-field may fairly be expected to yield coal for 1000 years, at the annual consumption of two millions of chaldrons; but as we have no data by which to discover how much coal has been already consumed, we cannot tell how much of these 1000 years has already elapsed. Besides this, Dr. Thomson has taken the average annual consumption much too low for the present time. The coals shipped from the Tyne, the Wear, and the Tees, in 1835, amounted to 4,368,144 tons. The quantity of waste coal is estimated at one-third of the whole. Without therefore taking into account the consumption of the immediate district, the annual quantity of coal taken from the mines is more than 6,552,216 tons.

On the other hand it appears that in this calculation the area of the coal-field is very much under-estimated, being taken at 180 square miles. Professor Buckland, in his examination before the House of Commons, limits the period of supply at the present rate of consumption to about 400 years. Mr. Baily, in his 'Survey of Durham,' states the period for the exhaustion of the coal to be about 200 years hence. Some proprietors of the coal-mines, when examined before the House of Commons, in 1830, extended the period of exhaustion to 1727 years. They assumed that there are 837 square miles of coal strata in this field, and that only 105 miles had been worked out. The small coal taken out of the pits is not considered worth shipment; large quantities of it were therefore often piled up near the mouths of the pits. These masses of coal were frequently set on fire, and burned for several years. Dr. Thomson describes two of these immense fires which were burning in 1814. About three miles to the north of Newcastle, and three miles off the road from Berwick, on the left hand, "one has been burning these eight years. The heap of coal is said to cover twelve acres. The other, on the right hand, is nearer the road and therefore appears more bright: it has been burning these three or four years (1814)." Of late years many more manufactories have been established in this district, by which, and by converting it into coke, most of the small coal is consumed.

Besides this coal-field there is another coal formation in the northern counties, which is minutely described by Dr. Thomson in the 'Annals of Philosophy,' November, 1814, under the name of the Independent Coal Formation. This tract terminates westward at Cross Fell, in Cumberland, is supposed to occupy the whole of Durham, and constitutes the whole of that part of Northumberland east of the Cheviots exclusive of the coal-field already described. The different strata of this coal formation amount to about 147. The coal-measures here differ from those we have just noticed, in having limestone as well as sandstone and slate-clay alternating with the beds of coal; the coal worked in this formation is slate-coal, and is considered inferior in quality to the Newcastle coal. There are several collieries, but the coal is only employed for home consumption. The lowest bed of these measures crops out near Cross Fell. The coal of which it is composed, provincially called crow-coal, falls into powder when exposed to the air, and cannot be burnt by itself. The poorer class make it up into balls with clay, and use it for fuel. This bed is 387 fathoms below the lowest of the Newcastle beds. ('Ann. of Phil.,' vol. iv.) There are numerous lead mines in this tract.

2. Detached Coal-Fields in the North of Yorkshire.—These are very limited in extent, being small insulated coal basins, lying in hollows in the gritstone. They occur near Middleham, Leyburne, Thorpefell, near Burnsell, and as far west as Kettlewell. The seam is seldom more than 20 inches thick. At Thedswell Moor the lowest seam is one yard, but the stratum diminishes and vanishes at the edges. Messrs. Conybeare and Phillips doubt whether these beds should not be referred to the thin coal seams subordinate to the millstone grit series, rather than to the principal coal-measures.

Coal is wrought in some parts of the great carboniferous chain extending from Penigent to Kirkby Stephen. Here the great 'Craven fault' occurs, described by Professor Sedgwick ('On the Carboniferous Chain from Penigent to Kirkby Stephen,' in 'Geol. Trans.,' vol. iv. series 2) as ranging along the line of junction of the central chain with the skirts of the Cumbrian system, passing along the south flank of Casterton Low Fell, up Barbondale, thence across the valley of Dent through the upper part of the valley of Sedbergh, and along the flanks of Bowe Fell, and Wildboar Fell, to the ridge which flanks Ravenstone Dale. Throughout the whole of this line there are enormous and most complex dislocations, which affect the strata of the coal formation and produce other phenomena. Only one of the coal strata in the lowest part of the coal-measures is sufficiently valuable to be worked; it varies from 18 inches to nearly 4 feet in thickness. At Turns Fell, near Hawes, in Yorkshire and at Tan Hill, near the highest part of the road from Brough to Argengarthdale, this coal is extensively worked, and is of good quality. The same seam is found near Kirkby Stephen. Horizontal drifts have been carried into this bed near the top of Penigent, of Whernside, and of Great Colm; but in these parts it is of bad quality and not fit for domestic use, being mixed with ferruginous and pyritous shale. This coal varies in thickness from a mere trace to 2 feet. It was once worked to some extent on the south side of the valley of Dent, by means of horizontal drifts under Great Colm. It was only a few inches in thickness, but said to be of so good a quality as to be in great request. About 70 or 80 years ago it was sent on pack-horses from this place as far as Kendal, for the use of blacksmiths' forges, &c. Kendal has long been supplied with fuel from the Lancashire coal-field; but this fact, of comparatively so recent a date, strongly illustrates the astonishing progress we have made in our modes of internal communication.

At the Barbon coal-pit in Westmoreland, a coal bed of this series is likewise wrought; the lower part of it is however so impure as to be unfit for ordinary purposes, and is chiefly consumed in lime-works. The following is a section of the strata as occurring in the Barbon colliery.—

	feet.	in.
1. Alluvial Soil	52	6
2. Plate (Calcareous Shale)	1	6
3. Limestone, the 4th or Mosdale Moor Limestone of the great section	27	0
4. Gritstone	27	0
5. Alternations of Shale and Gritstone	12	0
6. Shale	30	0
7. Crow Limestone	2	0
8. Plate with a 3-inch Crow-Coal	1	6
9. Gritstone	27	0
10. Coal	1	2

The strata of the coal are in general much less regularly continuous than the strata of limestone. This however is not always the case. Some of the thin bands of coal here appear to continue with astonishing regularity. The following example is quoted from Professor Sedgwick. "At Cross Pits, in the valley of Dent, the coal seam under the 12-fathom limestone is divided, by a band of clay half an inch thick, into two parts, with distinct mineral characters; and the same coal seam, with exactly the same subdivisions, has been found in the mountain on the opposite side of the valley at the distance of 3 or 4 miles measured in a straight line. This seems to prove that a bed not more than a fraction of an inch thick was originally continuous throughout an area probably several miles in diameter." ('Geol. Trans.' vol. iv. sec. 2, p. 101.)

3. Coal-Field of South Yorkshire, Nottingham, and Derbyshire.—This extensive field, which in character is closely allied to that of Newcastle, is considered by some geologists as a re-emergence of the same strata from beneath the covering of magnesian limestone under which it is concealed through the intervening space. This coal-field occupies an area extending north and south from a little to the north-east of Leeds nearly to Derby, a distance of more than 65 miles; its greatest width, 23 miles, is on the north, reaching nearly as far as Halifax to the west. On the south it extends towards the east to Nottingham, and is here about 12 miles wide; but in some parts it is much narrower. The strata of these coal measures range in the same manner as in the Northumberland coal-field, from north to south, dip to the east and rise to the west and north-west, in which directions the lowest measures at length crop out against the rocks of the millstone-grit series, which constitute the higher ridges of the Penine chain. The strata of this coal formation are very numerous. There are 20 beds of gritstone at the least, some of great thickness. Most of these beds consist of grains of semi-transparent silex united by an argillaceous cement; the lowest of these beds is termed the millstone grit, beneath which no workable coal is found. Besides these gritstone beds there are numerous strata of shale (slate-clay), bind (indurated loam), and clunch (indurated clay), alternating with several beds of coal of different thickness and value. A hard argillaceous rock called crow-stone forms in some places the floor of the coal beds, and is supposed to be a variety of the clunch still more highly indurated. The numerous faults in this coal-field render it extremely difficult to ascertain the exact number and order of the coal beds. Mr. Bakewell (p. 384) states their number at 30, varying from 6 inches to 11 feet, and the total thickness of coal at 26 yards. This however he considers as only an approximation. Three varieties of coal occur in these measures: hard, or stone-coal, which burns to a white ash; soft, or bright, which burns to a white ash; caking, or crozling, which usually burns to a red ash. The first is esteemed the best, and is in much greater demand than the others. The thickest bed is worked near Barnsby. In a pit near Middleton three seams are being worked; one at the depth of about 40 to 70 yards from the surface, another 38 yards lower, and the deepest from 28 to 32 yards deeper, making the whole depth from 106 to 140 yards. The upper seam is about 2 feet 8 inches thick, the middle seam from 2 feet 10 inches to 3 feet 4 inches, and the lower one from 4 feet 6 inches to 5 feet.

The strata of this field are traversed by an immense fault commencing from Allestry, in the south, and running in a zigzag direction through the south and east part of the field; the rise of the strata is said to be much more rapid on the western than the eastern side of the fault. Besides this great fault there are many others which traverse the field in various directions, and create an inextricable confusion by the rise and fall of the different strata, rendering it almost impossible to trace distinctly the continuation of each bed. This coal-field supplies the coal for the important manufactures which surround it, and also, by means of inland navigation, the midland counties south and east of Derbyshire.

A little to the west of the coal-field already described, coal has been found in two places about half-way between Ashborne and Derby, but it has not been worked.

4. Coal-Field of North Stafford.—There are two detached coal-fields: the one situated on the north-east of Newcastle-under-Lyne, distinguished as the Pottery Coal-Field; the other at Cheadle, to the east of the first. The form of the Pottery Coal-Field is triangular. Its vertex is near Congleton, from which point the sides diverge to the south-south-east and south-south-west, running in each direction about ten miles; the base is estimated at about seven miles: Newcastle is nearly in the centre of the base. The strata dip from the two sides to the centre of the area. On the eastern side the inclination westward is estimated at one foot in four; on the other side it is still more rapid. Between Burslem and its eastern limit, nearly in the centre of the coal-field, it has been ascertained that there are 32 beds of coal of various thickness, generally from about 3 to 10 feet each; but the strata are in general much dislocated in this field.

In the principal mines in this district coal is found at various depths, from 50 to 300 yards and more; there has been a mine worked at the depth of more than 400 yards. Some seams only 20 inches thick have occasionally been worked, but they are seldom worked under 3 or 4 feet thickness.

The Cheadle Coal-Field is an insulated basin surrounded by and reposing upon millstone grit; it is about five miles long and three miles broad, and is of little importance.

5. The Manchester or South-Lancashire Coal-Field is separated from that of South Yorkshire and Derbyshire by the range of lofty hills extending from near Colne to Blackstone Edge, and thence to Ax Edge in Derbyshire. It commences near the western side of this range in the north-west of Derbyshire, and continues thence to the south-western part of Lancashire, forming an area somewhat in the shape of a crescent, having Manchester nearly in the centre. The chord or span between the opposite horns is about forty miles. It runs nearly due north from Macclesfield to a few miles beyond Rochdale, a distance of thirty miles; the part between Macclesfield and Manchester is however very narrow, being in some places not two miles in width. From Rochdale it extends westward to Bolton and Chorley, south-west to Leigh and Prescot, north-west to Preston, and north to Colne. Viewing it as a whole, the strata rise towards the exterior edge of this crescent-shaped coal-field, along which the strata of millstone grit, on which they repose, crop out from beneath them, and dip towards its inner edge, where they are covered by the superior strata of the newer sandstone formation, which contain occasionally

beds of calcareo-magnesian conglomerate. Great disturbances have however interrupted the regularity of this arrangement, and caused divisions of the coal-measures, which render it difficult to trace out the exact dimensions of the field. At Disley, in Cheshire, it bifurcates into two branches, having an intermediate ridge or "saddle of millstone grit, the eastern branch forming a trough, of which the strata crop out on both sides against the millstone grit." This part of the field is a long narrow strip joined to the main field at Disley, and extending thence southward fifteen miles to near Mearbrooke in Staffordshire. The strata of the western branch of this bifurcation, extending from Disley to Macclesfield, dip again to the west, but not at so great an angle as they rose, on the east side of the intermediate ridge. In other parts of the coal-field great faults occur, but it has not been sufficiently investigated by the geologist for them to be distinctly traced. Mr. Bakewell has investigated a small portion, which he distinguishes as the Coal-Field of Bradford: the result of his observations is found in the second volume of the 'Geological Transactions.' This tract is rather more than two miles long, and little more than one mile and a furlong wide. It is situated on the river Medlock, a short distance east-south-east of Manchester. It is surrounded on every side, except the east, by the red-sandstone which prevails in the environs of Manchester. Beds of limestone pass under this and overlay the coal-measures, in which there are several beds of coal rising to the north, under an angle of 30°. One of these, near the centre of the field, is four feet in thickness. To the north of these inclined beds there is a considerable disturbance, and the direction of the beds becomes suddenly vertical. One of the vertical beds, together with its accompanying strata, bears so close a resemblance to the 4-feet coal above mentioned, that there is no doubt of their identity, and that the vertical stratum was, before the dislocation which severed them took place, a continuation of the first. With these vertical beds the coal-measures terminate: on the north an interval of the red-sandstone succeeds for about 1400 yards, when coal-beds again appear, rising as before towards the north. All this indicates considerable faults and subsidences, which however cannot be accurately traced at present. The coal from the Lancashire field supplies Manchester, Liverpool, and the surrounding districts.

6. The North Lancashire Coal-Field is one of little importance. It lies midway between Lancaster and Ingleton; it is about eight miles long and six miles wide, but it has never been thoroughly examined, and its strata cannot be distinctly stated.

7. The Whitehaven Coal-Field is situated on the west coast of Cumberland, and extends from near Egremont, south of Whitehaven, to near Allonby on the north.

Central Coal District.—Under this division are classed the coal-fields of Ashby-de-la-Zouch, of Warwickshire, and South Staffordshire.

1. The Coal-Field of Ashby-de-la-Zouch is of a very irregular figure, and so much dislocated that it rather forms two small basins than one continuous whole. The greatest length from north-west to south-east is about ten miles, the greatest breadth about eight miles. The eastern extremity of this area approaches almost close to the transition district of Charnwood Forest. This coal-field is described by Mr. Farey as "one of the highly curious but perhaps not uncommon occurrences in the red marl districts; a tract entirely surrounded by a fault, or a series of faults, which unite, seem lifted up through the red marl strata, and denudated, the coal strata having rapid dips in various directions, while the surrounding strata of red marl are horizontal, or as nearly so as may be." Of the two portions of the field, one ranges by Ashby Wold, about three miles on the west of Ashby; the other by Cole Orton, which is about the same distance on the east.

The Ashby Wold portion ranges from Swepston, four miles south of Ashby, to Brethy in Derbyshire: the inclination of the strata is towards Ashby; but between the out-crop of the beds and that town another crop has been traced near Brothorpe, dipping in a contrary direction. More than twenty coal-works have been opened on this line. The lowest shaft sunk is to the depth of 246 yards. One of the seams is from 17 to 21 feet thick. This great thickness is caused, it is supposed, by the running together of two or more seams—a circumstance which is known to occur in the coal-fields of South Staffordshire. The eastern portion of this district commences about a mile and a half north-east of Ashby, and extends about six miles in length, running parallel to the larger portion. The strata dip to east-north-east. In the pits belonging to Sir George Beaumont two coal-beds, each a yard and a half thick, are worked. On Cole Orton Moor several coal-seams, which have been proved to lie above these, have been worked at the depth of 116 feet.

2. The Warwickshire Coal-Field commences at Wyken and Sow, two villages about three miles east of Coventry, and continues in a north-west direction to Polesworth and Warcston, about five miles east of Tamworth, a distance of sixteen miles: its average breadth is about three miles. All the strata rise to the east-north-east, the inclination becoming greater towards the eastern edge of the field, where in many parts it makes an angle of more than 45° with the horizon: towards the west it decreases to about one foot in three, and lastly in five. The principal collieries are near the south of the field, at Griff and Bedworth. The depth of the first is 117 yards, and the principal seam three yards in thickness. The same seams are worked in the Bedworth mines, but there the first and second coal-seams of Griff run together and form a 5-yard seam. The intermediate strata of shale which separate them at Griff are found in the eastern shaft to be 33 yards, and in the western 25 yards thick; but they gradually decrease as they proceed westward, till at length they entirely vanish.

3. South Staffordshire or Dudley Coal-Field, the principal in the central district, extends from Beverton, near Badgely, on the north-east, to near Stourbridge on the south-west. The greatest length is about twenty miles, and its greatest breadth, from Walsall to Wolverhampton, is about seven miles, but it is very irregular towards the south, being almost divided into two parts. The area, from actual survey, has been found to be about sixty square miles. The southern portion, extending from Stourbridge to Bilston, about seven or eight miles in length and four in breadth, has been fully investigated by Mr. Keirs, and described by him in Shaw's 'History of Staffordshire.' No satisfactory account of the northern portions of this field has hitherto been published; many coal-seams, of eight, six, and four feet in thickness, are worked in it. The southern portion is of much more importance, as it contains seams from 30 to 45 feet in thickness. This enormous thickness is however not one continuous seam, but a number of seams, divided by layers of what the miners call band, which are very thin beds of clay-slate. The working of these thick seams is not so profitable as might be supposed. The pillars left standing in order to support the high roof are estimated at about one-third of the whole coal in the bed, and the small coal left in the mine is about equal to another third, so that only one-third of the whole is at present taken out of the mine.

In the coal-measures of this district there is an absence of the millstone grit, carboniferous limestone, and old red-sandstone, which usually lie under the coal-measures. The coal-measures rest, in the Dudley Coal-Field, on the transition rock at once, without any intermediate strata: this singularity is likewise observed in the Coalbrook Dale coal formation.

The coal district in South Staffordshire is traversed from north-west to south-east by apparently a line of hills, but they are not absolutely continuous, though they have a uniform general direction. On examination, the hills on the north and those on the south of Dudley are found to differ entirely in their character. The northern chain consists of highly inclined strata of limestone, against the sides of which all the coal-measures crop out at a considerable angle, but come nearer a horizontal position as they recede from these hills. The other chain of hills, on the south of Dudley, is entirely composed of one mass of basalt and amygdaloid, and the coal-measures preserve their usual level in approaching the hills, not cropping out as they do upon the limestone chain. Two opinions are entertained with regard to these basalt elevations: "they may be either the protruding edge of a vast basaltic dyke traversing the coal-field, or an overlying mass:" the latter is considered the more probable. The coal-measures on the south, near Stourbridge, appear to dip beneath the beds of the newer red-sandstone formation: the beds of this and of the Warwickshire coal-field dipping in opposite directions under the super-strata, give reason for supposing that they may extend continuously below this through the intervening space. The eastern side of the field, which extends a little beyond Walsall, is bounded by the same limestone with that of Dudley, and the coal-measures are observed again to crop out against it, thus lying in a basin between these two towns. That the coal-beds rise towards the north, and the upper ones crop out while others continue under the surface, is very satisfactorily shown by the comparison of the strata in different collieries. At Tividale the main coal is $60\frac{1}{2}$ fathoms below the surface; at Bradley it is only $20\frac{1}{2}$; and the greater number of beds which cover the main coal at the former place have entirely disappeared before the main seam reaches Bradley; and farther to the north the main seam also crops out and disappears altogether. A very curious phenomenon takes place at Bloomfield colliery, to the south of Bilston, thus described in the 'Geology of England,' p. 412:—"The two upper beds of the main coal, called the roof, floor, and top slipper, separate from the rest, and are distinguished by the name of the 'flying reed.' This separation grows wider, and at Bradley colliery amounts to 12 feet, four beds of shale (slate-clay) and ironstone being interposed. These two upper beds crop out, while the rest of the main coal goes on to Bilston, and is only eight yards thick."

This district supplies coals to the numerous iron-works in the immediate neighbourhood, and the manufactories of Birmingham and its vicinity; besides which, all the neighbouring counties, as far south as Reading and Gloucester, are supplied by means of inland navigation.

The clay ironstone occurs in various beds, but is only wrought in two: one of these is the bed under the main coal, and is wrought for iron-ore.

Many faults or dykes occur in this field; they are usually fissures in the beds, filled up with clay, and very frequently the levels of the different strata vary in consequence. There is a great fault near Bilston, which causes the dip of the strata to be reversed, the beds on the south side dipping south, and those on the north side dipping north: this is however an unusual circumstance.

Western Coal Districts.—The Coal-Fields of this division are dispersed around the transition district of North and South Wales. The north western district includes the coal-fields of Anglesey and Flintshire, the western those of Shropshire, the south-western those of South Wales, of South Gloucester and Somerset, and of the Forest of Dean.

1. Isle of Anglesey.—At the distance of about six miles from the Menai Straits, and running nearly parallel to them, a remarkable valley stretches across the whole island. This valley opens on the north into Red Wharf Bay, and on the south into the æstuary of Maltraeth; it is flanked on both sides by parallel bands of carboniferous limestone, in the depression between which coal has been found, and it is thought probable that the coal-measures may extend through the whole line. Coal has been worked near the Maltraeth æstuary; and a few years since shafts were sunk in the neighbourhood of Trefdaeth. Successful trials have likewise been made at Pentreberen, about five miles north-east of the former pits: the beds are said to be of a tolerable thickness, and the coals of a good quality.

2. Flintshire.—The Coal-Field of this county extends north and south from Llanasa, near the western cape of the æstuary of the Dee, to near Oswestry, in Shropshire, forming an exterior belt coextensive with the range of the mountain line from the north of the Clwyd. Where the carboniferous limestone is partially interrupted by the mountain of Selattyn the coal shales rest immediately on the transition slate, of which that mountain is composed. (Conybeare and Phillips, p. 419.) The greatest length of the district in which the coal-measures are found is about thirty miles, but it must by no means be understood that coal is worked throughout. At Oswestry there is a very small detached piece, not more than three miles long and half a mile broad; there is then an interval of some miles. Near Chirk another coal tract commences, and runs north for about five miles; then another interval occurs; and a little to the north of Wrexham the principal portion begins, and thence extends to the coast, and forms a narrow belt along it to the termination at the west cape of the Dee. The beds dip from one yard in four to two in three, sink beneath the æstuary of the Dee, re-appear on its opposite side, and finally sink beneath the strata of the newer red-sandstone. This position of the coal-measures has led to the conjecture that they are connected with the beds of the Lancashire coal-field. The coal formation here commences with the same strata as those of Derbyshire. The beds of coal vary in thickness from three quarters of a yard to five yards. In the Baggalt mines three seams are worked, varying from 3½ to 7 feet. Common, cannel, and peacock coal are found.

3. The Coalbrook Dale Coal-Field rests on transition rock: it extends from Wombridge, in the parallel of Wellington, to Coal Port, on the Severn, a length of about six miles; its greatest breadth is about two miles. The coal-measures are composed of the usual alternating strata, which occur without much regularity, except that each bed of coal is always immediately covered by indurated or slaty clay, and not by sandstone. The strata are 86 in number. In Madely colliery a shaft is sunk 729 feet through all the beds. The first coal-seam, which occurs at the depth of 102 feet, is very sulphurous, and not more than 4 inches thick; nine other beds of a similar nature, but rather thicker, occur between this and the depth of 396 feet. This coal is called 'stinking coal,' and is only employed in the burning of lime. The first seam of coal that is worked is 496 feet deep and 5 feet thick. Two other beds of coal occur, one 10 inches and the other 3 feet thick, before the bed of 'big flint' sandstone, which is found at the depth of 576 feet: nine beds of coal occur, of the aggregate thickness of 16 feet, between the 'great flint' and the 'little flint' bed (an interval of 100 feet). Beneath the 'little flint' and the lowest bed of the whole formation there is a sulphurous 8 inch coal. This account of the strata refers more particularly to the Madely colliery. The coal of this field is usually a mixture of slate-coal and pitch coal.

West of the Coalbrook Dale Field there are a few detached, narrow, and broken coal-fields in the plain of Shrewsbury, at the other side of the Wrekin.

Several small Coal Fields occur in the Brown Clee Hill and the Titterstone Clee Hill, which rise a few miles south of the Coalbrook Dale Field; the latter hill is about four miles south of the former. The coals in the Brown Clee Hill only lie in thin strata, while the principal stratum in the Titterstone Clee Hill is 6 feet thick. The coal fields on the Titterstone Clee Hill are represented as six detached portions, or separate basins, cut asunder and rendered irregular by a vast basaltic dyke, more than 100 yards wide, which intersects the hill. These coal-measures are more interesting to the geologist than the miner.

On the east of these hills, and between them and the Severn, a Coal-Field extends from Deuxe Hill and Billingsley on the north to the borders of Shropshire and Worcestershire on the south, a length of about eight miles, coal being worked in several points along this line. Coal is also worked near Over Arley, on the Severn, adjoining this tract on the west. Only a few miles from the Billingsley coal-field at Pensax, near the foot of the Abberley Hills, is "a small patch (rather than field) of coal-measures," and another similar piece about three miles to the west.

The South-Western Coal District comprehends the several Coal-Fields near the æstuary of the Severn and the Bristol Channel, including parts of the adjacent counties of Gloucester, Somerset, Monmouth, and Glamorgan. The various coal-fields distributed over this district are apparently insulated, yet they have several points of connection. "They all rest on one common base of old red-sandstone; they all appear to have been formed by similar agency and at the same era; to have been subject at a later period to the same revolutions; and lastly, to have been covered partially by similar overlying deposits." ('Geol. Trans.,' vol. i.) The several basins in the coal formation are divided by lines termed 'anticlinal,' formed by the saddles of the strata or meetings at the surface of their vertical angles, on each side of which the strata dip in opposite directions. The coal-measures are

1. Anticlinal line forming the crest of a hill. 2. The same line running along the course of a valley.

thus surrounded by exterior bands of mountain limestone and old red-sandstone, in the order of the outcrop of the subjacent beds. This district includes three principal coal basins, together with some smaller ones, adjacent to and closely connected with the two last. First, the South Welsh coal basin; second, that of South Gloucester and Somerset; third, that of the Forest of Dean.

1. The Coal-Field of South Wales is upwards of 100 miles in length, and the average breadth in the counties of Monmouth, Glamorgan, Caermarthen, and part of Brecon, is from 18 to 20 miles; it becomes much narrower in Pembrokeshire, being there only from 3 to 5 miles. This area extends from Pontypool on the east to St. Bride's Bay on the west, and forms a vast basin of limestone in which all the strata of coal and ironstone are deposited. The deepest part of the basin is between Neath and Llanelly: from a line ranging nearly east and west through Neath all the strata rise on the south towards the south, and on the north towards the north, cropping out at the edges. The limestone crops out at the surface all round the coal, except where its continuity is interrupted by Swansea and Caermarthen bays. The depths from the surface to the various strata depend upon local situations. The upper coal-seam does not extend a mile either north or south beyond Neath, and not many miles in an east or west direction, and its utmost depth is not above 50 or 60 fathoms; the next stratum of coal and those likewise beneath, being deeper, crop out at a greater distance from the centre; and so of the rest in proportion to their depth. The lowest bed is 700 fathoms deep at the centre, and all the principal strata lie from 500 fathoms deep to this depth. But this district is intersected by deep valleys which generally run in a north and south direction, intersecting the coal. By driving levels in the hills the beds of coal are found without the labour and expense of sinking shafts; there are also many pits in the low valleys. This basin contains twelve beds of coal from 3 to 9 feet thick, making an aggregate of 70½ feet; and there are eleven more from 18 inches to 3 feet, together equal to 24½ feet; the whole thickness is therefore 95 feet. A number of smaller seams likewise occur. On the south side of the basin, from Pontypool to Caermarthen Bay, the coal is principally of a bituminous nature; on the north-east it is a caking coal; on the north-west, anthracitic. It is this latter coal which has the greatest heating power. It is found in abundance near Swansea, and is cheap. Great faults occur in this field, which traverse it generally in a north and south direction, and throw the strata out of their level 40, 60, 80, or 100 fathoms. These dislocations are not often shown on the surface. A principal fault occurs at Cribbath, where the strata of limestone stand erect; another of considerable magnitude lies between Ystradvellte and Penderryn. These dykes are usually filled with clay, but one of some magnitude has been observed near Swansea, which is many fathoms wide and filled with fragments of the disrupted strata, the level of which differs by more than 240 feet. The rich ironstone of this basin supplies extensive iron-works in the neighbourhood. The principal beds of ironstone occur in the lower part of the coal-measures; the most valuable bed is found beneath the lowest coal. The strata of this coal formation dip much more rapidly on the south than on the north; on the south they make an angle of 45° with the horizon, and on the north dipping only 10°. The coal from the South Wales basin supplies the whole of Wales with the exception of the more northern counties, the whole of Cornwall, and the western half of Devonshire.

2. South Gloucester and Somerset Basin.—This basin occupies an irregular triangular space, bounded on the south by the Mendip Hills, which are a high range of mountain limestone resting on an arch of old red-sandstone. The vertex of the triangle is on the north, at the village of Tortworth in Gloucestershire: the western side from the Mendips to the vertex is formed by three insulated masses of high land, separated by narrow intervals, the widest of which is less than

three miles. Near Tortworth the range extending from Almondsbury is deflected suddenly to the south, and this may be considered the north-eastern frontier of the basin; it may also be traced through Wickwar to Sodbury. The south-eastern limit, from Sodbury to near Mells, the eastern extremity of the Mendips, is mostly concealed by overlying deposits. Partial denudations occur at Lansdown, near Wick Rock, where the limestone can be traced in the valleys dipping towards the centre of the coal basin. From Lansdown to the Mendips the continuity of the basin can be well ascertained, the coal-measures being uncovered in some of the valleys in which the principal collieries are situated. In other places shafts have been sunk through the overlying horizontal deposits beneath which the coal is worked. The greatest length of this area is 25 miles; the width, from the collieries near Bath to those of Bedminster near Bristol on the west, is about 11 miles. In this district there is much local irregularity, and the stratification of the coal-measures is so deranged that they have very different and varying levels. In some parts the beds are denuded, in others concealed by the more recent horizontal deposits; and thus the whole basin is divided into several detached coal-fields.

The uncovered areas may be divided into the northern, the central, the southern, the eastern, and the western coal-tracts. The northern is the most extensive and elevated: its greatest length, from the vertex of the basin near Tortworth to the village of Brislington on the left bank of the Avon near Bristol, is 12 miles; its greatest breadth from east to west is nearly four miles. The collieries of Iron Acton, Sodbury, and Kingswood are in this coal-tract. Along the northern limits of the basin, from Sodbury to Cromehall and Titheringtou, the coal-measures are exposed in immediate contact with the limestone; on the western, southern, and great part of the eastern border of the tract they are skirted by hills of red marl capped by lias. At Pucklechurch shafts are sunk to the coal through both the latter formations.

The central tract, which begins on the south of Dundry Hill, is divided into two parts by a narrow valley; the northern portion, about six miles in length, extends from Burnet on the north-east to Knowl Hill, near Stanton Drew, on the south-west; near Pensford it is about two miles in breadth. The southern division, extending from Temple Cloud on the west to between High Littleton and Timsbury on the east, is about three miles in length. To the south-east of this central coal-tract the coal-measures are entirely concealed by superjacent deposits through a distance of six miles. Throughout this space however many shafts are sunk—some through the red marl of the valleys, and some through the lias which occurs on higher ground. There are several of the latter description in the parishes of Timsbury and Poulton; but the deepest is on Clan Down near Radstock, which is sunk 200 fathoms before its horizontal adits are driven. Another shaft, beginning in the oolite, is sunk on the edge of the same Down near Paulton; but it is not so deep as the former, since here there is a rise in the strata, and the coal-seams are in consequence much nearer the surface. On the ascent of the hill above Chilcompton the coal-measures are again exposed to the extent of about an acre.

The southern coal-tract commences near the point where the road between Bath and Shepton Mallet crosses the Nettlebridge stream, and ends between Vobster and Mells; its greatest length is six miles, and greatest breadth two miles and a half. The coal-measures of the eastern coal-tract are laid open in the vale of the Buoyd at Wick and Upton, both in Gloucestershire; they are likewise exposed at Newton St. Leo, on the left bank of the Avon below Bath, dipping towards the interior of the basin. Several seams are worked at Upton and Newton. The western coal-tract lies at the south-east of Leigh Down, near Bristol. Beds of red marl form the upper strata in the shafts of all the coal-pits of this tract between Long Ashton and Bedminster. The coal-field of Nailsea, lying more to the west, is a continuation of this tract.

A great undulation in the strata of the coal-measures which form the coal-basin of Somersetshire and the south of Gloucestershire alters the apparent position of the seams so much that it is very difficult to ascertain the identity of each throughout the various collieries. The local names of the several seams also tend to confuse the geologist.

The chain of hills which limits the western boundary of this coal district presents remarkable anomalies between Clevedon and Portbury along its northern escarpment. A great fault ranging along the edge effects a very considerable subsidence of the strata. In consequence of this "the coal-measures, depressed to the level of the old red-sandstone, appear to occupy its place, and seem to dip beneath the mountain limestone, on which in fact they repose." ('Geol. Trans.,' vol. iv.)

The following are the principal subdivisions of the Coal-Measures in this basin, beginning with the highest:—The Upper Coal Shale; the Pennant Grit (sandstone); the Lower Coal Shale; and the Millstone Grit.

In the Bedminster colliery on the south-west of Bristol there are three seams of good bituminous coal: the deepest and uppermost are worked; the former is 4 feet 3 inches, the latter 2½ feet to 3 feet thick; the middle seam is only 1 foot. The interval between the two principal seams is 23 fathoms; the lowest shaft sunk is 127 fathoms deep. These beds are obviously referrible to the lower coal shale.

In the meridian of Pitcot, situated a little to the north-east of Nettlebridge, all the strata are vertical: a perpendicular shaft is there sunk to the depth of 80 fathoms in one bed of coal.

The total number of mines worked in this district is probably less than it was formerly, but the whole produce is certainly much greater, owing to improved methods in working. The seams of coal are very thin in comparison with those which are worked in the principal coal-fields of England, and in most of those would be rejected as not worth the working.

3. The Forest of Dean Coal-Basin occupies an irregular elliptical area, circumscribed by the triangle formed by the Wye, the Severn, and the road from Gloucester to Ross; the largest diameter from north-north-east to south-south-west is about ten miles, the shorter about six miles. All the strata dip uniformly towards the centre of the basin. The whole of this coal-tract, together with the high land that surrounds it, constitutes a mountain group, the average height of which above the level of the sea is about 900 feet. The aggregate thickness of the whole strata of the coal-measures is, according to Mr. Mushet, 500 fathoms; he divides the different strata into seven series, in which there are 27 beds of coal.

On the north of the Forest of Dean basin, and at the distance of a few miles, is the Newent coal-field, a very small tract surrounded and concealed by overlying strata of the new red-sandstone.

Scotch Coal-Fields.—Several small Coal-Fields occur in Dumfriesshire, forming narrow basins in the valleys of the great southern transition chain of Scotland. In the valley of the Nith, in the parishes of Sanquhar and Kirkconnel, there is one of these coal-basins, about 7 miles in length and 2½ miles in breadth. Three seams of workable coal have been discovered, averaging in thickness from 3 to 4½ feet. The range of the seams is in the direction of the Nith; the measures are disturbed by a dyke running north and south, by which the strata are much depressed on the east side. In the parish of Canobie, adjoining Cumberland, coal is worked in two pits: the principal seam is 5 feet 10 inches thick.

The principal coal-district of Scotland occupies the tract which forms the great central lowland of Scotland, and lies between the great transition chain on the south and the still loftier primitive mountains of the Highlands on the north. "The whole of this wide tract is occupied by the coal-measures, the carboniferous limestone, and the old red-sandstone, associated in every possible manner with vast accumulations of every variety of trap." (Conyb. and Phil.)

To begin with the most eastern county in this tract in which coal is found:—In the parish of Dunbar, on the east coast of Haddington, there are indications of coal, but no seams have yet been found of sufficient thickness for working. In the parish of Ormiston, in the west of the same county, coal is found in abundance; there are three workable seams of coal, varying from 28 to 43 inches in thickness, and the coal is of good quality.

Coal occurs in Fifeshire, on the north side of the Forth. There are mines in the parish of Dysart, where coals were first raised in Scotland nearly 400 years ago. Coal is wrought in several places in Mid-Lothian. In Lanark the coal-fields are numerous and extensive. The Wilsontown coal-basin and the Climpy basin both occur in the parish of Carnwath; the latter is on the west side of the first, the crop of the one nearly approaching the other. There are several seams of coal in these basins. The main coal, or lowest, is called the 4-feet coal; another seam is about 2 feet in thickness. The accompanying strata are sandstone, varying in composition and hardness, bituminous shale, slate-clay, and thin beds of ironstone alternate with the coal. Several small faults, or hitches, as they are here called, traverse the field. On the south-west part of the field the main coal is generally 14 feet below the crow coal, which is the next superior bed; on the north-east the space between the same beds is only about 2 feet. These basins form part of the great coal-basin of the Clyde, which extends on both sides of that river, and the centre of which is near Dalziel. On the same side of the river, in the parish of Monkland, there are many collieries, in which the thickest bed of coal is 9 feet, and it is of good quality. On the left bank of the river coal is wrought in several places. Several mines are worked in the parish of Rutherglen, and others in the adjoining parish of Cambuslang. There are several also in Hamilton, Stonehouse, and Douglass. Throughout this district seven seams of coal are usually found within 415 feet of the surface; five of these seams are of sufficient thickness and good quality to be wrought. The following shows the situation and thickness of the seams of coal in the pits in the parish of Cambuslang:—

	feet.	in.
Upper soil (earth and clay) . . . from 20 to	30	0
Argillaceous white freestone	20	0
Shale, with vegetable impressions, from 30 feet to 40 feet	35	0
1st Seam, soft coal	4	6
Interval (hard freestone, &c.)	26	6
2nd Seam, soft coal	3	6
Interval (shale)	63	6
3rd Seam, shaft coal	5	0
Interval { shale, 20 feet; hard ironstone, from 6 to 18 inches; shale and freestone } .	65	2
4th Seam, soft coal	6	0
Interval { shale; freestone }	83	0

	feet.	in.
5th Seam, soft coal	3	0
Interval { ironstone / shale }	10	0
6th Seam, hard coal, good for iron works, forges, &c.	3	6
Interval (shale)	1	6
7th Seam, soft coal	1	6
Till, &c., with thin seams of coal	84	0
	445	8

The thickness of the coal and of the freestone varies considerably in different parts, and the numbers here given must be taken only as an approximation. The strata are frequently deranged by faults, several of which run from east to west. In their general arrangement the strata usually run nearly parallel to each other, although they have always a considerable angle of elevation, and uniformly dip towards the Clyde. A great fault occurs between Hamilton and Quarter, and none of the principal seams are wrought for some miles north of this spot, the coal beds being sunk nearly 100 fathoms lower than those out of the fault. The main seam worked at Quarter is 5 feet 6 inches thick, and consists of four distinct varieties of coal.

This Coal-Basin of the Clyde extends into Renfrew, where there are many collieries. Coal is wrought in the parish of Eastwood, in that county, in several seams of various thickness, but none exceed 2 feet 6 inches. The whole are of good quality. Five of them are wrought in pits varying in depth from 10 to 40 fathoms. The coal-measures here consist of the usual series of freestone, shale, &c., dipping generally to the south-west. This coal formation partly surrounds the Loch of Castle Semple, and continues without interruption into Ayrshire, around Kilbirnie Loch, and onwards to Ardrossan. Coal occurs in different places in Dumbarton, where, among other parishes, it is wrought in Easter Kilpatrick. It is also found abundantly in Stirlingshire, along the southern base of the Lennox Hills. Coal likewise occurs throughout Linlithgow, and is worked extensively in that county; it is likewise found in Clackmannan and in the south of the counties of Perth and Kinross.

Some of the richest and most valuable bands of ironstone are obtained from the coal-measures of Scotland, chiefly in the basin of the Clyde. The manufacture of iron in this district is very extensive. In the year 1849 nearly 700,000 tons of pig-iron were wrought in this district. The Scotch beds include a large proportion of sandstone and a peculiar limestone, worked at Burdie House near Edinburgh. The remains of plants and animals are found in these rocks, and amongst the latter the *Megalichthys*, a fossil fish of large size and interesting structure. [MEGALICHTHYS.]

Irish Coal-Fields.—Mr. Griffiths, in his 'Report on the Leinster Coal District,' gives an excellent summary of the Irish coal-fields, from which what follows is taken:—"If we except the Leinster district my knowledge of the coal-fields of Ireland is as yet very limited; and though each in its turn will form the subject of a separate report, I think it right to draw attention to them in this place, by giving such general information as I possess respecting their situation and circumstances. Coal has been discovered in more or less quantity in seventeen counties of Ireland; but I believe the island contains but four principal coal-districts namely, the Leinster, the Munster, the Connaught, and the Ulster. The two former contain carbonaceous or stone-coal, and the latter bituminous or blazing coal.

"The Leinster coal-district is situated in the counties of Kilkenny, Queen's County, and county of Carlow. It also extends a short distance into the county of Tipperary, as far as Killenaule. This is the principal carbonaceous coal-district. It is divided into three detached parts, separated from each other by a secondary limestone country, which not only envelops, but in continuation passes under the whole of the coal-district; a fact which was indisputably, though accidentally, proved by the Grand Canal Company, who sank a pit through 18 yards of black slate-clay and flinty slate into the limestone in search of coal. The Leinster coal-district is therefore of subsequent formation to the limestone.

"The Munster coal-district occupies a considerable portion of the counties of Limerick and Kerry, and a large part of the county of Cork. It is by much the most extensive in Ireland; but as yet there is not sufficient information respecting the number, extent, or thickness of the beds of coal it may contain.

"Coal and culm have been raised for near a century in the neighbourhood of Kanturk, in the county of Cork. At Dromagh colliery I understand the work has been carried on to a very considerable extent, and its annual supplies of coal and culm have materially contributed to the agricultural improvement of an immense extent of the great maritime and commercial counties of Cork and Limerick, which must otherwise have continued neglected and unreclaimed.

"Many circumstances combine to make the examination of this district of peculiar interest and importance; and as a recent application has been made by the Cork Institution to the Dublin Society to aid the undertaking, it is probable that this immense district will shortly be accurately explored. From all that has been ascertained, it is very clear that the dip of the beds and the quality of the coal differ materially from those of the Leinster district. In the Munster district the beds run east and west, and dip to the south, forming an angle of 45°. In the Dromagh colliery, where all the beds which have been discovered have been successively and in general successfully wrought, four beds incline on each other, and at no greater distance than 200 yards. The first of these beds is a 3-feet stone-coal, and is the leading bed. All faults, checks, and dislocations, similar to those which are discoverable in this bed, are in general to be encountered in the other three. The names of the four beds are, the *coal-bed*—this lies farthest to the north; the *rock-coal*, so called from its being comparatively of harder quality than the other beds; the *bulk-bed*, so called from its contents being found in large masses or bulks; and *Bath's-bed*, so called from the name of a celebrated English miner, by whom it had been many years ago discovered and worked. The coal-bed consists of 3-feet solid coal, and is not sulphurous; the rock-coal is nearly of the same thickness with the leading bed, but is very sulphurous, and, having the soundest roof, is the most easily wrought. The other beds are of the culm species, but of peculiar strength. . . . The bulk-bed forms immense bulks and masses of culm, in which the miners have frequently been unable to retain the ordinary directions of roof and seat.

"No work has been undertaken in the Munster coal-district to a greater depth than 80 yards. The present work at the Dromagh colliery is at that depth; it is heavily watered, and consequently expensively wrought. The quality of the coal and culm improves as the work descends. . . .

"The Connaught coal-district stands next in order of value and importance to the Leinster and Munster, and possibly may be found to deserve the first place when its subterranean treasures shall be explored. At present nothing is known, except that the outer edges of several beds of coal have been observed, but they have not been traced to any distance, so that their extent is by no means ascertained. The coal is of the bituminous species. This coal is particularly adapted to the purposes of iron-works, foundries, &c. &c.

"The Ulster coal-district is of trifling importance when compared with the foregoing. It commences near Dungannon, in the county of Tyrone, and extends in a northern direction to Coal Island, and in continuation to the neighbourhood of Cookstown. No beds of coal worth working have hitherto been discovered between Coal Island and Cookstown, but certainly the coal strata extend there. The principal collieries are at Coal Island and at Dungannon. The coal of this district is bituminous. I understand that indications of coal have been observed at Drumquin, in the county of Tyrone; and also at Petigoe, to the north of Lough Erne. Possibly the coal formation may extend from the neighbourhood of Cookstown westward to the north of Lough Erne.

"Besides the foregoing principal coal-districts, there are others of less consequence. Bituminous coal has been found in the neighbourhood of Belturbet, in the county of Cavan, and at the collieries of Ballycastle, in the county of Antrim; but the Antrim coal-district is not very extensive. These collieries have been wrought for a number of years. The coals are of a slaty nature, and greatly resemble both the coal and the accompanying rocks which occur in Ayrshire, and probably they belong to the same formation."

Continental Europe.—France.—In the centre and south of France some small coal-fields occur in the valleys of the Loire, the Allier, the Creuse, and the Dordogue, the Aveyron, and Ardèche, between ridges proceeding from the primitive central group connected with the Cevennes; and, in a few localities, some of the thickest beds of coal yet discovered have been found. In the north of France, the coal-formation occupies a very large tract of country, running westward from Hardinghen, near Boulogne, by Valenciennes, and thence up the Schelde and down the Meuse to Eschweiler, beyond Aix-la-Chapelle. The total area of coal in France is probably not less than 2000 square miles. Its annual yield is not less than 4,000,000 tons. These deposits are of the same age as those of England, but they rest on granite or other crystalline and metamorphine rocks.

Belgium.—The district along the Meuse, between Namur and Liège, is said to resemble in its geological structure, as well as picturesque features, the Somersetshire and South Gloucester district: the strata being broken and deranged, exhibit, if possible, still more contorted and inverted positions of the respective beds. The defiles of the Sambre and the Meuse ('Geol. Trans.,' vol. i., 2nd series) present an exact counterpart of those of the Avon and the Wye. There are two principal coal-fields in Belgium, the one extending to the east and known as the Liège Coal-Field, and the other west forming the Hainault division. The seams are generally thin, remarkably numerous, and presenting an apparent multiplication by doublings of the strata. A kind of coal is found in Belgium called Fleuu Coal, which is not found in Great Britain. It burns rapidly, giving out a disagreeable smell. [BELGIUM, in GEOG. DIV.]

Germany.—The coal-districts in the north of Germany are probably the prolongation of the Belgium formation. On the north-east and south-east of the Harz Mountains, near Ballenstadt and Neustadt, the coal-formation occurs resting on the transition rock of that group. In Saxony coal is found in many places along the northern foot of the Erzegebirge. It is extensively worked near Zwickau and near Dresden. There is a very extensive coal-district in Bohemia, extending into Upper Silesia. This district lies between the great primitive chain of the Erzegebirge and the Riesengebirge, on the north, and the great district of primitive slate which occupies the larger part of Bohemia south of the Beraun and Upper Elbe. More than forty beds of coal are supposed to be worked in this district. The whole annual supply from Prussia and the German States of the Zollverein exceeds 2,750,000 tons.

Russia.—Good coal has been found in Southern Russia, near Toula, lat. 54°, long. 37°, where it is worked; but the quantity is so small, and the difficulty of working it beneath a loose and half-liquid bed of quicksand is so great, that it seems unlikely to be of much utility. Coal has also been worked at Bakhmout, lat. 48°, loug. 38°, in the government of Katerinoslaf. (Mr. Strangways on the Geology of Russia, 'Geol. Trans.,' vol. i., 2nd series, p. 35.)

Sweden.—Coal occurs in this country near Helsingborg at the entrance of the Baltic, and also in the island of Bornholm. [BORNHOLM, in GEOG. DIV.]

Spain.—Both bituminous coal and anthracite are found in Spain. The richest beds are in Asturias, where the measures are so much broken and altered as to be worked by almost vertical shafts driven through the beds. The area covered by coal-beds in Spain is not exactly known, but it is said to be the largest in Europe, presenting upwards of 100 workable seams varying from 3 to 12 feet in thickness. (Austed.)

Hungary and some other countries in the east of Europe contain coal-measures which appear to belong to the carbouiferous period. It has been conjectured that coal exists in several parts of continental Greece. Coal is said to be found north of Constantinople.

Asia.—In Asia coal has long been known in China, where it is said to have been worked as early as the 13th century. Mr. Williams says that both bituminous coal and anthracite are seen in the coal marts of the north of China. Coal is likewise found in the countries immediately around the Persian Gulf, but of a very indifferent description. In most parts of Cutch, coal occurs in abundance and of good quality; it ignites quickly, and burns to a white ash. Coals are also found in Bundelcund. There are large mines in the district of Burdwan, 130 miles from Calcutta, and worked to the extent of 14,000 or 15,000 tons annually. They are situated on the banks of a river connected with the Hoogly, and were first worked about thirty-five years ago, but they have not been in extensive operation more than twenty-five years; the principal seam is about 9 feet thick, and is about 90 feet from the surface. Coal has likewise been got from a mine opened near Bhaugulpoor, on the Ganges, about 300 miles from Burdwan. Another coal-field has been discovered on the banks of the Hoogly, near Merzipoor, about forty miles from Calcutta; the coal is found close to the surface, and the thickness of the principal seam is said to be 2 feet. Coal of good quality likewise occurs in the Birman Empire.

America.—Professor Ansted says, "It is only within a few years that the coal-measures of the continents of America have been in any way known, and we are even now in ignorance of many details with regard to the greater number; but enough is ascertained to convince any unprejudiced person that the supply of mineral fuel there obtainable is amply sufficient for the requirements of the whole civilised world for thousands of years, even should the demand increase rapidly and the consumption continue to bear reference to the multiplication of all kinds of industrial occupation. There are in North America four principal coal areas, compared with which the richest deposits of other countries are comparatively insignificant. These are the great central Coal-Fields of the Alleghanies; the Coal-Field of Illinois and the basin of the Ohio; that of the basin of the Missouri; and those of Nova Scotia, New Brunswick, and Cape Breton. Besides these there are many smaller coal areas which in other countries might well take rank as of vast national importance, and which even in North America will one day contribute greatly to the riches of various states. We will endeavour to give a brief outline of the main facts concerning the chief of these districts.

"The Alleghany or Appalachian Coal-Field measures 750 miles in length, with a mean breadth of 85 miles, and traverses eight of the principal states in the American Union. Its whole area is estimated at not less than 65,000 square miles, or upwards of 40,000,000 of acres. The area is thus distributed—

Name of States.	Area in Acres.
Alabama	2,250,000
Georgia	100,000
Tennessee	2,750,000
Kentucky	5,750,000
Virginia	13,500,000
Maryland	350,000
Ohio	7,500,000
Pennsylvania	9,500,000
	41,700,000

"Making a liberal deduction for unproductive portions, denuded and eroded strata, and the parts of the seams out of reach, we may still fairly calculate that there exists in this district an area of 25,000,000 acres of productive coal-measures. The working has already commenced in most of the states above mentioned, though not generally to any very considerable extent. Thus in Alabama, the beds alternate with the usual sandstones, shales, and clays, and the coal-seams worked seem to be from 4 to 10 feet thick, and are quarried at the surface. They repose on grits and appear on the two sides of an anticlinal. The coal is bituminous and used for gas. In Kentucky both bituminous and cannel coal are worked in seams about 3 or 4 feet thick, the cannel being sometimes associated with the bituminous coal as a portion of the same seam; and there are in addition valuable bands of iron-ore. In Western Virginia there are several coal-seams of variable thickness, one 9½ feet, two others of 5 feet, and others 3 or 4 feet. On the whole there seems to be at least 40 feet of coal distributed in thirteen seams. In the Ohio district the whole coal-field affords on an average at least 6 feet of coal. The Maryland district is less extensive, but is remarkable as containing the best and most useful coal, which is worked now to some extent at Frostburg. There appears to be about 30 feet of good coal in four seams, besides many others of less importance. The quality is intermediate between bituminous and anthracitic, and it is considered well adapted to iron-making. Lastly, in Pennsylvania there are generally from two to five workable beds, yielding on an average about 10 feet of workable coal, and amongst them is one bed traceable for no less than 450 miles, consisting of bituminous coal, its thickness being from 12 to 14 feet on the south-eastern border, but gradually diminishing to 5 or 6 feet. Besides the bituminous coal there are in Pennsylvania the largest anthracitic deposits in the States, occupying as much as 250,000 acres and divided into three principal districts. The Illinois Coal-Field, in the plain of the Mississippi, is only second in importance to the vast areas already described. There are four principal divisions traceable, of which the first or Indiana district contains several seams of bituminous coal, distributed over an area of nearly 8000 square miles. It is of excellent quality for many purposes; one kind burning with much light and very freely, approaching cannel coal in some of its properties; other kinds consist of caking or splint coal. In addition to the Indiana Coal-Field, there appears to be as much as 48,000 square miles of coal area in the other divisions of the Illinois district. Although these are less known and not at present much worked, 30,000 square miles are in the State of Illinois, which supplies coal of excellent quality and with great facility. The coal is generally bituminous. The third great coal area of the United States is that of the Missouri, which is little known at present, although certainly of great importance. From the account given of these localities the reader will be able to appreciate in some measure the mineral resources of the United States, and may perceive also the importance of geological knowledge in recognising the laws of the position of a material so valuable.

"British America contains very large supplies of coal in the provinces of New Brunswick and Nova Scotia. The former presents three coal-fields, occupying in all no less than 57,000 square miles; but the latter is far larger, and exhibits several very distinct localities where coal abounds. The New Brunswick coal-measures include not only shales and sandstones, as is usual with such deposits, but bands of lignite impregnated with vitreous copper-ore and coated by green carbonate of copper. The coal is generally in thin seams lying horizontally. It is chiefly or entirely bituminous."

Nova Scotia contains a great quantity of coal. The great coal-field of Pictou has been traced from Carriboo Harbour to Merigomish, comprising an area of more than 100 square miles. The seams of coal resemble much more those of Staffordshire than those in the north of England. One bed is described by a practical miner, who went to Nova Scotia to superintend the opening of the mines, as 40 feet in thickness; it is not however equally good throughout, and it was thought advisable to work only 10 feet of the upper part. According to Bouchette, the seams of this field vary in thickness from 1 foot to 50 feet. The coal is highly bituminous and burns well. There is another coal-field, also of considerable extent, in the north-west part of the county of Northumberland, between the river Macan and the shores of the Chignecti Channel. In this district there are eight strata of coal, varying from 1 foot to 4 feet in thickness. This coal is not considered so good as that of Pictou. There are also indications of coal in the township of Londonderry and at Onslow; on the north shore of the Mina's basin; at the head of Pomket Harbour, in the upper district of the county of Sydney; and on the south shore of Wallace Harbour, in the county of Cumberland. (Bouchette.)

Coals of excellent quality are got in Cape Breton. The coal-measures have been traced in the western part of the island, on Inhabitants River, at Port Hood, and at Mabou. On the east the Sydney Coal-Field is of great extent; it commences at Miray Bay and runs along the coast to the Great Bras d'Or, being in length about 40 miles, and averaging 5 miles in breadth. "From a minute calculation, after deducting harbours, bays, and all other interpositions, it appears that there are 120 square miles of land, containing available veins of coal." (Bouchette.) The measures in this district contain fourteen beds of coal, varying from 3 to 11 feet in thickness. The coal is wrought at Sydney Harbour and at Lingan.

Coal is found very abundantly in Australia, and is worked extensively in the Newcastle district, on the Hunter's River. A coal formation likewise occurs in Van Diemen's Land; and coal has been found and is wrought in several parts of New Zealand.

Fossils of the Coal Formation.

The plants found in this deposit are so important that a separate article, COAL PLANTS, is devoted to them. The animal remains found have only been occasionally alluded to; we accordingly furnish a list of the genera of animals found in the entire Carboniferous System of Great Britain, as given in Professor Tennant's list of British Fossils. Where the species are more than one, the number is given, but where there is but one the specific name is added.

COAL PLANTS. That coal is the result of the mineralisation of vegetable remains is abundantly proved, both by the numerous impressions of plants found in connection with it, and by the traces of organisation which are still discoverable in it.

In general the impressions of plants occur chiefly in the shale of the coal-measures, that is, in the mud which separates the seams of coal, or in the sandstone or ironstone associated with the coal formation; and as such impressions are much more distinct than any that occur in the coal itself, it is chiefly from them that our ideas of the vegetation from which coal has been produced have been derived. They are often present in inconceivable beauty and abundance, as may be imagined from Dr. Buckland's graphic account of those in the coal-mines of Bohemia. In his 'Bridgewater Treatise,' he says:—"The finest example I have ever witnessed is that of the coal-mines of Bohemia just mentioned. The most elaborate imitations of living foliage upon the painted ceilings of Italian palaces bear no comparison with the beauteous profusion of extinct vegetable forms with which the galleries of these instructive coal mines are overhung. The roof is covered as with a canopy of gorgeous tapestry, enriched with festoons of most graceful foliage, flung in wild irregular profusion over every portion of its surface. The effect is heightened by the contrast of the coal-black colour of these vegetables with the light ground-work of the rock to which they are attached. The spectator feels himself transported, as if by enchantment, into the forests of another world; he beholds trees of forms and characters now unknown upon the surface of the earth, presented to his senses almost in the beauty and vigour of their primeval life; their scaly stems and bending branches, with their delicate apparatus of foliage, are all spread forth before him, little impaired by the lapse of countless ages, and bearing faithful records of extinct systems of vegetation, which began and terminated in times of which these relics are the infallible historians."

Such remains consist chiefly of impressions of leaves separated from their branches, and of casts of trunks more or less in a broken state; and with them occur now and then pieces of wood or remains of trees in which the vegetable texture is to some extent preserved. Of the leaves the greater part is more or less mutilated; those of ferns, which are extremely numerous, have lost their fructification in the majority of instances; and it frequently happens that the leaflets of compound leaves have been disarticulated either wholly or partially. Stems or trunks are in all cases in a state which must be supposed to result from decay previously to their conversion into coal; destitute of bark, or with the principal part of that envelope gone, and often pressed quite flat, so that all trace of their original convexity is destroyed. Where ripe fruits are met with, they are not in clusters as they probably were when alive, but separated into single individuals. Of flowers there is no trace that can be satisfactorily identified; for *Antholithes Pitcairniæ*, the most perfect that has yet been discovered, is altogether of a doubtful nature.

It will at once be seen that the investigation of plants in such a condition is very much more difficult than that which is presented by a recent Flora. The nature of the inquiries, and the difficulties presented to an investigator of the plants of the coal formation, have been well described by Dr. Joseph D. Hooker, in a paper 'On the Vegetation of the Carboniferous Period as compared with that of the Present Day,' in the second volume of the 'Memoirs of the Geological Survey of Great Britain.' His remarks are arranged under four heads—the nature of the plants, their geographical distribution, relation to the soil, and the reciprocal influence of the whole mass of the vegetation on the surface it covers:—

"1. Of the mutual affinities of the groups under which the majority of the genera of coal-plants arrange themselves little more can be said but that the ferns occupy the lower end of the series and the *Coniferæ* possibly the highest; but this depends upon the view taken of the affinities of *Sigillariæ*, the most important group. These are classed by some observers amongst Ferns, by others with *Coniferæ*, another considers them as linking these two widely-different families, whilst a fourth ranks them much higher than either. The affinities of another group, *Calamites*, are entirely unascertained. Of the whole amount of species in each no conjecture can be formed, or any but a very rough one, of the number into which those with which we are familiar as of common occurrence should be divided. The Ferns far outnumber probably all the others; but this again materially depends on the value according to the markings of *Sigillariæ*, as means of dividing that genus; for if the slight differences hitherto employed be insisted upon, the number of the so-called species may be unlimitedly increased.

"2. With regard to the geographical distribution of the species, &c., it appears that a uniformity once existed in the vegetation throughout the extra-tropical countries of the Northern Hemisphere, to which there is now no parallel; and this was so whether we consider the coal-plants as representing all the flora of the period, or a part only, consisting of some widely-distributed forms that characterised certain local conditions. Nor is this uniformity less conspicuous in what may be called the vertical distribution; the fossils in the lowest coal-beds of one field very frequently pervading all the succeeding beds, though so many as thirty may be interposed between the highest and the lowest.

"3. Of the relations between the soil and the plants nourished by it, little more is recognisable than that the *Sigillariæ* have been particularly abundant on the under clay, which, judging from the absence of any other fossils but *Sigillariæ* roots (*Stigmaria*), seems to have been either in itself unfriendly to vegetation, or so placed (perhaps from being submerged) as to be incapable of supporting any other. The latter is the most probable, because both *Sigillariæ* and their *Stigmaria* roots occur in other soils, besides under clay, and are there accompanied by *Calamites*, Ferns, &c. The *Coniferæ* again are chiefly found in the sandstones, and their remains being exceedingly rare in the clays, shales, or ironstones, it may be concluded that they never were associated with the *Sigillariæ* and other plants which abound in the coal-seams, but that they flourished in the neighbourhood, and were at times transported to these localities. The quantity of moisture to which these plants were subjected must remain a question so long as some authors insist upon the *Sigillariæ* being allied to plants now characteristic of deserts, and others to such as are the inhabitants of moist and insular climates. The singular succulent texture and extraordinary size of both the vascular and cellular tissues of many, possibly indicate a great amount of humidity. The question of light and heat involves a yet more important question, some of the coal-plants of the arctic regions being considered identical with those of Britain. How these can have existed in that latitude under the now prevailing distribution of light and heat has not been hitherto explained; they are too bulky for comparison with any vegetables inhabiting those regions at the present time, and of too lax a tissue to admit of a prolonged withdrawal of the stimulus of light, or of their being subjected to continued frosts.

"4. The consequence of the existence of the coal-plants has been the formation of coal; but how this operation was conducted is a question yet unsolved. The under-clay or soil upon which the coal rests, and upon which some of the plants grew, seems in general to have suffered little change thereby, further than what was effected by the intrusion of a vast number of roots throughout the mass. The shales on the other hand are composed of inorganic matter, materially altered by the presence of the vegetable matter they contain. The iron-clays again present a third modification of this mixture of organic and inorganic matter, often occurring in the form of nodules. These nodules seem to be the result of a peculiar action of vegetable matter upon water, charged with soil and a salt of iron; the ironstone nodules of existing peat-bogs appearing altogether analogous to those of the carboniferous period, whether in form or in chemical constituents. Here then the botanist recognises in one coal-seam a vegetable detritus under three distinct phases, and which has been acted upon in each by very different causes. In the under-clay there are roots only; these permeate its mass as those of the water-lily and other aquatic plants do the silt at the bottom of still waters.

"The coal is the detritus either of those plants whose roots are preserved in the under-clay, or of those together with others which may have grown amongst them or at a distance, and have been afterwards drifted to the same position. Above the coal is the third soil, bearing evidence of the action of a vigorous vegetation; this is the shale, which has all the appearance of a quiet deposit from water charged with mineral matters, and into which broken pieces of plants have fallen. Here there is so clear a divisional line between the coal and shale that it is still a disputed point whether the plants contained in the latter actually grew upon the former, or were drifted to that position in the fluid which deposited the mineral matter. Amongst the shales are also interspersed in many cases innumerable stumps of *Sigillariæ*, similar to those whose roots occur in the under-clay, and which are themselves found attached to those roots in soils similar to the under-clays, but unconnected with any seam of coal. These stumps are almost universally erect, are uniformly scattered over the seams, and otherwise appear to have decidedly grown on the surface of the coal; the shales likewise seem deposited between these stumps. The rarity of *Sigillariæ* roots (*Stigmaria*) in this position is probably due to their being incorporated with the coal itself, though they sometimes occur above that mineral and between the layers of shale. The seams of ironstone (or black band) are the last modifications of soil by vegetable matter to which allusion has been made. When these are uniform beds or layers, they may be supposed to be the deposit from water charged with iron and soil which has percolated through the peat, and in so doing absorbed a great deal of vegetable matter. The layers of nodular ironstone are simple modifications of these, and may be caused by the sedimentary particles contained in the fluid, which instead of being deposited in a uniform stratum, are aggregated round bits of vegetable matter (as fern leaves, stems, or cones) which served as nuclei.

"Now, though each of these points admits of some explanation when taken separately, and some illustration from the action of an existing vegetation on the soil, &c., it is very difficult to understand their combined operation over so enormous a surface—for instance, as one of the American coal-fields—and even more to account for their regular recurrence according to some fixed law in every successive coal-seam throughout the whole carboniferous formation."

Coal-plants may be divided for practical purposes into three classes: 1, those of which only wood still containing organic structure has been found; 2, those which have an obvious analogy with recent plants; 3, those with which no existing analogy has been traced.

1. *Coal-Plants of which Wood only containing Organic Structure has been found.*

The existence of wood in the coal formation with its texture still preserved, is a discovery of very modern date. Mr. Nicol, of Edinburgh, claims the credit of having first invented the art of preparing fossil wood so as to show its structure microscopically; Mr. Witham has investigated the subject extensively, and he has been followed by Messrs. Lindley, Hutton, and others. The result of these inquiries has been, that wood still preserving its texture exists in a mineral state extensively throughout the coal-mines of the north of England; that it in most cases has a structure analogous to, although not identical with, that of recent coniferous wood; and that in those cases in which its structure is not coniferous it is unlike that of any existing trees.

Coniferous wood is known amongst other things by the presence of small discs upon the sides of its woody tubes; differences in the arrangements of these discs have given rise to the formation of the genera *Peuce* and *Pinites*, to one or other of which all the coniferous coal-wood seems referrible. Mr. Nicol believes that it may all be referred to either the existing genera *Pinus* or *Araucaria*. Specimens of this kind of wood occur sometimes of considerable size. A trunk of *Pinites Brandlingi* has been found 72 feet long, and another of *Pinites Withami* 36 feet long.

The wood to which Mr. Witham's genus *Anabathra* apparently belongs is known by its longitudinal section representing tubes marked by parallel transverse lines resembling the steps of a ladder. This is very uncommon, and is stated by Messrs. Lindley and Hutton to belong to the genus *Stigmaria*, mentioned hereafter.

Specimens in ironstone also have occurred of the wood of the genus *Lepidodendron*. It consists principally of loose cellular tissue, having near the centre a zone of spiral vessels, connected with the bases of the leaves by arcs of spiral vessels, and having rudiments of wood on the outside of the zone.

2. *Coal-Plants which have an obvious Analogy with Recent Plants.*

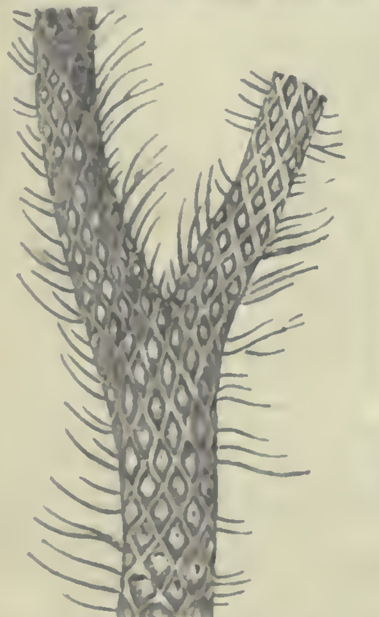
Coniferous plants have but few remains, except wood, by which they can be recognised. A cone of *Pinus anthracina* has been met with, and there is reason to believe that certain stems called *Bothrodendron*, having numerous minute dots upon their surface, and deep circular oblique concavities 4 or 5 inches across, at intervals of 10 or 11 inches, are also remains of trees of this description. It is probable moreover that some of the fossils referred to the genus

Lepidodendron are really coniferous plants, especially *L. longifolium;* but upon this point nothing certain is known.

It was at one time supposed that the remains of palms had been found: the evidence, however, upon which this supposition rests is considered by M. Brongniart and Dr Hooker as insufficient. The only portions of plants supposed to be palms that have been found, are the remains of fruits. These remains are generally oblong 3-sided or 6-sided bodies, not more than an inch long. They have been named *Trigonocarpum Noggerathi.*

Trigonocarpum Noggerathi.

Lycopodiaceous plants, or what are considered analogous to them, form a very large proportion of the vegetable remains of the north of England coal-field. They are represented by impressions closely covered either with lozenge-shaped spaces disposed in a spiral manner, or by small scale-like leaves, which are supposed to have produced those spaces by falling off. When they branch they have often been observed to do so in a forked or dichotomous manner. Sometimes they are minute, and no larger than existing *Lycopodia*, but they are occasionally found of considerable size, some having been seen which, although mere fragments, were between 40 and 50 feet long, and more than 4 feet in diameter. An idea of their appearance will be gained from the accompanying figure of *Lepidodendron Sternbergii.*



Lepidodendron Sternbergii.

Lepidostrobus variabilis.

Associated with them are narrow sharp-pointed leaves resembling scales, which no doubt belonged to them, but which are distinguished by the name of *Lepidophyllum.* In the same formations are found cones of different sizes, consisting of small sharp-pointed lax scales, in the axils of which were seeds: these have been supposed to be the fructification of *Lepidodendron*; but as there is no actual certainty of the fact, they bear the name of *Lepidostrobi.* The above figure represents *Lepidostrobus variabilis.* [LEPIDOSTROBUS.]

Lepidodendra are usually quoted as an instance of ancient species belonging to the same genus as modern plants of very humble stature (the existing *Lycopodia*, although they acquire sometimes the length or height of three or four feet, are always more like mosses than trees), having arrived at gigantic dimensions in the remote ages when coal was deposited. This is the opinion of M. Adolphe Brongniart and Dr Joseph Hooker, who have both studied this subject carefully. Dr. Lindley has however expressed the opinion that the *Lepidodendra* are allied to the *Coniferæ.* He argues, in the first place, that there is no certainty whatever that the most gigantic *Lepidodendra* were not fir trees, analogous to *Araucaria;* a conjecture which is rendered the more probable by Mr. Nicol's discovery that some of the specimens of fossil coniferous wood are nearly identical with the wood of that genus. Now, the Norfolk Island Pine, which is a species of *Araucaria*, is one of the largest of known trees. In the second place, it is asserted that *Lepidodendron Harcourtii* is not a Lycopodiaceous plant at all, but an extinct genus, intermediate in organisation between *Coniferæ* and *Lycopodiaceæ*, connecting Gymnosperms and Acrogens more directly and satisfactorily than any known plant. Dr. Lindley admits that with regard to the small species of *Lepidodendron*, it is more probable that they belonged to the genus *Lycopodium;* but there is nothing remarkable in their stature.

Ferns are the most abundant of all plants in the shale of the coal, almost every yard of it being more or less marked by their impressions, and very often containing them in great multitudes. It has been estimated that of the vegetable remains belonging to the Coal Flora, one-half at least of the species are ferns. They are in most cases destitute of fructification, so that they cannot be arranged according to the system in use for recent species; and consequently M. Adolphe Brongniart, the great writer upon these subjects, has divided them into genera characterised chiefly by the way in which the veins are disposed. The number of ferns renders it convenient that some such classification should be formed, and M. Brongniart's plan has been adopted by all other writers. It is no part of our object to go into such details in this place, but it will be useful to many of our readers to know what the differences are between some of the most common of these fossil genera. Such are the following:—

Pecopteris consists of species whose leaves are once, twice, or thrice pinnated, with the leaflets either adhering by the whole breadth of their base, or by the centre only. The midrib runs quite through to the point, and the veins are planted upon it somewhat perpendicularly.

Pecopteris lonchitica, a little magnified.

Neuropteris has leaves divided like those of *Pecopteris*, but the midrib does not reach the apex of the leaflets; on the contrary, it divides off right and left into veins, and gradually disappears.

Neuropteris gigantea.

Odontopteris has leaves like the last, but its leaflets adhere to the stalk by their whole base; there is no midrib; and the veins spring side by side at once from the base of the leaflet, passing onwards towards the point.

Odontopteris Brardii.

Sphenopteris has twice or thrice pinnatifid leaves; the leaflets are narrowest at the base, and the veins generally arranged as if they radiated from the base; the leaflets are more frequently wedge-shaped than any other figure.

Sphenopteris artemisiæfolia, magnified.

Lonchopteris has the leaves several times pinnatifid, and the leaflets more or less united to one another at the base; there is a distinct midrib, and the veins are reticulated.

Lonchopteris Bricii.

Cyclopteris has the leaves simple, and either altogether undivided or only lobed at the margin; they are more or less orbicular, and are filled with veins radiating from the base; there is no midrib. Specimens of this genus are common in ironstone nodules.

Cyclopteris orbicularis.

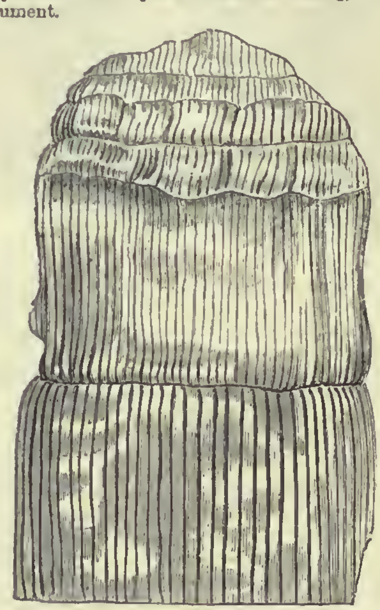
Schizopteris is like the last, except that the leaf is deeply divided into numerous unequal segments, which are usually lobed and taper-pointed.

Under the name of *Caulopteris* are comprehended all the kinds of stems of tree-ferns. They are found in the form of short, round, or compressed truncheons, marked externally by oblong scars of considerable size, much wider than the spaces that separate them, and having their surface irregularly interrupted by projecting points. Such appearances are owing to the manner in which the woody parts of the leaf when fresh were connected with the stem. The fragments to which this name is given no doubt belong to leaves bearing other names; but as the stems and leaves are never found united, it is impossible to identify them. Remains of tree-fern stems are of such rare occurrence that up to the present time not more than two or three specimens have been found in the rich coal-fields of Great Britain.

Dr. Joseph Hooker observes, with regard to the species of fossil ferns, that the characters on which many of them have been founded are quite insufficient to prove them distinct. He shows that amongst recent ferns the presence of the fructification is alone sufficient to show the identity of forms that, according to the method of procedure amongst fossil ferns, would be widely distinct.

3. *Coal Plants with which no existing Analogy has been satisfactorily traced.*

Calamites are fossils found in short, jointed, cylindrical, or compressed fragments, with channels furrowed in their sides, and sometimes partially surrounded by a bituminous coating, the remains of a cortical integument.



Calamites dubius.

They were originally hollow, but the cavity is usually filled up with the substance into which they themselves are converted. They were separable at their articulations, and, when broken across at that part, show a number of striæ originating in the furrows of the sides, and turning inwards towards the centre of the stem, which however they do not reach. It is not known whether this structure was connected with an imperfect diaphragm stretched across the hollow of the stem at each joint, or whether it merely represents the ends of woody plates of which the solid part of the stem was composed. Their extremities have been discovered either to taper gradually to a point, or to end abruptly, the intervals becoming shorter and smaller. The latter are believed to have been the root-ends of these plants, the others the extremity of their branches. Various speculations upon the nature of these plants are to be found in M. Adolphe Brongniart's works, and in Lindley and Hutton's 'Fossil Flora.' The former botanist concludes that they were plants allied to *Equisetum*, only of a more gigantic stature. Later botanists, on the contrary, adduce what they consider ample evidence to show the supposition that *Calamites* were analogous to *Equiseta* to be unfounded; and that they more probably were a race of plants which have now become extinct. It is particularly urged that the presence of bark in *Calamites*, the existence of which M. Adolphe Brongniart admits, is quite conclusive against these plants being related to the *Equisetaceæ*. Dr. Hooker also points out the absence of siliceous matter in the *Calamites*, a substance always found to be present in recent *Equisetaceæ*.

Stigmaria is one of the most common vegetable forms in the coal formation; not a mine is opened, nor a heap of shale thrown out, but there occur fragments of an irregularly-compressed roundish form, apparently portions of a stem, marked externally with small cavities in the centre of slight tubercles arranged irregularly, but somewhat in a quincuncial manner. The axis of these fragments is often hollow, or different in texture from the surrounding part. From the tubercles arise long ribbon-shaped bodies, said to have been traced to the length of twenty feet. Although for a long time regarded as an independent plant, there is now no longer any doubt that *Stigmaria* is the root of *Sigillaria*. In various places specimens of *Sigillaria* have been found standing upright *in situ*, with the *Stigmaria* proceeding from it as roots.

Stigmaria ficoides.

Sigillaria comprehends all those columnar gigantic stems which occur commonly in the sandstone of the coal in an erect or nearly erect position, but which are prostrate and crushed flat in the coal-shale, and which are marked by flutings with a single row of small scars between them. In diameter they vary from 6 to 36 inches, and they must have sometimes been full 40 or 50 feet high.

It is believed, from the very compressed state of many specimens, that these plants must have been of a soft nature, and, from the general absence of scars of large size, that they must have been very little branched.

Of the foliage of *Sigillaria* little or nothing is known. The scars, especially in the larger species, are much too broad to be regarded as the point of attachment of leaves such as may be supposed to have been the case in *Lepidodendron*. The great mass of the stems of *Sigillaria* seems to have been of a soft and succulent character, but the remains of a central column of a denser texture are sufficiently obvious in many of the upright stems. These have been called *Endogenites*. "That this slender column," says Dr. Hooker, "represented all the vascular tissue of this plant, I cannot doubt from examination of *Stigmaria*, whose vascular column often assumes the same appearance."

The affinities of these plants have been variously estimated. Artis, Lindley, Hutton, and Corda, have referred them to *Euphorbiaceæ*; Schlotheim to Palms; Von Martius to *Cactaceæ*; Sternberg to Ferns; Brongniart to *Cycadaceæ*. Dr. Hooker, regarding *Sigillaria elegans* as their type, places them not far from *Lycopodiaceæ*, and near to *Lepidodendron*. "That it was," he says, "of much completer structure and higher organisation than either, is incontestable; but the indications of a relationship with any individual group higher in the series, or with *Cycadeæ* in particular, appear to me far too feeble to justify our considering it as tending to unite these two natural orders." It is a plant which must be considered as belonging to the great family of Ferns, displaying a relationship, though only of analogy, to *Cycadeæ* in one point and to *Euphorbiaceæ* and *Cactaceæ* in others."

Sigillaria reniformis.

Asterophyllites are very common plants, with narrow pointed whorled leaves, which vary in figure and in size, but which, together with the slenderness of the stem to which they belong, give the plants much the appearance of the modern genus *Galium*. They present however no further affinity to Exogenous Plants than this analogy of form.

Sphenophyllum, with many of the characters of the last genus, has broad wedge-shaped leaves, the veins of which are forked. That circumstance has led to the notion that it was related to Ferns, especially to the genus *Marsilea*.

Sphenophyllum Schlotheimii. Asterophyllites foliosus.

Such are the more common of the plants whose remains are traced in the coal-measures. One of the first things which strikes us in casting the eye on the list is the little variety of form apparent in the old flora. Instead of the infinite diversity of plants which are contained in a modern forest, nothing here presents itself except fir-trees, ferns, and a small number of species whose nature is unknown. Not a trace is found of grasses, or the numerous herbs and shrubs that are now met with in all regions clothed with vegetation; and of the vast class of Exogens not one authentic instance occurs. Ferns, too, would seem to have constituted in themselves one-half of the entire Flora, and yet it is only in a few rare cases that they have been met with in a state of fructification. These circumstances have led to the hasty inference that in the beginning nature was in reality but little diversified; that a few forms of organisation of the lower kind only were all that clothed the face of the earth; and that it was only in after-ages that nature assumed her many-coloured ever-varying robe. And yet it has been at the same time admitted that in those early days vegetation was more luxuriant and vigorous than at the present hour. It is not a little singular that the true explanation of this circumstance should not have been hit upon without any direct experiment having been instituted for the purpose of demonstrating how it is really to be explained; for, considering that all geologists are of accord in the opinion that the plants which formed coal were for a period of some duration floating in water, a partial destruction of them might easily have been supposed to be the result. Professor Lindley has proved that plants are capable of enduring suspension in water in very different degrees, some resisting a long suspension almost without change, others rapidly decomposing and disappearing. One hundred and seventy-seven plants were thrown into a vessel containing fresh water; among them were species belonging to the natural orders of which the flora of the coal-measures consists, and also to the common orders, which, from their general dispersion over the globe at the present day, it might have been expected should be found there. In two years one hundred and twenty-one species had entirely disappeared; and of the fifty-six which still remained, the most perfect specimens were those of Coniferous Plants, Palms, *Lycopodiaceæ*, and the like; thus showing in the clearest manner that the meagre character of the Coal Flora may be owing to the different capabilities of different plants of resisting destruction in water. The same experiment accounts for the want of fructification in fossil ferns; for it showed that one of the consequences of long immersion in water is a destruction of the fructification of those plants.

A much more important fact is the presence of certain tropical forms of vegetation, such as tree-ferns, in the coal; and the quasi-tropical character of other species, as *Araucaria*-like *Coniferæ*. This is the more startling when connected with another fact, that the coal-measures of Newcastle are of the same age as those of Newfoundland, and even of Melville Island, in 75° N. lat.

From this it has been inferred that the northern parts of the world enjoyed in remote ages a climate where frost and snow, and the inclement seasons of arctic regions were unknown; that they were at least as hot as equinoctial countries now are; and that the inhospitable hyperborean plains of Melville Island at one time displayed the noble scene of a luxuriant and stately vegetation. Palms, it has been said, were there, and they are the especial and princely denizens of the tropics; tree-ferns occur, and they now only exist in the primeval forests of the torrid zone, haunting their deepest recesses, breathing a damp and equable atmosphere, and living, like vegetable eremites, without even a parasite to fix itself upon their trunks and keep them company. *Stigmariæ*, *Sigillariæ*, and even *Calamites* have been enlisted in the cause of this theory, notwithstanding that no one can say what they may have been. And in confirmation of all this, the preponderance of ferns has been appealed to as having its parallel nowhere except in the hottest and dampest islands of Polynesia.

In opposition to this view it has been asserted that the presence of these tropical forms of vegetation in northern latitudes is no proof of what the climate in which they were deposited formerly was, because they may have been drifted to their present situations by currents. The perfect state of many of the remains offers however great difficulties in the way of this supposition; for although they are very much broken, yet the angles of most fossil plants are by no means water-worn, and in *Sigillariæ*, &c. are as sharp as they ever were. Nor is the state of those tropical stems and fruits, which in modern times reach the coasts of Ireland and Norway, at all like that of the buried plants of the coal-measures.

Another difficulty in the way of admitting a high temperature in northern regions in former days is suggested by considering the duration of the days. Without a diurnal change of light and darkness plants cannot exist; absence of light blanches them, by the accumulation of undecomposed carbonic acid; absence of darkness destroys or dwarfs and deforms them, by the incessant decomposition of their carbonic acid. Now, however this may be reconciled with a country like England, in which the winter days are of moderate length, it is less reconcilable with the northern parts of North America, and not at all with Melville Island, in which there are 94 days when the sun is never above the horizon, and 104 days that he never sets. With regard to the transportation of the coal, the absence of indications of washing, and the frequent occurrence of upright stems, seem to lead to the conclusion that in most instances the plants which formed coal have grown at the most within a few hundred miles of the places where they are now deposited, and probably in their very vicinity. From this statement we must at present except the coal of Melville Island; for although the vegetable impressions in the English coal-measures are by no means water-worn, yet those in the British Museum from Melville Island are so rubbed and damaged that there is no doubt they have travelled long distances before they were deposited.

The opinion that the plants of the coal-measures afford evidence that the climate where they grew must have been tropical, has been founded upon three classes of facts, each of which requires separate examination; the one, the excessive development of certain forms of vegetation; another, the presence of the remains of palms and tree-ferns, which are usually considered incapable of existing unless in a tropical atmosphere; the third, the excessive disproportion of ferns to other plants.

With regard to the first argument it may be answered, that we know too little of the real nature of the *Sigillariæ*, *Lepidodendra*, *Calamites*, and other plants, to form a correct opinion. It is almost certain that all these plants are in reality destitute of living analogies; and therefore as we do not know what they were, we have no means of judging what kind of climate they required. Supposing that some of the *Lepidodendra* were closely allied to the modern genus *Araucaria*, as is highly probable, yet that fact does not afford any proof of a tropical climate; for *Araucaria Dombeyi* now inhabits the cold mountains of southern Chili, and is at this day uninjured in the severest of our English winters; while *Cunninghamia Sinensis*, and species of *Callitris* or *Dacrydium*, with which other remains of *Lepidodendra* may be compared, although not European, are by no means of tropical habits, but are found on the mountains of New Zealand and Van Diemen's Land, where they are exposed to a far from temperate climate. Moreover, *Salisburia adiantifolia*, which would certainly be considered a tropical form of *Coniferæ*, if found in an extinct state only, is one of the hardiest of trees, and a native of the rigorous climate of Japan. But even supposing *Sigillariæ* could be found to have been succulent plants, allied to *Cactaceæ* or *Euphorbiaceæ*, as some think, still no real evidence of their having required a tropical climate for their development would be afforded by them, because there is nothing in the mere organisation of succulent plants which unfits them for cold climates. A capability of enduring cold is something immaterial and independent of organisation, about which nothing can be judged à priori; for turnips, cabbages, Jerusalem artichokes, house-leek, and many other hardy plants are in parts as succulent as *Cactaceæ*. All arguments therefore to prove that the north of Europe was formerly tropical, deduced from the presence of such plants as those now mentioned, are inadmissible.

Nor is the argument derived from the presence of palms and tree-ferns of much greater force. In the first place, we have seen that there is really no grounds for believing that palms existed; and as for tree-ferns, we have them in New Zealand, and especially on the south side of Van Diemen's Land, where the mean temperature probably does not exceed 54° Fahrenheit. So that, all things considered, it is by no means safe to take the remains of these plants as good evidence of a tropical climate, or of a climate materially unlike that which we now experience.

The only remaining argument to be considered is that derived from the great preponderance of ferns in the Coal Flora. It is said by Adolphe Brongniart, that as it is only in damp tropical regions that we now find ferns equal in the number of their species to all the species of other plants, and as this same proportion is found in the Coal Flora, that therefore the climate under which the Coal Flora was produced must have been damp and tropical. But as, by the experiment already mentioned, it was shown that when a given number of plants of entirely different habits are plunged into the same vessel of water, by far the greater part is decomposed before ferns begin to be affected, it is obvious that no estimate of what the proportion of ferns to other plants really was, can now be formed; and consequently this argument also falls to the ground.

From these facts it appears then that we may safely adopt the following conclusions:—

1. That coal is of vegetable origin.
2. That at the period of its deposit, the earth was covered with a rich vegetation, of which only a small portion has been preserved; and that of this portion all the species and several of the races are totally unknown at the present day.
3. That the climate may possibly have been something milder than it now is, but that there is no evidence in the vegetable kingdom to show that it was materially different from that of the present day.

The following is a list of the species of plants that have been found in the coal-measures of Great Britain, as given by Professor Tennant in his 'Stratigraphical List of British Fossils.' Very few species indeed appear to have been found in other parts of the world that are not found in Great Britain:—

Alethoptheris Cistii, Gopp.
A. heterophylla, Gopp.
A. Lindleyana, Presl.
A. lonchitidis, Sternb.
A. Mantelli, Gopp.
A. nervosa, Gopp.
A. Sauverii, Gopp.
A. Serra, Gopp.
A. Serlii, Gopp.
A. urophylla, Gopp.
A. vulgatior, Sternb.
Anabathra pulcherrima, Lindley.
Annularia fertilis, Sternb.
A. longifolia, Brong.
Antholithes anomalus, Morris.
A. Pitcairnia, Lindley.
Aphlebia adnascens, Presl.
Artisia approximata, Brong.
A. distans, Brong.
A. transversa, Presl.
Aspidiaria Anglica, Presl.
A. confluens, Presl.
A. cristata, Presl.
A. quadrangularis, Presl.
A. undulata, Presl.
Asterophyllites comosus, Lindley.
A. foliosus, Lindley.
A. galioides, Lindley.
A. jubatus, Lindley.
A. rigidus, Lindley.
Bechera charæformis, Sternb.
B. grandis, Sternb.
Bornia equisetiformis, Sternb.
Bruckmannia grandis, Lindley.
B. longifolia, Sternb.
B. rigida, Sternb.
B. tenuifolia, Sternb.
B. tuberculata, Sternb.
Calamites approximatus, Brong.
C. cannæformis, Schlot.
C. Cistii, Brong.
C. decoratus, Brong.
C. dubius, Brong.
C. inæqualis, Brong.
C. Lindleyi, Sternb.
C. nodosus Schlot.

C. pachyderma, Brong.
C. ramosus, Brong.
C. Steinhaueri, Brong.
C. Suckowii, Brong.
C. undulatus, Brong.
C. varians, Sternb.
C. verticillatus, Lindley.
Cardiocarpon acutum, Brong.
Carpolithes alatus, Lindley.
C. helicteroides, Morris.
C. marginatus, Artis.
C. sanmodes, Morris.
Caulopteris Phillipsii, Lindley.
C. primaeva, Lindley.
Chondrites Prestricii, Morris.
Cyclopteris dilatata, Lindley.
C. flabellata, Brong.
C. oblata, Lindley.
C. obliqua, Brong.
C. orbicularis, Brong.
C. reniformis, Brong.
Cyperites bicarinata, Lindley.
Favularia tessellata, Lindley.
F. nodosa, Lindley.
Flabellaria borassifolia, Sternb.
Halonia disticha, Morris.
H. gracilis, Lindley.
H. regularis, Lindley.
H. tortuosa, Lindley.
H. tuberculosa, Lindley.
Lepidodendron Bucklandi, Brong.
L. elegans, Brong.
L. Harcourtii, Lindley.
L. longifolium, Brong.
L. obovatum, Sternb.
L. plumarium, Lindley.
L. selaginoides, Sternb.
L. Serlii, Presl.
L. Sternbergii, Brong.
Lepidophyllum intermedium.
L. lanceolatum.
L. trinerve, Lindley.
Lepidostrobus comosus, Lindley.
L. ornatus, Lindley.
L. pinaster, Lindley.
L. variabilis, Lindley.
Lycopodites cordatus, Sternb.
L. phlegmarioides, Sternb.
Megaphyton Allani, Presl.
M. approximatum, Lindley.
M. distans, Lindley.
Myriophyllites gracilis, Artis.
Neuropteris acuminata, Brong.
N. acutifolia, Brong.
N. angustifolia, Brong.
N. attenuata, Lindley.
N. cordata, Brong.
N. flexuosa, Sternb.
N. gigantea, Sternb.
N. heterophylla, Brong.
N. Loshii, Brong.
N. macrophylla, Brong.
N. rotundifolia, Brong.
N. Soretii, Brong.
N. tenuifolia, Sternb.
Noeggerathia flabellata, Lindley.
Odontopteris Britannica, Presl.
O. Lindleyana, Sternb.
O. obtusa, Brong.
O. Schlotheimii, Brong.
Pecopteris abbreviata, Brong.
P. adiantoides, Lindley.
P. arborescens, Brong.
P. Bucklandi, Brong.
P. dentata, Brong.
P. heterophylla, Lindley.
P. laciniata, Lindley.
P. Miltoni, Brong.
P. muricata, Brong.
P. obliqua, Brong.
P. oreopteridis, Brong.
P. plumosa, Brong.
P. pteroides, Brong.
P. repanda, Lindley.
P. villosa, Brong.
Peuce Withami, Lindley.
Pinites ambiguus, Witham.
P. anthracina, Lindley.
P. Brandlingi, Lindley.
P. carbonaceus, Witham.
P. medullaris, Lindley.
P. Withami, Lindley.
Pinnularia capillacea, Lindley.
Pitys antiqua, Witham.
P. primaeva, Witham.
Poacites cocoina, Lindley.
Rhodea dissecta, Presl.
R. furcata, Presl.
Sagenaria aculeata, Presl.
S. caelata, Brong.
S. ophiura, Brong.
Selaginites patens, Brong.
Sigillaria alternans, Lindley.
S. catenulata, Lindley.
S. contracta, Brong.
S. elongata, Brong.
S. flexuosa, Lindley.
S. Knorrii, Brong.
S. leioderma, Brong.
S. laevigata, Brong.
S. Murchisoni, Lindley.
S. notata, Brong.
S. oculata, Lindley.
S. ornatum, Brong.
S. reniformis, Brong.
S. Saullii, Brong.
Sphenophyllum dentatum, Brong.
S. emarginatum, Brong.
S. erosum, Lindley.
S. Schlotheimii, Brong.
Sphenopteris acutifolia, Brong.
S. adiantoides, Lindley.
S. affinis, Lindley.
S. artemisaefolia, Sternb.
S. bifida, Lindley.
S. caudata, Lindley.
S. Conwayi, Lindley.
S. crassa, Lindley.
S. crenata, Lindley.
S. cuneolata, Lindley.
S. dilatata, Lindley.
S. elegans, Brong.
S. excelsa, Lindley.
S. gracilis, Brong.
S. Hibbertii, Lindley.
S. latifolia, Brong.
S. linearis, Sternb.
S. macilenta, Lindley.
S. multifida, Lindley.
S. obovata, Lindley.
S. polyphylla, Lindley.
S. tenella, Brong.
S. trifoliata, Brong.
Stigmaria ficoides, Brong.
Trigonocarpum Dawesii, Lindley.
T. Noeggerathii, Brong.
T. oblongum, Lindley.
T. olivaeforme, Lindley.
T. ovatum, Lindley.
Ulodendron Allani, Buckl.
U. Conybearii, Buckl.
U. Lucasii, Buckl.
U. majus, Lindley.
U. minus, Lindley.
Walchia piniformis, Schlot.

More recent investigations have enlarged this list: at the same time it should be remembered, that there is considerable doubt as to whether all these forms should be regarded as species. The following table drawn up by Mr. Pattison in his chapters on Fossil Botany will give an idea of the comparative abundance and diversity of the plants of the Coal period in Great Britain as compared with that of any other geological period :—

Formation.	Plants found Fossil.	
	Genera.	Species.
Tertiary	21	120
Chalk	3	4
Greensand	7	9
Wealden	8	11
Oolite	34	89
Lias	7	10
New Red-Sandstone	6	6
Coal-Measures	58	279
Devonian and Silurian	1	1
	145	529

COASSUS. [Cervidae.]

COBAEA'CEAE, a small natural order of Plants, separated by D. Don from *Polemoniaceae*. It has a leafy 5-cleft equal calyx; an inferior campanulate regular 5-lobed corolla, imbricate in aestivation; 5 unequal stamens rising from the base of the corolla, with 2-celled compressed anthers; superior 3-celled ovary, surrounded by a fleshy annular hypogynous disc; the ovules several, ascending; simple style; trifid stigma; the fruit capsular, 3-celled, 3-valved, with a septicidal dehiscence; the placenta very large, 3-cornered in the axis, its angles touching the line of dehiscence of the pericarpium; the seeds flat, winged, imbricated in a double row, their integument mucilaginous, fleshy albumen, and a straight embryo; the cotyledons foliaceous; the radicle inferior. The species are climbing shrubs, with alternate pinnated leaves, the common petiole being converted into a tendril. G. Don observes that this order is readily distinguished from *Bignoniaceae* and *Pedalineae* by the flowers being regular and pentandrous, and in the presence of albumen in the seeds; and from *Polemoniaceae* by habit and its winged seeds. Lindley places the genus *Cobaea*, which is the only one of the order, in *Polemoniaceae*, and says, "The differences of importance between the one and the other appear to consist in the former having an unusually large lobed disc, a septicidal dehiscence, and climbing habit; distinctions, I fear, of too little moment to be admitted as of ordinal value."

There are two species of *Cobaea*, *C. scandens* and *C. lutea*: the former has large campanulate flowers, with a short tube of a dark dirty purple colour; the latter has yellowish flowers, about half the size of those of *C. scandens*. The *C. scandens* is a great favourite in our gardens, and is a rapid-growing and abundant-flowering climber. It will grow in the open air in summer, and should be trained against a south wall, or against a house, when it flowers profusely. It is adapted for conservatories and greenhouses. It may be propagated by seeds or cuttings.

(Don, *Dichlamydeous Plants*; Lindley, *Natural System*.)

COBALT ORES. Cobalt is not found in the native state, and its ores, though not numerous, require a more minute examination than they have hitherto received. We shall notice those which are best known.

Bright White Cobalt or *White Cobalt* occurs crystalline and massive; the primary form is a cube, the planes of which are usually striated; colour silver-white; streak grayish-black; lustre metallic; hardness 5·5, yielding with difficulty to the knife, and not very frangible; specific gravity 6·3 to 6·5; fracture uneven; cleavage parallel to the faces of the cube; before the blowpipe on charcoal gives arsenical fumes, and tinges borax of a deep blue.

It is found in fine crystals at Tunaberg in Sweden, in Norway, Silesia, and Cornwall.

It is met with also amorphous, arborescent, botryoidal, and stalactitic. The following is the analysis of the crystals from Tunaberg by Klaproth and Stromeyer :—

Cobalt	44	36·7
Arsenic	55	49·0
Sulphur	00·5	5·6
		6·5
	99·5	97·8

Tin-White Cobalt or *Hard White Cobalt* occurs massive and crystallised in cubes and octohedrons; colour tin-white, but sometimes externally tarnished; fracture fine-grained and uneven; lustre metallic; it yields with difficulty to the knife, and is hard and brittle; specific gravity variously stated, from 6·74 to 7·7; yields arsenical vapour when heated with the blowpipe, and tinges borax deep blue.

The massive is amorphous, arborescent, botryoidal, &c. The amorphous occurs in Cornwall, and the crystallised at Skutterud in Norway. Analysis of the crystals by Stromeyer :—

Cobalt	33·10
Arsenic	43·46
Iron	3·23
Sulphur	20·00
	99·79

Gray Cobalt occurs massive and crystallised; primary form a cube; colour grayish tin-white; streak grayish-hlack; lustre metallic; hardness 5·5; specific gravity 6·466; fracture uneven; cleavage indistinct. The massive occurs amorpbous and reticulated. It is found principally at Schneeberg in Saxony, and is used in the mauufacture of smalt.

Earthy Cobalt occurs massive, amorphous, hotryoidal, pulverulent, &c.; colour yellowish-brown and bluish-hlack; specific gravity 2 to 2·4; tbe fracture of tbe massive is earthy and dull, but polished by friction, and yields to the knife readily; when heated on charcoal gives an arsenical odour, and a deep blue colour with borax: it is found in Hesse, Saxony, Bohemia, and also in Cheshire and Cornwall.

Sulphuret of Cobalt occurs yellowish-wbite and steel-gray; streak gray; it is amorphous or botryoidal, and externally brilliant; fracture uneven. According to Hitsinger it consists of—

Cobalt	43·2
Copper	14·4
Iron	3·53
Sulphur	38·50
Earthy Matter	·33
	99·96

Arseniate of Cobalt—Cobalt Bloom—Red Cobalt—occurs fibrous, massive, and crystallised; primary form an oblique rhombic prism; colour various shades of red passing into crimson; sometimes grayish; translucent, transparent; it is soft, light, and flexible; specific gravity 2·948; the massive variety amorphous, botryoidal; structure fibrous, radiating; before the blow-pipe emits arsenical odours, and tinges borax blue: it occurs in Saxony, Bohemia, Scotland, and Cornwall, &c.

Analysis by Bucholz:—

Arsenic Acid	37·9
Oxide of Cobalt	39·2
Water	22·9
	100

Sulphate of Cobalt—Red Vitriol—is of a pale rose-red colour, and occurs investing other minerals, in small masses and in stalactites; the masses are semi-transparent and crystalline; it is soluhle in water; translucent; lustre vitreous, often dull externally: it occurs among the mining heaps near Hanau and in Salzburg.

COBALTINE, an Arsenical Ore of Cobalt containing sulphur. It is of a silver-white colour inclining to red. It is found in Sweden, Norway, Siberia, and Cornwall.

COBITIS, a genus of Fishes belonging to the Abdominal *Malacopterygii* and family *Cyprinidæ*. This genus includes tho Loaches, fishes generally of diminutive size, which may be distinguished by tbeir having the head small; mouth but slightly cleft, without tecth, and furnished with harbules on the upper lip; body elongated, covered with small scales, and invested with a mucous secretion; ventral fins situated far back, dorsal fin placod above them; gill-openings small; branchiostegous rays tbree in number.

C. barbatula, the Loach, Loche, or Beardie, is common in most of our running waters. It is about 4 inches in length, and of a dirty pale-yellow colour, mottled with hrown; its upper lip is furnished with six barbules, one of which springs from each corner of the mouth, and the otbers are situated on the fore part.

Like fishes in general which have barbules, the Loaches feed at the bottom of the water. The species above described spawns in March or early in April, and is very prolific.

C. tænia (Linn.), the Spined Loach, or Groundling, is a far less common species than the above; its form is more compressed; the harbules are very short, and consequently less conspicuous: tbe principal character however consists in its having two spines, one before each eye. From tbis character and some other differences of minor importance, tbis fish, and several others baving tbe same structure, have been separated from tho true loaches, and now constitute the genus *Botia* of Mr. Gray.

The Loachos aro extremely restless during stormy weather, when they generally riso to the surface of tho water, wbich from their restlessness is kept iu constant agitation.

COB-NUT or HOG-NUT, a name given in the West Indies to the fruit of a species of *Omphalea*. [OMPHALEA.] It is also applied to the larger forms of the cultivated Hazel-Nut. [CORYLUS.]

COBRA. [VIPERIDÆ.]

COCA, the dried leaf of *Erythroxylon Coca*, is one of those stimulating narcotics which belong to tbe same class with tobacco and opium, but is more remarkable than either of tbem in its effects upon the human system. The plant is found wild in Peru, according to Pöppig, in the environs of Cuchero, and on the stony summit of the Cerro de San Cristohal. It is cultivated extensively in the mild hut very moist climate of tho Andes of Peru, at from 2000 to 5000 feet above tho sea: in colder situations it is apt to be killed, and in warmer districts the leaf loses its flavour.

A detailed account of it is given by Pöppig and Sir William Hooker in the 'Companion to the Botanical Magazine,' whence we extract the following information. It forms a shrub from 4 to 8 feet high, the stem coverod with whitish tubercles, which appear to be formed of two curved lines set face to face. The leaves are oblong, acute at each end, 3-ribbed, on short petioles, with a pair of intrapetiolary brown acute stipules. Flowers in little fascicles; peduncles sharply angled; calyx 5-cleft; petals obloug, concave, wavy, with a jagged plaited membrane arising from within their hase; stamens 10; styles 3; fruit a 1-seeded oblong drupe.

Erythroxylon Coca.

Tho effects of this drug are said to be of the most pernicious nature, exceeding even opium in tho destruction of mental and bodily powers. The coca leaf is chewed hy the Peruvians, mixed with finely-powdered chalk, and brings on a state of apathy and indifference to all surrounding objects, the desire for which increases so much with indulgence in it, that a confirmed Coca-chewer is said never to have been reclaimed. Pöppig describes such a person in his usual graphic manner:—

"Useless for every active pursuit in life, and the slave of his passions, even more than the drunkard, he exposes himself to tbe greatest dangers for the sake of gratifying this propensity. As tbe stimulus of the coca is most fully developed when the body is exhausted with toil, or the mind with conversation, the poor victim then hastens to some retreat in a gloomy native wood, and flinging himself under a tree, remains stretcbed out tbere, heedless of night or of storms, unprotected by covering or by fire, uncouscious of the floods of rain and of the tremendous winds which sweep the forest; and after yielding himself, for two or three entire days, to the occupation of cbewing coca, returns home to his abode, with trembling limbs and a pallid countenance, the miserable spectacle of unnatural enjoyment. Whoever accidentally meets the Coquero under such circumstances, and hy speaking interrupts the effect of this intoxication, is sure to draw upon himself the hatred of the half-maddened creature. Tbe man who is once seized with the passion for this practice, if placed in circumstances which favour its indulgence, is a ruined being. Many instances were related to us in Peru, wbere young people of the best families, by occasionally visiting the forests, have begun using the coca for the sake of passing the time away, and, acquiring a relish for it, have, from that period, been lost to civilisation; as if seized by some malevolent instinct, they refuse to return to their homes; and, resisting the entreaties of their friends, who occasionally discover the haunts of these unhappy fugitives, either retire to some more distant solitude, or take the first opportunity of escaping when they bave been brought back to the towns."

The immoderate addiction of the Peruvians to the use of this drug is such tbat their forests bave long since ceased to be able to supply tbeir wants; and tho cultivation of the plant has been carried to a very great extent, not only under the Incas, but beneath the local government of the Spaniards, who seem to bave been no more able to resist the temptation of a large revenue from the mouopoly of this article than European nations from tbe consumption of ardent spirits. It is said that in the year 1583 the government of Potosi derived a sum of not less than 500,000 dollars from the consumption of 90,000 to 100,000 baskets of the leaf. The cultivation of Coca is therefore an important feature in Peruvian husbandry, and, it is added, so lucrative, that a coca plantation, whose original cost and current expenses amounted to 2500 dollars during tbe first 20 months, will, at tbo end of 10 months more, bring a clear income of 1700 dollars. Pöppig states that Coca has now become a sort of necessary evil; that thousands of persons would be deprival of their means of existence if its consumption were put a stop to; and that the value of it in Peru and Bolivia amounts to above two and a half millions of dollars a year.

The exciting principle of the Coca has not yet been inquired into. It is stated by Pöppig to be of so very volatile a nature that leaves only twelve months old become perfectly inert and good for nothing. "Large heaps of the freshly-dried leaves, particularly while the warm rays of the sun are upon them, diffuse a very strong smell, resembling that of hay in which there is a quantity of melilot. The natives never permit strangers to sleep near them, as they would suffer violent headaches in consequence. When kept in small portions, and after a few months, the coca loses its scent and becomes weak in proportion. The novice thinks that the grassy smell and fresh hue are as perceptible in the old state as when new, and this is to be expected with the Peruvian, who never uses it without the addition of burnt lime. Without this, which always excoriates the mouth of a stranger, the natives declare that coca has not its true taste, a flavour, by the bye, which can only be detected after a long use of it. It then tinges green the carefully-swallowed spittle, and yields an infusion of the same colour. Of the latter alone I made trial, and found that it had a flat grass-like taste, but I experienced the full power of its stimulating principles. When taken in the evening it was followed by great restlessness, loss of sleep, and generally uncomfortable sensations; while, from its exhibition in the morning, a similar effect, though to a slight degree, arose, accompanied with loss of appetite. The English physician, Dr. Archibald Smith, who has a sugar plantation near Huanuco, once, when unprovided with Chinese tea, made a trial of the coca as a substitute for it, but experienced such distressing sensations of nervous excitement that he never ventured to use it again. The Peruvian increases its effects by large doses, utter retirement, and the addition of other stimulating substances. The inordinate use of the coca speedily occasions bodily disease, and detriment to the moral powers; but still the custom may be persevered in for many years, especially if frequently intermitted, and a Coquero sometimes attains the age of fifty, with comparatively few complaints. But the oftener the orgies are celebrated, especially in a warm and moist climate, the sooner are their destructive effects made evident. For this reason the natives of the cold and dry districts of the Andes are more addicted to the consumption of coca than those of the close forests, where, undoubtedly, other stimulants do but take its place. Weakness in the digestive organs, which, like most incurable complaints, increases continually in a greater or less degree, first attacks the unfortunate Coquero. This complaint, which is called 'opilacion,' may be trifling at the beginning, but soon attains an alarming height. Then come bilious obstructions, attended with all those thousand painful symptoms which are so much aggravated by a tropical climate. Jaundice and derangement of the nervous system follow, along with pains in the head, and such a prostration of strength that the patient speedily loses all appetite; the hue of the whites assumes a leaden colour, and a total inability to sleep ensues, which aggravates the mental depression of the unhappy individual who, spite of all his ills, cannot relinquish the use of the herb to which he owes his sufferings, but craves brandy in addition. The appetite becomes quite irregular, sometimes failing altogether, and sometimes assuming quite a wolfish voracity, especially for animal food. Thus do years of misery drag on, succeeded at length by a painful death."

(Pöppig, *Reise in Chile, &c.*, vol. ii.; Hooker, *Companion to Bot. Mag.* i. and ii.)

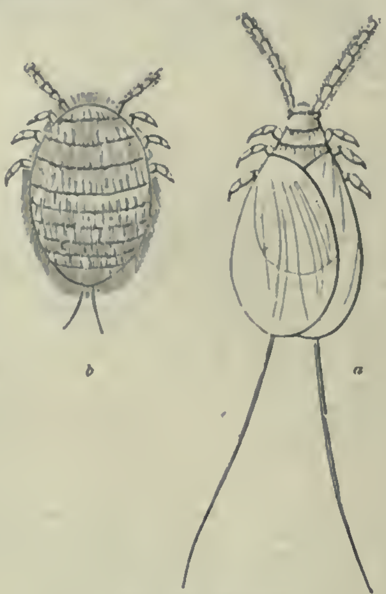
COCCIDÆ (Leach), *Gallinsecta* (Latreille), a family of Insects placed by Latreille and others at the end of the *Homoptera*. These insects apparently have but one joint to the tarsi, and this is furnished with a single claw. The males are destitute of rostrum, and have two wings, which when closed are laid horizontally on the body: the apex of the abdomen is furnished with two setæ. The females are apterous, and provided with a rostrum. The antennæ are generally filiform or setaceous.

The insects belonging to this family live upon trees or plants of various kinds: they are of small size, and in the larva state have the appearance of oval or round scales, hence they are called Scale Insects. They are closely attached to the plant or bark of the tree they inhabit, and exhibit no distinct external organs. At certain seasons, when about to undergo their transformation, they become fixed to the plant, and assume the pupa state within the skin of the larva. The pupa of the males has their two anterior legs directed forwards, and the remaining four backwards; whereas in the females the whole six are directed backwards. When the males have assumed the winged or imago state they are said to issue from the posterior extremity of their cocoon.

In the spring time the body of the female becomes greatly enlarged, and approaches more or less to a spherical form. In some the skin is smooth, and in others transverse incisions or vestiges of segments are visible. It is in this state that the female receives the embraces of the male, after which she deposits her eggs, which are extremely numerous. In some the eggs are deposited by the insect beneath her own body, after which she dies, and the body hardens and forms a scale-like covering, which serves to protect the eggs until the following season, when they hatch. The females of other species cover their eggs with a white cotton-like substance, which answers the same end.

Upwards of thirty species of the family *Coccidæ*, or *Gallinsecta*, are enumerated in Mr. Stephens's 'Catalogue of British Insects;' several of these however have undoubtedly been introduced with the plants they inhabit, and to which they are peculiar.

Many of the exotic *Cocci* have long been celebrated for the beautiful dyes they yield. The *Coccus Cacti* of Linnæus may be mentioned as an instance. The female of this species is of a deep brown colour, covered with a white powder, and exhibits transverse incisions on the abdomen. The male is of a deep red colour, and has white wings.



Coccus Cacti, magnified.
a, the male; *b*, the female.

This insect, which when properly prepared yields the dye called cochineal, is a native of Mexico, and feeds upon a particular kind of Indian fig, which is cultivated for the express purpose of rearing it. [COCHINEAL.]

C. Ilicis, an insect found abundantly upon a small species of evergreen oak (*Quercus coccifera*), common in the south of France and many other parts, has been employed to impart a blood-red or crimson dye to cloth from the earliest ages. ('Introduction to Entomology,' by Kirby and Spence, vol. i. p. 319.)

C. Polonicus is another species which is used in dyeing, and imparts a red colour. It is now chiefly employed by the Turks for dyeing wool, silk, and hair, and for staining the nails of women's fingers. (Kirby and Spence, vol. i. p. 320.)

But we are not only indebted to the *Coccus* tribe for the dyes they yield; the substance called Lac is also procured from one of these insects (the *Coccus Lacca.*) This species inhabits India, where it is found on various trees in great abundance. "When the females of this *Coccus* have fixed themselves to a part of the branch of the trees on which they feed (*Ficus religiosa*, and *F. Indica*, *Butea frondosa*, and *Rhamnus Jujuba*), a pellucid and glutinous substance begins to exude from the margins of the body, and in the end covers the whole insect with a cell of this substance, which when hardened by exposure to the air becomes lac. So numerous are these insects, and so closely crowded together, that they often entirely cover a branch; and the groups take different shapes, as squares, hexagons, &c., according to the space left round the insect which first began to form its cell. Under these cells the females deposit their eggs, which after a certain period are hatched, and the young ones eat their way out." (Kirby and Spence, vol. iv. p. 142.)

C. adonidum, the Mealy Bug, is an insect well known in our hothouses. It attacks vines, pine-apples, and other plants. It is of a reddish colour, and is covered with a white mealy powdery-looking substance—hence its name.

C. Vitis, the Vine-Scale, is another species which does great mischief to vines on account of the rapidity with which it is propagated.

C. Hesperidum is found on orange-trees. *C. Testudo*, the Turtle-Scale, is found on stove-plants exposed to a high temperature.

Many ways are recommended of getting rid of these insects. Brushing them off with cold or lukewarm water, when plants will bear it, is a good plan. Painting with spirits of turpentine, or exposing them to the fumes of turpentine, or tobacco, or sulphur has also been found effectual.

COCCINELLA. [TRIMERA.]

COCCOLITE, a general name for granular varieties of *Pyroxene*. [PYROXENE.]

COCCO'LOBA, a genus of Plants belonging to the natural order *Polygonaceæ*. It has a 5-parted calyx, eventually becoming succulent; the filaments 5, inserted into the base of the calyx, and forming a short ring by their union; the styles 3; stigma simple; the nut 1-seeded, bony, covered with the succulent enlarged calyx; the embryo in the middle of the albumen.

C. uvifera, Sea-Side Grape, has cordate roundish shining leaves. It is a tree 20 feet in height, with flexuose branches. The leaves are very beautiful, being of a full bright glossy green colour, with the principal nerves of a deep red. As the fruit advances to maturity it becomes surrounded by the succulent perianth, which forms an obovate reddish purple berry, not unlike a small pear. The nut in the inside is roundish, very acute, 3-lobed at the base, and attached by the centre. The embryo has foliaceous cotyledons. The leaves, wood, and bark of this plant are powerfully astringent, and a decoction of them is evaporated to form the substance called Jamaica Kino. The astringency depends on the presence of tannin, but there is in addition present in the wood a red colouring-matter which is used as a dye. The wood is also valued for cabinet-work. The fruit is eatable, and is exposed for sale in the West Indian markets, but is not valued much. It is a native of the sea-coasts of most of the West Indian Islands and the adjoining shores of America. There are several other species of *Coccoloba* natives of the West Indies. They are all of them evergreen-trees. They grow freely in a light loamy soil, and ripened cuttings taken off at the joint and placed under a hand-glass in a pot of sand will root freely. They require a stove.

(Loudon, *Encyclopædia of Plants;* Lindley, *Flora Medica.*)

COCCO'STEUS, a genus of Fossil Fishes, with a tuberculated scaly covering, from the Old Red-Sandstone of Gamrie, Cromarty, Caithness, and the Orkney Islands. (Agassiz.)

COCCOTHRAUSTES, a genus of Insessorial Birds belonging to the family *Fringillidæ*. It has the following characters:—Beak conical, very thick at the base, tapering rapidly to the point; culmen rounded; the commissure slightly arched; lower mandible nearly as large as the upper, its cutting edges inflected, and shutting within those of the upper. Nostrils basal, lateral, oblique, oval, nearly hidden by the short feathers at the base of the beak. Wings long, rather powerful, the second and third quill-feathers of nearly equal length and rather longer than the first. Legs with the tarsi short, not exceeding the length of the middle toe, the outer toe longer than the middle one; claws sharp and curved, the hind-toe and claw broad and strong. Tail short and more or less forked.

C. vulgaris, the Hawfinch, Haw Grosbeak, Grosbeak, of the English; Gylfinbraff of the Welsh; Le Grosbec and Pinson Royal of the French; Frogione, Froccione, Frosone, Frisone, Friggione, of the Italians; Kernbeisser, Kirsch Kernbeisser, Kerschfink, Nusbeisser, of the Germans; Appel-Vink of the Netherlanders; *Loxia Coccothraustes* of Linnæus; *Fringilla Coccothraustes* of Temminck; *Coccothraustes vulgaris* of Brisson.

It has the rump, head, and cheeks, red-brown; edging round the bill, space between that and the eye, a line beyond the eye and throat, deep black; a large ash-coloured collar just below the nape; back and greater part of the wings deep brown, but there is an oblique white stripe upon the wing, and beyond it a considerable space of a light whitish colour going off into chestnut; secondary quills as if cut off square at the ends, or, as Edwards says with justice, like the figures of some of the ancient battle-axes, glossed with rich blue, less conspicuous in the female; tail-feathers white within, of a blackish-brown on the external barbs; lower parts of the bird vinous-red; iris pale red (according to Temminck); feet and bill grayish-brown. Length seven inches.

The female is generally like the male, but with the colours much less brilliant.

The young of the year before the moult are very different from the adults and old birds. Throat yellow; face, cheeks, and summit of the head dirty yellowish; lower parts white or whitish; sides marked with small brown streaks, with which all the feathers are terminated. As the young bird advances in age some red vinous feathers appear disposed irregularly upon the belly; the upper parts are of a tarnished brown, spotted with dirty yellowish; bill whitish brown, except at the point, where it is deep brown. (Temminck.)

Mr. Gould ('Birds of Europe') says that in the male the beak and feet in winter are of a delicate flesh-brown, the former becoming in summer of a clear leaden hue, the ends straw-colour, and in some instances white; the top of the head, the cheeks, and rump, of a chestnut-brown. The rest of the description does not differ much from M. Temminck's.

Varieties.—White, yellowish, or grayish. Wings and tail often white. Plumage often variegated with white feathers.

Food, Habits, Reproduction, &c.—Hard seeds and kernels form the principal food of the Grosbeak, but we have seen it feeding on the berries of the hawthorn (whence its name), and shot it when so employed; so that it is probable that the soft part of fruits is not disagreeable to it, although the bill is evidently formed for cracking the stony kernel. Willughby states that it breaks the stones of cherries, and even of olives, with expedition. The stomach of one which he dissected in the month of December was full of the stones of holly-berries. The majority of ornithologists give the Hawfinch credit for forming a nest beautifully constructed of lichens and vegetable fibres, with a lining of feathers and other soft materials. But, according to Mr. Doubleday, who has thrown much light on the history of this bird, and discovered it breeding in Epping Forest in May and June, the nest, which is made in some instances in bushy trees at the height of five or six feet, and in others near the top of firs at an elevation of twenty or thirty feet, is remarkably shallow and carelessly put together, being scarcely deeper than that of the dove. In materials it resembles that of the bullfinch, but is not to be compared with it in neatness and compactness of construction. Eggs, from four to six in number, of a pale greenish-white, varying in intensity, spotted and streaked with greenish-gray and brown. Mr. Gould states that he has known the bird to breed near Windsor, and a few other places; but certainly nowhere so abundantly as on the estate of W. Wells, Esq., at Redleaf, near Penshurst, Kent. This gentleman informed Mr. Gould that he had, with the aid of a small telescope, counted at one time eighteen on his lawn.

Mr. Selby remarks that in the pairing season it probably utters a superior song, as Montagu says that even in winter, during mild weather, he has heard it sing sweetly in low and plaintive notes.

Distribution.—Plentiful in some districts of France; permanent and not uncommon in Italy; common in Germany, Sweden, and part of Russia. In Mr. Selby's 'Illustrations,' and indeed in most other English works, the Hawfinch is noticed as an occasional visitant. Dr. Latham says that "the hawfinch visits us chiefly in winter, but one was shot in the summer months near Dartford, in Kent." He goes on to remark that White records another instance at the same season, and says that it had the kernels of damsons in its stomach, "These," continues Dr. Latham, "might possibly have bred here. though we have no authority for its ever being the case." This authority now exists in the observations of Mr. Doubleday. "The hawfinch," says Mr. Doubleday, "is not migratory, but remains with us during the whole of the year." This observer sufficiently accounts for the rarity of its appearance:—"Its shy and retiring habits leading it to choose the most secluded places in the thickest and more remote parts of woods and forests, and when disturbed it invariably perches on the tallest tree in the neighbourhood."

Grosbeak (*Coccothraustes vulgaris*).

C. chloris, the Greenfinch or Green Grosbeak; Grosbec Verdier of the French; *Loxia chloris* and *Fringilla chloris* of authors.

The male has the upper parts and breast yellowish-green; the head tinged with gray; the edges of the wings, outer webs of primary quills, with the basal part of the tail-feathers, yellow. Female with the upper parts greenish-brown; the breast grayish-brown; the wings and tail marked yellow, as in the male. Young similar to the female, with faint brown streaks on the back.

This bird is common in all the countries of Southern Europe, and is found generally in the cultivated parts of England, Ireland, and Scotland. It remains in this country all the year round, and frequents gardens, shrubberies, orchards, small woods, and cultivated lands. It feeds on grain, seeds, and insects. Its notes are harsh and inharmonious. The eggs are white tinged with blue, from four to six in number.

(Yarrell, *British Birds;* Macgillivray, *Manual of British Birds.*)

CO'CCULUS, a genus of Plants belonging to the natural order *Menispermaceæ*, consisting of climbers, whose leaves are usually more or less heart-shaped, and the flowers small, and either white or pale green, in loose panicles or racemes; in most cases they are diœcious, and are always very minute. The distinguishing characters of the genus are:—Six sepals in two whorls, a corolla of 6 petals, 3 or 6 distinct stamens, terminal 2-celled anthers opening vertically; 3, 6, or more ovaries; and 1-celled 1-seeded drupes. The species are usually powerful bitter febrifuges. *Cocculus crispus*, a twining plant found in Sumatra and the Moluccas, with a tubercled or warted stem, is employed by the Malays for the cure of intermittent fevers. Owing to its intense bitterness and twining habit it was called *Funis felleus* by Rumf. Another plant, the *Menispermum* *fenestratum* of Roxburgh, is in great repute among the Cingalese, who slice it, steep it in water, and swallow it along with the infusion as a stomachic.

C. villosus, a plant common in the hedges of Bengal, with variable downy leaves and axillary solitary female flowers, succeeded by deep purple berries the size of peas, is a species of considerable importance to the Hindoos. The juice of its ripe berries makes a good durable bluish-purple ink, according to Roxburgh, who adds some further particulars concerning its uses:—"A decoction of the fresh roots, with a few heads of long pepper, in goats' milk, is administered for rheumatic and old venereal pains; it is reckoned heating, laxative, and sudorific. The fresh leaves taste simply herbaceous; rubbed in water they thicken it into a green jelly, which is sweetened with sugar, and drank, when fresh made, to the quantity of half a pint twice a day, for the cure of heat of urine in gonorrhœa. If suffered to stand for a few minutes, the gelatinous or mucilaginous parts separate, contract, and float in the centre, leaving the water clear, like Madeira wine, and almost tasteless. Curry is made of the leaves, for people under a course of its roots, or jelly of the leaves."

The species most important to Europeans is that which produces the celebrated Calumba Root, *Cocculus palmatus*, from which a valuable bitter is procured. This plant is a native of Mozambique and Oibo, abounding in the thick forests that cover the shores of those countries, and extending inland for 15 or 20 miles. The Africans of these parts call it Kalumb. It has a large fleshy deep yellow root, divided into many irregular forks or fangs, which are amputated by the collectors, cut into slices, strung on cords, and hung to dry in the shade. The stem is covered with a thick whitish-green glandular fur: the leaves are large, rounded, heart-shaped, and deeply divided into from 5 to 7 sharp-pointed lobes. The plant is now cultivated in the island of Mauritius.

Cocculus palmatus.
a, male flower; *b*, under side, showing calyx; *c*, stamen; *d*, petal; *e*, bractea.

The name given to this genus is that of a kind of seed imported from the East Indies under the name of Cocculus Indicus Berries, which possess a powerful bitter poisonous principle, that, according to Goupil, exists principally in the kernel. The plant is found in the forests of Malabar, and when transplanted to the botanic garden, Calcutta, grew in a few years so as to extend over a large mango-tree, with a stout woody stem as thick as a man's wrist, covered with deeply cracked, spongy, ash-coloured bark. The leaves were very exactly cordate, entire, obtuse, or emarginate, of a hard texture, shining on the upper surface, and from 4 to 12 inches long, by from 3 to 8 inches broad. This plant is the *Menispermum Cocculus* of Linnæus, the *Cocculus suberosus* of De Candolle; but according to Messrs. Wight and Arnott, it does not properly belong to the latter genus, having the stamens combined into a central column and no corolla. They call it *Anamirta Cocculus*.

Dr. Christison recommends "the medical jurist to make himself well acquainted with the external characters of those berries, because, besides being occasionally used in medicine, they are a familiar poison for destroying fish, and have also been extensively used by brewers as a substitute for hops—an adulteration which is prohibited in Britain by severe statutes." This fruit is a berried drupe, varying in size from that of a pea to that of a laurel (or bay) berry; subglobose, emarginate, dark brown, opaque, rough, and wrinkled; the external integument, or husk, is very brittle; within is the seed or kernel, lunulate, oily, with a nauseous and intensely bitter taste. The kernel contains about one part in the hundred of Picrotoxia, or Menispermia, as some term it. Upon this principle its poisonous properties depend. It seems to act by exhausting the irritability of the heart, and if the dose be considerable its fatal effects are very speedily displayed. What renders it a more redoubtable agent is the circumstance of its leaving scarcely any trace of its presence on the coats of the stomach. *Cocculus Indicus* is never used internally in the practice of medicine, but an ointment formed of the powdered berries is very efficacious in some cutaneous diseases, such as *Porrigo Capitis* and *Sycosis Menti*. It speedily allays the inflammatory state; but its employment requires great care. Creasote will probably supersede it in such cases.

Calumba is the root of the *Cocculus palmatus*, a native of the forests of the east coast of Africa, whence it is sent to Ceylon, and thence to Europe. It occurs in the form of tranverse sections, the bark of which is thick and easily separable; the woody portion is spongy, of a yellow colour, and when old much perforated by worms. The odour is faintly aromatic, the taste bitter and slightly acrid. It contains much starch, a yellow azotised matter, a yellow bitter principle, traces of a volatile oil, woody fibre, salts (chiefly of lime and potassa), oxide of iron, and silex. The active principle is Calumbine, which may be obtained either by alcohol or ether. As Calumba contains nothing which can decompose the salts of iron it may be given along with them. The powder is a good form: the infusion soon spoils, but is otherwise a very excellent form; a tincture or extract retains the virtues, and keeps a long time.

Other roots are often fraudulently substituted for Calumba. Some of these are supplied by America, others by Africa. The American, which is the most common in England and the north of Europe, is the root of the *Frazera Waltera* (Mich.), a native of the marshes of Carolina. It may be distinguished from the true by its whiter colour, lighter texture, the presence of longitudinal pieces, and the taste being at first sweetish, and not nearly so bitter as genuine Calumba. Chemical tests further assist in discriminating them: solution of proto-sulphate or of permuriate of iron, does not trouble the tincture of the real, while it gives the false a dark green colour; the tincture of the genuine yields with tincture of galls a copious dirty gray precipitate, but the false none. The substance of the true is rendered blue by iodine, the false brown. In large doses the spurious causes vomiting, but the genuine allays that action.

Slices of bryony root are often employed to adulterate Calumba root.

COCCUS. [Coccidæ.]

COCCYZUS. [Cuculidæ.]

COCHINEAL is extremely rich in the finest red colouring-matter, and has been long employed in scarlet dyeing and in the manufacture of carmine. [Carmine, in Arts and Sc. Div.]

Cochineal has been analysed by Pelletier and Caventou, and they find that it contains:—1, a colouring-matter to which they have given the name of carmine, or carminium; 2, a peculiar animal matter; 3, fatty matter which is soluble in ether, and consisting of stearine, oleine, and an odorous acid; 4, phosphate of lime and of potash, chloride of potassium, and carbonate of lime, and potash combined with an organic acid.

Carminium was obtained by Pelletier and Caventou by digesting Cochineal in ether; treating the residue repeatedly with boiling alcohol, allowing it to cool; treating the deposit formed with pure alcohol, and then adding a volume equal to its own of pure sulphuric ether: a deposit of Carminium is thus formed.

The chief use of Cochineal is the dyeing of scarlet; the fine colour which it yields is converted to this tint by means of chloride of tin usually called Muriate of Tin, and by the dyer Tin Spirits.

The insect which constitutes Cochineal feeds chiefly upon the *Cactus cochinellifera* and *C. opuntia*. [Coccidæ.] The female insect only is collected. Several varieties are distinguished in commerce, and have different degrees of value attached to them, dependent chiefly upon the different methods employed to kill and dry the insects. When dried they resemble small grains scarcely so large as a pepper-corn, ovate, convex above, plane below, transversely furrowed, externally blackish-brown, but as if dusted with a white powder, light, friable, the internal substance consisting of extremely small grains, obscurely purple, but when reduced to powder of a rich purple. Inodorous, but with a bitter-sweet acrid taste. They impart to water or alcohol by digestion an intensely red colour. The colouring principle is termed Carmine. Adulterations are effected either by mixing old insects consisting of the mere skin or grains artificially prepared with the genuine.

Cochineal has hitherto been employed mostly as a colouring material either of tinctures or of other things, the nature of which it is wished to disguise; but lately it has been stated to possess diuretic and antispasmodic powers, aud to be useful iu pertussis, or hooping-cough. Its claim to this character requires yet to be established hy further evidence.

COCHLEA'RIA (from *Cochleare*, a spoon, the leaves of the species beiug hollowed out like the bowl of a spoon), a genus of Plants belonging to the natural order *Cruciferæ*, the sub-order *Pleurorhizeæ*, the tribe *Alyssineæ*. It has sessile ovate-globose or oblong silicles, with ventricose very couvex valves, with a promineut dorsal nerve; many seeds, not margined; the calyx equal at the base, spreading; the petals entire; the stamens toothless. The species are aunual or perennial herbs, usually smooth aud fleshy, but sometimes pubescent. The flowers are mostly white.

One of the most common species of this genus, as formerly defined, is the common Horse-Radish (*C. Armoracia*). This species however is now referred by some botanists to a new genus, *Armoracia*, and is described by Babington, iu his 'Manual of British Botany,' as *A. rusticana*. The genus *Armoracia* differs from *Cochlearia* in its globose pouches or silicles being destitute of a prominent dorsal nerve. The Horse-Radish, though described in hooks on British Botany, can scarcely be considered a native of Great Britain, as the wild specimens are evidently escapes from gardens.

C. officinalis, common Scurvy-Grass, has the radical leaves cordate, reniform, stalked; the stem-leaves sessile, oblong-sinuate, half embracing the stem; the pouch globose or ovate. It is a native of Great Britain, in muddy places near the sea-coast. This plant varies much in size, and two or three varieties have been described. The *C. Grœnlandica* of Smith aud Witheriug appears to be nothing more than a diminutive variety of this species. In France the Scurvy-Grass is called Cranson Officinal; in Germany Löffelkraut. When fresh it has a peculiar smell and a bitter acrid taste, which are quite lost by drying. The fresh plant is a stimulaut, and possesses the antiscorbutic virtues of the whole order. It has however a peculiar reputation in the disease called scurvy; hence its common name. It is sometimes used as a salad. When cultivated the seeds should be sown in July, iu drills eight inches apart, and when the plants are up they should be thinned to about six inches apart. Those plants which are taken out may be placed in new beds. They will all be fit for use in the following spring.

C. Danica has the leaves all stalked, the radical ones cordate, somewhat lobed; the stem-leaves 3-5-lobed, subdeltoid uppermost, mostly shortly stalked; the pouch roundish, elliptical. It is found in Great Britain, in a few places on the sea-coast. It is a more abundant native of the sea-coasts of the north of Europe, and is a native of Kamtchatka.

C. Anglica, English Scurvy-Grass, has the radical leaves stalked, ovate-oblong, entire; the stem-leaves oblong, entire or toothed, mostly sessile, the upper ones embracing the stem; the pouch oval, oblong veined. It is a uative of muddy sea-shores about the mouths of rivers, especially in Great Britain; hut is fouud in Norway and Lapland and other parts of Europe.

There are several other species of *Cochlearia* described; they are however most of them insignificant plauts, inhabitants of northern climates. For the culture and medical properties of *C. Armoracia* see HORSE-RADISH, in ARTS AND SC. DIV.

COCHLICELLA. [HELICIDÆ.]

COCHLICOSSA. [HELICIDÆ.]

COCHLIODUS, a genus of Placoid Fishes, from the Carboniferous Limestone of Armagh and Bristol. (Agassiz.)

COCHLITOMA. [HELICIDÆ.]

COCHLODESMA. [THRACIA.]

COCHLODINA. [HELICIDÆ.]

COCHLODONTA. [HELICIDÆ.]

COCHLOGENA. [HELICIDÆ.]

COCHLOHYDRA. [HELICIDÆ.]

COCHLOSPERMUM, a genus of Plants placed by Lindley in the natural order *Cistaceæ*, found in Asia, Africa, and South America. Botanists usually place it amongst the Theads (*Ternströmiaceæ*); but its parietal placentæ, acrisomerous flowers, and curved embryo lying in the midst of albumen, seem fatal objections to that association.

C. Gossypium is a large tree with downy shoots. Leaves 5-6 inches long, 5-lobed; ovary beneath on cylindrical downy stalks. Panicle terminal. Flowers large, and bright yellow. The trunk yields the gum Kuteera, which in the North-Western Provinces of India is substituted for Tragacanth.

C. insigne grows in Brazil on the plains in the western desert, part of the province of Minas Geraes, and also on the Caturges of Minas Novas. The leaves are coriaceous, palmate, 5-lobed, the lobes folded together coarsely and sharply double serrated, when full grown nearly smooth. A decoction of the roots is employed in internal pains, especially such as result from falls or accidents; it is also said to heal abscesses already commenced. *C. tinctorium* is used in cases of amenorrhœa, and also as a yellow dye.

(Lindley, *Flora Medica*; Lindley, *Vegetable Kingdom*.)

COCHLOSTYLA. [HELICIDÆ.]

COCK. [PHASIANUS.]

COCK OF THE WOOD. [CAPERCALI.]

COCKATOO. [PSITTACIDÆ.]

COCKATRICE, one of the names by which the Basilisk was known. "Many opinions," says Dr. Thomas Browne, in his 'Pseudodoxia Epidemica,' "are passant coucerning the basilisk, or little king of serpents, commonly called the Cockatrice; some affirming, others denying, most doubting, the relations made hereof. . . . . That such an animal there is, if we evade not the testimony of Scripture and human writers, we cannot safely deuy." This is very true; and it is equally true that the alleged generation of the Basilisk or Cockatrice, and the powers attributed to it in ancient times, were the most ridiculous fables.

Of Basilisks or Cockatrices there were said to be three, if not four kinds. Oue species burued up whatever they approached;—a sort of breathing upases, they made a desert wherever they went, for everything animal and vegetable withered before them; a secoud were a kind of wandering Medusa's heads, and their look, like Vathek's eye, caused an instaut horror, which was immediately followed by death *; the touch of a third caused the flesh to fall from the bones of the wretched auimal with which they came in contact; and a fourth, a concentratiou of evil, was said to be produced from the eggs of extremely old cocks (*Ova centonina*)), hatched under toads or serpents. There are authors who maintain that this parentage did not belong exclusively to oue kiud only, but that it was the origin of the whole infernal brood.

The Greek word Βασιλίσκος is often translated in Latin by the word *Regulus*. When mention is made of these Basilisks or Cockatrices in the Holy Scriptures, nothing appears to occur in the sacred volume beyond words expressive of a very poisonous and deleterious serpent, intended, in the opiuion of many commentators, to typify siu, misery, destruction, God's judgments, and the principle of evil, or Anti-Christ. Thus, in Psalm xci. 13, it is written—"Super aspidem et basiliscum ambulabis," which in the old quarto Bible, 'imprinted at London by Robert Barker, printer to the Kiug's most excellent Majestie, 1615,' is translated—"Thou shalt walke upon the lion and aspe;" and iu the more modern editions, "Thou shalt tread upon the lion and adder." In the 'Booke of Common Prayer,' by the same printer (Robert Barker), 1613, the passage stands, "Thou shalt goe upon the lion and adder," and so in the more modern editions. Again (Proverbs xxiii. 32), speaking of the abuse of the wine-cup, "Mordebit ut coluber et sicut Regulus venena diffundet," which in the old edition above alluded to is rendered, "Iu the end thereof, it will bite like a serpent aud hurt like a cockatrice;" and, in the modern version, "At the last it biteth like a serpeut and stingeth like an adder." So, Isaiah xiv. 29, "Ne læteris," &c. "de radice euim colubri egredietur Regulus," &c., in the old quarto, "Rejoyce not (thou whole Palestina) hecause the rod of him that did beate thee is broken; for out of y^e serpeuts roote shal come forth a cockatrice, and the fruit thereof shall be a fiery flying serpent:" and lix. 5, speaking of the wicked, "Ova aspidis rumpunt et telas aranearum texunt; qui comederit de ovis ejus morietur, et quod fractum erit erumpet in Regulum:" iu the old quarto, "They hatch cockatrice egges, aud weave the spiders webbe: he that eateth of their egges dieth, and that which is trod upon breaketh out into a serpent;" which the commentator thus explains, "Whatsoever commeth from them is poison and bringeth death. They are profitable to no purpose." The preseut editiou reads, "They hatch cockatrice-eggs, and weave the spider's-web: he that eateth of their eggs dieth, and that which is crushed breaketh out iuto a viper." Also Jeremiah viii. 17, "Ecce ego mittam vobis serpentes Regulos," &c., which the same old edition renders, "For behold I will send serpents aud cockatrices amoug you, which will uot bee charmed: and they shall sting you, saith the Lord;" which the commentator explains as follows: "God threateneth to send the Babylouians among them, who shall utterly destroy them in such sort as by uo meaues they shall escape." The modern edition scarcely varies from the old quarto, except in the substitution of the word 'bite' for 'stiug.'

These Basilisks were called Kiugs of Serpents, because all other dragons and snakes, behaviug like good subjects, and wisely not wishing either to be burnt up, or struck dead, or to have their flesh fall from their bones, although they were in full feast upon the most delicious prey, were supposed, the moment they heard the distant hiss of their king, to turn tail in a 'sauve qui peut' style, leaving the sole enjoyment of the bauquet to the royal monster.

Of the ancient profaue writers, Aristotle, as might be expected, says nothiug about the wonders of the Cockatrice; but Pliny, who dearly loved a fable, mentions the Basilisk more than once: thus ('Hist. Nat.' book viii. c. 21, and book xxix. c. 4) he enters at length into its deadly attributes, aud records the praises with which magicians celebrate the efficacy of its blood, which was considered an admirable antidote against sorcery (veneficia). Dioscorides, Galen, Solinus, Ælian, and others, are eloquent upon Basilisks, as are Avicenna, Grevinus, Scaliger, and many more.

Browne (*Pseudodoxia*) is of opinion that what "we vulgarly call a cockatrice, and wherein (but under a different name) we intend a formal identity and adequate conception with the basilisk, is not the basilisk of the aneients, whereof such wonders are delivered; for this

* Lady Anne, in Shakspere's play of Richard III., in answer to Richard's observation on her eyes, says—

"Would they were basilisks to strike thee dead!"

of ours is generally described with legs, wings, a serpentine and winding tail, and a crist or comb somewhat like a cock; but the basilisk of elder times was a proper kind of serpent, not above three palms long, as some account, and differenced from other serpents by advancing his head, and some white marks or coronary spots upon the crown, as all authentic writers have delivered." The following is Pliny's description ('Hist. Nat.' viii. 21). After stating that the Basilisk, like the beast Catoblepas, slays with its eye, he proceeds:—"The Cyrenaic province produces him of the greatness of not more than twelve fingers, and remarkable for a white spot, like a diadem, on his head. He drives away all serpents by his hissing, nor does he impel his body like the rest by a multiplied flexion, but advances lofty and upright (celsus et erectus in medio). He kills the shrubs, not only by contact, but by breathing on them, scorches up the green herb, and splits the rocks: such power of evil is there in him. It was formerly believed that if killed by a spear from on horseback, the power of the poison conducted through the weapon killed not only the rider, but the horse also." To this Lucan alludes in these lines.—

> "Quid prodest miseri basiliscus cuspide Mauri
> Transactus? velox currit per tela venenum,
> Invaditque manum."

Such a prodigy was not likely to be passed over in the legends of the saints. Accordingly we find that a good man (vir quidam justus) going to a fountain in the desert, suddenly beheld a Basilisk. He immediately raised his eyes to heaven, and with a pious appeal to the Deity, laid the monster dead at his feet. A somewhat similar miracle is related of the abbot St. John, who, by prayer, slew a Basilisk that lay hid in the bottom of a deep well, and reduced the monks of a monastery built by him to the greatest distress for want of water. Leo IV., by a similar piety, is said to have delivered Rome from a Basilisk whose breath afflicted the inhabitants with a terrible pestilence in his pontificate.

Jonston enumerates the attributes of the Basilisk in silence, till he comes to its alleged power of annihilating with the eye, when he sagely remarks, "Intuitu interimere vix crediderim, quis enim primus vidisset?"—"I would scarcely believe that it kills with its look, for who first could have seen it?" The worthy physician was not aware that those who went to hunt the Basilisk of this sort, took with them a mirror which reflected back the deadly glare upon its author, and, by a kind of poetical justice, slew the Basilisk with its own weapon.

It is curious to observe that Browne, who treats most of the fables about the Basilisk with contempt, is still unable to resist the story of its killing with the eye. We think we can trace a little of the sympathetic theory maintained by Sir Kenelm Digby and others, in the following passage: "According to the doctrine of the ancients, men still affirm that it killeth at a distance, that it poisoneth by the eye, and by priority of vision. Now that deleterious it may be at some distance, and destructive without corporal contaction, what uncertainty soever there be in the effect, there is no improbability in the relation. For if plagues or pestilential atoms have been conveyed in the air from different regions; if men at a distance have infected each other; if the shadows of some trees be noxious; if torpedoes deliver their opium at a distance, and stupify beyond themselves; we cannot reasonably deny that (besides our gross and restrained poisons, requiring contiguity unto their actions) there may proceed from subtiller seeds more agile emanations, which contemn those laws, and invade at a distance unexpected. That this venenation shooteth from the eye, and that this way a basilisk may empoison, although thus much be not agreed upon by authors, some imputing it unto the breath, others unto the bite, it is not a thing impossible; for eyes receive offensive impressions from their objects, and may have influences destructive to each other; for the visible species of things strike not our senses immaterially, but streaming in corporal raies, do carry with them the qualities of the object from whence they flow, and the medium through which they pass. Thus, through a green or red glass, all things we behold appear of the same colours; thus, sore eyes affect those which are sound, and themselves also by reflexion, as will happen to an inflamed eye that beholds itself long in a glass: thus is fascination made out; and thus also it is not impossible what is affirmed of this animal; the visible raies of their eyes carrying forth the subtillest portion of their poison, which, received by the eye of man or beast, infecteth first the brain, and is from thence communicated unto the heart."

But if the author of the 'Inquiries into Vulgar and Common Errors' here shows something of the lingering look with which most men regard received prejudices, he makes amends by declaring war against the story of the mode of the Cockatrice's production. "As for the generation," says he, "of the basilisk, that it proceedeth from a cock's egg hatched under a toad or serpent, it is a conceit as monstrous as the brood itself." Jonston, who appears to regard with a proper horror most of the nefarious proceedings of the Cockatrice, treats this part of the subject quite professionally. "Quomodo," remonstrates the sage doctor of medicine, "formari a gallo intra ovum possit cum utero destituatur non video." It is supposed that the idea took its rise from an Egyptian tradition concerning the ibis, "for an opinion it was of that nation that the Ibis feeding upon serpents, that venomous food so inquinates their ovall conceptions, or eggs within their bodies, that they sometimes came forth in serpentine shapes; and therefore they alwaies brake their eggs, nor would they endure the bird to sit upon them." (Browne.) Baptista Porta is of opinion that if a hen's-egg be placed in a ditch full of serpents, corruption (tabes), arsenic, and other poisons, it will produce an animal noxious to the sight and touch: at the same time he puts the experimentalist on his guard, lest in trying to produce this animal he might (like Frankenstein) give birth to a creature that would do him a mischief.

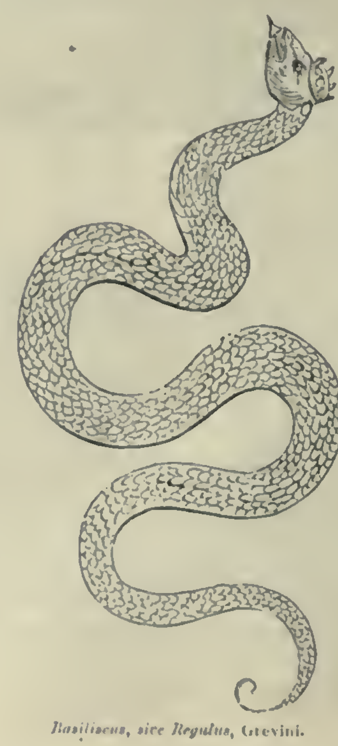
But what was to attack this terrible and unapproachable monster? There is an old saying that "everything hath its enemy;" and the Cockatrice quailed before the weasel. (Pliny, Solinus, and others.) The Basilisk might look daggers, the weasel cared not;—in he went to the scratch. When it came to biting, the affair became more serious; but the weasel retired for a moment to eat some rue (which, of course, was the only plant which the Basilisks could not wither, and was always growing where they lay), returned to the charge, and never left the enemy till he lay stretched dead before him. So that when men found out the den of a Basilisk, they had only to turn in a weasel, and the thing was done. The monster, too, as if conscious of the irregular way in which he entered the world, was supposed to have a great antipathy to a cock; and well he might; for as soon as he heard the cock crow, he expired. This we learn from Ælian; and African travellers, consequently, carried with them the 'bird of dawning' as a specific against Cockatrices.

The Basilisk was of some use after death. Thus we read that its carcass was suspended in the Temple of Apollo, and in private houses as a sovereign remedy against spiders'-webs, and that it was also hung up in the Temple of Diana, for which reason no swallow ever dared to enter the sacred place.

The reader will, we apprehend, by this time have "supped full" of absurdities, but still we can imagine his anxiety to know what a Cockatrice was like. We therefore subjoin from Aldrovandus, in whose work he will find two others made out of skates (Raia), a couple of figures, one of which he seems to owe to Cardan, and the other to Grevinus. In both it will be seen that

> "What seemed his head
> The likeness of a kingly crown had on."

Basiliscus in solitudine Africæ virens.



Basiliscus, sive Regulus, Grevini.

In these cuts will be seen an example of the 'Somnia Portentaque Thessala,' which have vanished before the light of science. [BASILISK.]

COCOA-PLUM, the fruit of *Chrysobalanus Icaco*. [CHRYSOBALANUS.]

COCOON. [BOMBYCIDÆ; PUPA.]

COCOS, a genus of Plants belonging to the natural order of Palmæ. It is thus defined by Von Martius :—Both male and female flowers on the same spadix. Spathe simple; flowers sessile. Males: calyx 3-leaved; corolla of 3 petals; stamens 6; a rudiment of a pistil. Females: 3 sepals and 3 petals rolled together; ovary 3-celled; stigmas 3, sessile; drupe fibrous; putamen with three

Cocoa-Nut Palm (*Cocos nucifera*).

a, lower portion of the spathe opened; *b*, branchlet, with female flowers—the males on the upper end dropped off; *c*, female flower; *d*, stamens; *e*, female corolla; *f*, male corolla; *g*, germen.

pores at the base; albumen homogeneous, hollow; embryo next one of the pores at the base; stems either lofty or middle-sized, slender, ringed, or crowned by the bases of the petioles, with a pale fibrous wood; leaves pinnated; the pinnæ lanceolate or linear; flowers pale yellow; drupes brown, green, or orange-colour, rather dry. The genus contains several species.

Cocos nucifera, the common Cocoa-Nut Palm. This plant is found all over the tropical parts of the world, especially in the vicinity of the sea, growing within reach of salt-water, and establishing itself upon reefs and sandbanks as soon as they emerge from the ocean. Its principal range is said by Mr. Marshall to be between the equator and the 25th parallel of latitude, and in the equinoctial zone to an altitude of about 2900 feet. Its great importance to man has caused it to be cultivated wherever the climate is favourable to its growth; and accordingly it is sometimes found occupying extensive tracts to the exclusion of all other trees: the whole Brazilian coast from the river San Francisco to the bar of Mamanguape, a distance of 280 miles, is, with few breaks, thus occupied; and it was estimated that in the year 1813 no fewer than 10,000,000 trees were growing on the south-west coast of Ceylon.

The Cocoa-Nut Palm rises like a slender column to from 60 to 90 feet in height; its stem is of a soft fibrous nature, and is marked on the outside by rings produced by the fall of its leaves; two such leaves are said to drop off annually, and consequently the age of an individual is equal to half the number of the annular scars of its stem. About a dozen or fifteen leaves, each from 12 to 14 feet long, crown the summit of the stem; and as these are not inaptly compared to gigantic ostrich-feathers, they give the plant the air of an enormous tuft of vegetable plumes. A reticulated substance, resembling coarse cloth, envelops the base of each leaf-stalk, but falls off before the leaf is full grown. The flowers proceed from within a large pointed spathe, which always opens on the under side. In wet seasons the tree blossoms every five or six weeks, so that there are generally fresh flowers and ripe nuts on the tree at the same time: there are commonly from five to fifteen nuts in a bunch; and in good soils a tree may produce from eight to twelve bunches, or from 80 to 100 nuts annually.

In hot countries the uses to which the Cocoa-Nut Tree is applicable are innumerable. The roots are chewed in place of the areca-nut; gutters, drums, and the posts of huts are formed from the trunk; the young buds are a delicate vegetable; shade is furnished by the leaves when growing, and after separation from the tree their large size and hard texture render them invaluable as thatch for cottages; they are moreover manufactured into baskets, buckets, lanterns, articles of head-dress, and even books, upon which writing is traced with an iron stylus. Their ashes yield potash in abundance; their midrib forms oars; and brushes are formed by bruising the end of a leaf with a portion of the midrib adhering to it.

The sap of the tree during the time of blossoming ascends in large quantities: it is very sweet, and flows freely on the stem being punctured. In Ceylon it is daily collected by a class of people known as 'toddy-drawers,' who get up early to procure it for the use of the inhabitants. If allowed to stand, this toddy ferments, and forms palm-wine, from which an ardent spirit called arrack is distilled. By further distillation sugar is procured from this spirit, which is called 'gaggheng sugar.' This sugar, mixed with lime, forms a powerful cement, which resists moisture, endures great solar heat, and will take a fine polish. A farinaceous matter contained in the stem is a good substitute for sago. The ripe fruit is a wholesome food, and the milk it contains is a grateful cooling beverage; indeed, these together form the principal sustenance of the poor Indians in many countries. The nuts are inclosed in an outer husk, which has three flat sides terminating at the top in a blunt point. This peculiar form seems to be a special provision for the dissemination of the species; growing, as it does, near the shores of seas and rivers, its large seeds drop into the water, and their shape particularly adapts them for sailing; one edge, being downwards, forms the keel, while the upper surface, being flat, is acted upon by the wind, and so propelled along on the surface until it reaches some coral reef or shore, where, when stranded, it vegetates and rises to be a magnificent palm, affording food and shelter in abundance. The shell of the Cocoa-Nut is inclosed in a fibrous husk, which has now become a considerable article of commerce on account of the strength and durability of the fibre. Its preparation is very simple, consisting of little more than beating the husks to separate the fibres, which are dry and but loosely held together, and afterwards drawing them through a coarse comb or heckle, by which the refuse is cleaned out; it is then spun into yarns of different thickness, and is now extensively manufactured in Europe into ropes and matting: it is also used to stuff mattrasses and cushions. In India it is very generally used as cordage for vessels, and for fishing-nets; its lightness recommends it especially for the latter purpose. Its durability is surprising; perhaps no other vegetable-fibre will resist so long the action of alternate dryness and moisture. The hair-like fibre is made also into scrubbing-brushes; and the poorer classes in many places use the entire husk for the same purpose. The imports of cocoa-nut yarn and rope into England are greatly increasing: in the year 1851 (as nearly as can be ascertained) 10,661 tons were brought into Liverpool from Ceylon and Bombay. The oil of the Cocoa-Nut is valuable as an export: it is used largely in Europe for burning, in the manufacture of torches, and in the composition of pharmaceutical preparations. Mixed with dammer (the resin of *Shorea robusta*), it forms the substance used in India for paying the seams of boats and ships.

The name Cocoa seems to be a contraction of the Portuguese Macaco or Macaco, a 'monkey,' and to have been given from the resemblance between the end of the shell, where the three black scars are, and the face of a monkey. These three scars indicate the places through which the three embryos of the fruit, if equally and completely developed, would be protruded. But as out of the three ovules originally formed in the Cocoa-Nut two are constantly abortive, it happens that one only of the scars has to fulfil its destined purpose: that one is known by its being easily pierced by a pin; the others are as hard as the remainder of the shell. It is immediately below the soft scar that the embryo of the Cocoa-Nut is formed, and the use of the scar is to allow of a passage through the shell of the nut for the germinating embryo, which, without this wise contrivance, would be unable to pierce the hard case in which it is confined.

Cocoa-Nuts are brought to Europe as wedges to set fast the casks and other round packages in the cargo of vessels; their freight therefore costs nothing.

COCUMIGLIA, the name of a kind of Plum (*Prunus Cocumilia*) found wild in Calabria, and having the reputation of being a powerful febrifuge. It is described as bearing a general resemblance to the cultivated plum, but with short double peduncles, elliptical-obovate leaves, which are smooth, crenelled, and tapering to each end, the crenelling and the petioles covered with deciduous glands, and with ovate-oblong fruit of a dull tawny-yellow colour, with a slightly incurved point, and an austere astringent flavour. It is abundant about Sile, and on the mountains which overlook Monteleone, Staiti, Cotrone, and Mesoraca, on the sides exposed to the sea, as far as the height of about 3000 feet. The bark of this species is in extensive use for the cure of the intermittent fevers of Calabria, both in private practice and in the military hospitals, where it is preferred to cinchona. The bark of the root is principally employed either in decoction or extract; and its valuable qualities are attested by Savaresi, Polizzi, Tenore, and other Neapolitan physicians. The medicinal properties of the Cocumiglia are said to have been discovered by a noble citizen of Monteleone, who annually caused a considerable quantity of the extract to be prepared and distributed among the Calabrian peasantry. It is worthy of notice that febrifugal properties are assigned by Mérat to the bark of the common sloe; and, considering the very close affinity between the Cocumiglia, the sloe, the bullace, and the common cultivated plum, it is highly probable that similar qualities are possessed by all of them. The bark should be collected in the months of November, December, or January.

CODDY MODDY, a Gull in its first year's plumage. (Montagu.) [LARIDÆ.]

CODEIA, an alkali existing in Opium. [PAPAVER.]

COD-FISH. [GADIDÆ.]

CODIUM, or *Sea-Purse.* [ALGÆ.]

CŒLACA'NTHUS, a genus of Fossil Fishes, which occurs in the Coal Formation and the Magnesian Limestone of the north of England. (Agassiz.)

CŒLEBOGYNE, a genus of Plants belonging to the natural order *Euphorbiaceæ*. This genus was named by Mr. J. Smith from a specimen grown in the Royal Gardens at Kew. It is remarkable for the fact that being diœcious, the pistiliferous flowers have ripened their fruit and produced seeds containing a perfect embryo without the presence of the staminiferous plants. This appears to be quite an exceptional case to the law of production of the embryo by the agency of the pollen-cells coming in contact with the ovule. Further observation may detect some hitherto undiscovered means by which the pollen-cells of perhaps an allied plant may come in contact with the pistils of the *Cœlebogyne.* (*Linnæan Transactions.*)

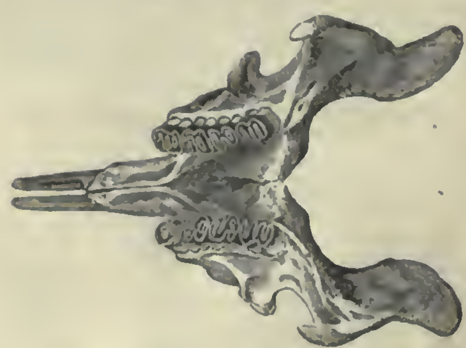
CŒLO'GENYS (Illiger), a genus of Rodent Animals belonging to the division without clavicles. Its place with the older naturalists was either among the Rats (*Mus*) or among the Hares. Linnæus, in his last edition (the 12th), arranges it under his extensive genus *Mus*, with the denomination of *Mus Paca*, and quotes, among others, Ray, who termed it *Mus Brasiliensis*. Waterhouse places it with *Dasyprocta* in the sub-family *Dasyproctina*.

The genus *Cœlogenys* possesses two strong incisor teeth in each jaw, the upper ones flattened in front and truncated obliquely, chisel-like; the lower slightly compressed laterally, and rounded on the anterior face. But these incisors, though of some strength, are small when compared to those of the porcupines and of the beaver. Like all the true Rodents, *Cœlogenys* has no canines, and a void space or bar separates the incisors from the molars, which amount to 8 in each jaw, and are not unlike those of the Agouti, that is to say, they are composed of complicated riband-like plates of enamel set in the interior bony cement, which vary and become more or less visible according to the greater or less attrition which the crowns have undergone. But, in *Cœlogenys*, besides the difference in the complications, the molars augment in size from the first to the last, which is one-third larger than the tooth that precedes it. (F. Cuvier.) There is also a striking peculiarity in the great development and projection of the zygomatic arches, which are enormously large, giving great breadth to the face, and descending unusually low. These were remarked by Daubenton; and Buffon observed that, on each side and towards the lower part of the upper jaw, there existed a sort of longitudinal fold, destitute of hair in the middle, so that, at first sight, it might be mistaken for the mouth of the animal. This fold, which Buffon does not seem to have investigated, is the opening of a shut sac of some extent, extending upwards behind the arch formed by the cheek and temporal bones, whose inner surface, as far as the sac extends within them, is lined by a continuation of the integument of the face, and, in addition to it, the animal is furnished with true cheek-pouches in their usual situation. These last are capable of being greatly dilated, and when filled, they are said to occupy the whole space beneath the zygomatic arches.

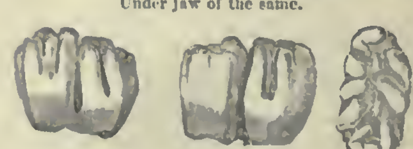
Dental formula:—Incisors, $\frac{2}{2}$; molars, $\frac{8}{8} = 20$.

Skull of *Cœlogenys.*

Upper Jaw of the same.



Under Jaw of the same.



Germ of the first molar, enlarged. View of the outside, inside, and crown. F. Cuvier.

F. Cuvier observes, that the Pacas are, among the Omnivorous Rodents, what the Capybaras are among the Herbivorous section. The first possess molars with roots distinct from their crowns, to the number of 4 on each side of either jaw. Those of the upper jaw are nearly of a size; but, in the lower, they diminish gradually from the last to the first. All the molars, before they have been subjected to the process of mastication, present, on the upper surface of the crown, 4 tubercles, which more or less completely divide the tooth broadwise, and are separated by three transverse furrows, more or less large or deep. When the crown of the tooth is exposed to mastication, the top of the tubercles begins to wear away, and the enamel, instead of forming a sort of hood or cap, presents a series of riband-like foldings, the outlines of which are conformable to the tubercles and furrows. In proportion to the continuance of the abrasion, the tubercles are successively effaced; and, finally, nothing is to be seen but the enamel, which hoops the tooth externally, and that which penetrates the interior and is there complicated, the plaits going very deep, so that the ribands of enamel, whose edges are exposed on the triturating surface, change their appearance with the age of the animal, and terminate by disappearing in a great measure.

The Pacas approach the Capybaras and the Agoutis most nearly, and are closely allied to the latter by their general form and the similarity of their organisation. The dental and generative systems in both are very nearly alike; neither have clavicles, nor indeed has the Capybara; and though the Agouti has only three toes on the hind feet, the two additional hind toes of the Paca are hardly more than rudiments. The great differences consist in the zygomatic development, the folding back of the skin under the zygomatic arch—and the consequent bluff appearance of the head—the cheek-pouches, and the fur.

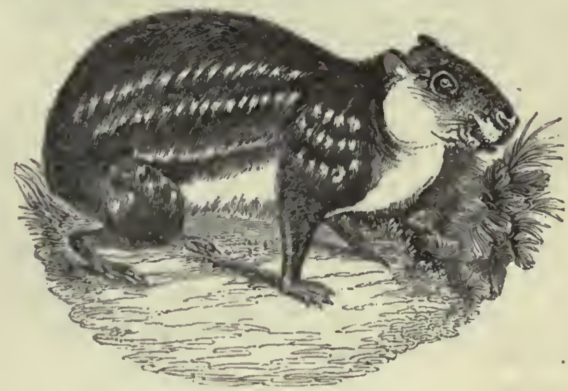
F. Cuvier records two species, *C. subniger* and *C. fulvus*; but Baron Cuvier, in the last edition of the 'Règne Animal,' treats them as varieties of the same species.

C. Paca (Rengger), the Paca. It is the *Mus Paca*, Linnæus; *Cavia Paca*, Schreber; *C. subniger*, F. Cuvier; *C. niger*, F. Cuvier; *Osteossera platycephala*, Harlan; Le Pag, D'Azara.

Its general appearance reminds the observer of the Pachydermatous animals, for it is thick-set and stubby. The legs are thick, the neck short, the head heavy, the body rounded, the gait clumsy, but the motions of the animal are prompt and sudden. All the feet have five toes, which anteriorly have the ordinary proportions, but posteriorly the analogues of the little toe and great toe are extremely short in proportion to the rest, and almost rudimentary, like the upper or lateral toes in the hog. The claws are conical, thick, and strong, and proper for digging. The tail is reduced to a naked immoveable tubercle, a few lines in length. The principal male organ is directed backwards, and there is no external appearance of the testicles. The external ear is moderate in size, rounded, and simple. There is nothing particular about the eye, the pupil of which is round. The nostrils, which are large and almost united, open transversely at the muzzle. The tongue is very soft, short, and thick. The upper lip is divided, the interior of the mouth is furnished with cheek-pouches, and, externally, the large area formed by the development of the zygomatic arch is lined on its inner surface with a continuation of the skin of the cheeks, which is reflected from the face, so as to form a hollow pouch, of which there is no other example among mammiferous animals, and the use of which it is difficult to divine, if the great development of the zygomatic arch be not destined to preserve the true cheek-pouches (abajoues) from external shocks. Strong whiskers spring from the sides of the muzzle, and from behind the eye. The fur is composed of silky hairs, very short, very thin, and very stiff, of a blackish-brown on all the upper parts of the body, excepting four rows of parallel spots, which begin at the shoulders and terminate at the buttocks: the spots of each row are so approximated, that when viewed in a particular direction they seem to form an uninterrupted line, and the row nearest the belly is almost confounded with the colour of that part, which is white, as well as the under parts of the lower jaws, the internal surface of the limbs, and the claws. Length of the body, from the occiput to the insertion of the tail, 16 inches: length of the head, from the occiput to the end of the muzzle, 5 inches. Height, to the shoulders 12 inches—to the top of the buttocks (train de derrière) 14 inches, French. (F. Cuvier.)

This animal is better known as the Paca of zoologists generally, and, after the Capybara and Coypu, is one of the largest of the South American Rodents. It is the Spotted Cavy of Pennant and Bewick, the Pag of the Brazilians, Paig of the inhabitants of Paraguay, Ourana of some of the tribes of Guyana and Pakiri of others, the Pak of the colonists of Cayenne, and the Water-Hare of those of Surinam. In all these countries it is common, with the exception of Paraguay, where, according to D'Azara, it is very rare. They formerly existed in the islands of the West Indies.

In a state of nature the habitation of the Paca is in low humid forests, and in the neighbourhood of water. The animal digs a burrow like the rabbit, but much less deep; indeed it is so near the surface, that the foot of the pedestrian often breaks through, and, sinking into the tunnel, drives out the tenant. There are generally three issues to a burrow, and the aperture of these the animal covers with dry leaves and branches. To take it alive, the hunter stops two of these apertures, and digs into the third; but when the penetralia are reached, the hapless besieged makes a most determined resistance, fighting the enemy with ferocity, and trying to bite. When undisturbed, it often sits up and washes its head and whiskers with its two fore paws, which it licks and moistens with its saliva at each ablution, like a cat; and with these fore paws, as well as with the hind ones, it often scratches itself and dresses its fur. Though heavy and corpulent, it can run with a good deal of activity, and often takes lively jumps. It swims and dives with great adroitness, and its cry resembles the grunting of a young pig. Its food consists of fruits and tender plants, which it seeks in the night, hardly ever quitting its burrow in the day, the strong light of which, as is the case with other nocturnal animals, is oppressive to its eye. The planter often rues the visits made by these midnight foragers to his sugar-canes. The female is said to bring forth at the rainy season, and to produce but a single young one, which stays a long time with the mother. The Pacas are very cleanly creatures, never dropping their excrements near their dwellings, but going to a considerable distance for that purpose.



The Paca (*Cœlogenys Paca*).

In captivity, according to F. Cuvier, no animal can exhibit less intelligence. When offended, it throws itself violently at the object which has displeased it, and then makes a grumbling, which breaks out into a kind of barking; and when it is not eating it is sleeping. But it requires a soft and well-made bed; and, to obtain this, it collects with its mouth hay, herbage, straw, anything indeed that suits its purpose, of which it makes a little heap, and then lies down in the centre of it. This bed it never defiles, but goes to the extremity of its cage the farthest removed from it, and constantly resorts to the same spot for the same purpose. If, says F. Cuvier, it is but little favoured on the side of intelligence, it appears on the other hand to be recompensed by a large share of instinct, to judge, at least, by appearances. Mr. Bennett, from his observation of one which lived for some months in the Garden of the Zoological Society in the Regent's Park, says that it is quiet and contented in captivity. Buffon, who kept one for some time in his house, found it familiar and mild.

The flesh is stated to be excellent and of good flavour; but as it is very fat and rich, it soon cloys: it is prepared for cookery by being scalded like a sucking pig. Piso gives the following character of its merits for the table:—"Carne est tenera, pingui lardo non indigens, si assetur, sed inter epulas magnatum, sicut lepores et capreæ in Europâ, habetur." Its skin is of no value to the furrier; but its thickness might make it available in the useful arts. F. Cuvier thinks that it would be possible to introduce this animal into our European rural establishments, and that it would form a very good acquisition in the department of domestic economy.

C. laticeps (Lund) is a fossil species founded upon a cranium from the caverns of Brazil. In this species the surface of the frontal bone and zygomatic arch are smooth. It also differs from the last species in the infra-orbital opening being larger, the upper part of the bony ring which incloses it narrower, and the zygoma is thrown more boldly forwards. Dr. Lund distinguishes a second species from the same caverns, which he calls *C. major*. It is much larger than the last. Mr. Waterhouse says, "From the caverns above alluded to the British Museum contains numerous remains referrible to the genus *Cœlogenys*. The most characteristic specimen among these is a considerable portion of a skull, in which I can find no points which would lead me to suppose it belonged to a species distinct from the common Paca."

CŒLOPTY'CHIUM, a genus of *Spongiadæ*, proposed by Goldfuss, for some fossils of the Chalk.

CŒNURUS. [ENTOZOA.]

CŒREBA. [NECTARINIDÆ.]

COFFE'A, a Cinchonaceous genus, consisting of many species of tropical berry-bearing shrubs, one of which, *Coffea Arabica*, is celebrated for the agreeable stimulating effect of an infusion of its roasted albumen. This substance, the coffee of commerce, is to that plant what the flour is to corn, the white meat to a cocoa-nut, and the aromatic ruminated substance to a nutmeg. It is a secretion formed in the interior of the seed, and enveloping the embryo plant, for whose support it is destined when it first begins to germinate; it constitutes the principal part of the seed, the embryo itself being a minute body lying in a cavity at one end of the albumen. Unskilful observers are often unable to find the embryo; but it may readily be seen by the following simple means:—Take a new sample of small fine unroasted Mocha coffee, and throw it into boiling water; the embryo will, after a little while, be expelled with force from the albumen in a majority of cases.

The genus *Coffea* is known among Cinchonaceous Plants by having a tubular corolla, with four or five spreading divisions; stamens arising from the naked throat of the corolla, and either extending beyond it or inclosed within it; and a succulent berry containing two cells lined with a cartilaginous membrane, of the texture of parchment, in each of which cells there is a single seed, convex at the back and deeply furrowed in front, in consequence of the albumen being rolled inwards.

Coffea Arabica is an ever-green shrub, with oval shining wavy sharp-pointed leaves, white fragrant five-cleft clustered corollas with projecting anthers, and oblong pulpy berries, which are at first of a bright red, but afterwards become purple. It is stated by Niebuhr to have been brought from Abyssinia to Yemen by the Arabs from a country similar to their own plains and mountains. By that people it has for ages been cultivated in the hilly range of Jabal, in a healthy temperate climate, watered by frequent rains, and abounding in wells and water-tanks. Here the plants are grown in grounds that are continually irrigated, and in soil from one to one and a half foot deep. Among the plantations are interspersed various kinds of trees, whose shade has a beneficial effect upon the coffee-bushes. When in flower, they diffuse a most delicious fragrance, in the midst of which the natives fix their habitations. The fruit begins to ripen in February; and when the seeds are prepared, they are conveyed to the city of Beit el Fakih, whence part goes to Mocha, and another portion to Hodeida and Loheia, whence it finds its way to Djedda and Suez for the Turkish and European markets.

Coffee Plant (*Coffea Arabica*).

a, Corolla opened, showing the stamens; *b*, pistil; *c*, berry; *d*, *e*, sections of the same; *f*, embryo.

Richness of soil in the West Indies has been thought to be the cause of the inferior quality of coffee grown in that part of the world, and to the supposed dryness of Yemen has been ascribed the excellence of Mocha coffee. But it has been shown that the Arabs counteract the effect of any dryness in the air by abundant irrigation; and that moreover it is not in the Tehama or dry parts of the country that it is cultivated, but on hill-sides, where the temperature is much lower, and where it rains daily for four months in the year.

The seed of *Coffea Arabica* consists of much horny albumen, and a peculiar principle or alkaloid, termed Cafeine, which contains more nitrogen than any other known vegetable substance. The seed is used in a raw state in medicine, and, when roasted, both as a medicine and still more extensively as an article of diet. The coffee-plant begins to produce fruit when two or two and a half years old; but the quality of the seeds from young stems is not so good as that from stems four or five years old. The size and colour of the bean (as the inner part of the seed is called) vary considerably, those from the West Indies being larger than those from the East. Much more depends upon the manner of roasting and making the coffee, than upon the quality of the bean. The superiority of French coffee, in the preparation of which little or no Mocha coffee is used, proves this position. Beans of a good quality are hard and heavy, sink quickly in water, are of a light yellowish-green colour, not discoloured or black, and possess the odour of coffee, which though faint is peculiar, and are free from any damp smell. Beans recently collected, or only two or three months from the tree, are not so good as those about a year old; when older than this they become deteriorated. From the analysis of Seguin and Schrader, coffee consists of coffee-bitter (impure cafeine), solid fat, resin, a little aromatic principle, gum, albumen (this albumen, according to Seguin, unites with the yellow coffee-bitter, and forms a green), and lignin.

The taste of raw coffee is somewhat sweetish; but the application of heat in the process of roasting produces important changes. The bean increases to nearly twice the original size, while it loses about one third of its weight: a powerful and agreeable odour is evolved, and a large quantity of empyreumatic oil, which appears in small drops on the surface, is formed along with a bitter principle, probably by an alteration in the cafeine, and of the saccharine matter. The roasting should take place in a close revolving iron cylinder, over a clear but moderate fire, and should not be carried too far: when the beans have acquired a light chestnut colour, the roasting should be discontinued. The beans are then to be cooled quickly by being tossed up into the air, and the grinding, or rather rough pounding, should be performed in a covered mortar or mill. The drink should be prepared from it as soon as possible, by infusion, which is preferable, unless some apparatus be employed by which a kind of decoction is made in a close vessel. About half an ounce of coffee powder should be used for every eight ounces (half a pint) of water. In Britain the roasting is generally carried too far; and the subsequent parts of the process, instead of being performed immediately, are often postponed for days or even weeks, by which the aroma is dissipated: when made the liquid is generally deficient in strength and clearness. The employment of white of egg or fish-skin for clarification is decidedly objectionable: clearness is thus purchased, but at the expense of the strength.

The addition of milk (which should always be hot) and of sugar heightens the nourishing qualities of this beverage, and in the morning renders it a more substantial article for breakfast. When taken after dinner to promote digestion it should be without milk, and, where the palate can be reconciled to it, without sugar.

There is much uncertainty as to the first introduction of coffee into the western parts of Europe. The Venetians, who traded with the Levant, were probably the first to use it. We find it mentioned in the year 1615 by Peter de la Valle, and thirty years after this some gentlemen returning from Constantinople to Marseille brought with them a supply of this luxury, together with the vessels required for its preparation.

Coffee was first introduced into England in the year 1652, fourteen years earlier than the introduction of tea. The first coffee-house was opened in George Yard, Lombard Street, by a Greek named Pasque, who was brought from Turkey by a merchant of the name of Edwards.

The adulterations of ground coffee are very considerable; the most important of these is chicory, a dark brown powder made from the roasted roots of the *Chicorium Intybus*. It is perfectly harmless, and by some is thought to be an agreeable addition to the coffee: it is not however of so much value, and should not therefore be added to the coffee by the dealer, but sold separately, so that those who desire to add it may purchase it themselves. Various other seeds are used either as imitations or adulterations of coffee, such as Rye-Chick Peas (*Cicer arietinum*), Broom Seeds (*Spartum scoparium*), the Yellow Water-Iris (*Iris pseudacorus*), and the Dandelion root (*Leontodon taraxacum*). It has been suggested to use the leaves of the coffee-plant in infusion the same as those of the tea-plant, and it is said they form a very agreeable beverage; but the berries are too valuable in themselves to permit the trees being injured by the loss of their leaves, as they would be were there any demand for them as an article of diet.

For medical uses, trade, and cultivation, see COFFEE, in ARTS AND SC. DIV.

COIX, a genus of Plants belonging to the natural order of Grasses. One of the species, *C. Lachryma*, has hard stony fruits, which are known by the name of Job's Tears. These fruits are supposed by some writers to be strengthening and diuretic.

COLAPTES. [PICIDÆ.]

COLARIS. [CORACES.]

COLCHICACEÆ. [MELANTHACEÆ.]

COLCHICUM, a genus of Plants belonging to the natural order *Melanthaceæ.* It has a coloured funnel-shaped perianth, with a very long subterranean slender tube, and a somewhat campanulate 6-parted limb; 6 stamens inserted into the throat of the tube; a 3-celled ovary; numerous ovules in 2 or 4 rows; 3 long filiform styles; stigmas somewhat clavate; capsule 3-celled, 3-partible, opening inwardly; seeds numerous, roundish, with a shrivelled skin.

C. autumnale, Meadow Saffron, is a plant with a solid bulb-like rootstock, found wild in various parts of Europe, as well as in Great Britain, and forming a gay carpet in the autumn in the fields, where its lively purple crocus-like flowers spring up. Its under-ground stems, or bulbs, as they are called, and its seeds, abound in an acrid stimulating deleterious principle, which has been carefully examined by modern chemists, and the plant forms an important article in the Materia Medica, large quantities of both rootstocks and seeds being annually consumed in the manufacture of Eau Médicinale, and other medicinal preparations. The rootstock is irregularly egg-shaped, and covered with a dry brittle brown skin; at its base it bears a bud, which feeds upon the parent stock, exhausting and finally replacing it every year. Its flowers are large, pale purple, and spring up in the autumn without leaves, forcing themselves readily through the soil, and expanding just their orifice, together with the anthers and stigmas, above the surface of the soil, while the tubular part with the ovary and filaments, remains enveloped in membranous sheathing spathes below the soil. Each stock produces six or eight of these flowers. The stamens are six, the ovaries three, each with a long thread-shaped style, and not adhering in any degree to the tube of the flower. These are succeeded by three little follicles, which slightly adhere to one another by their inner edge, and in the spring are elevated above the soil by their lengthened footstalk. At this time, too, the foliage makes its appearance in the form of an erect tuft of broad, oblong, shining, sheathing leaves. Each follicle contains several oblong seeds. It is found in the moist rich pastures of England, and in various other countries of Europe.

Colchicum is so very like an autumn crocus that an inexperienced observer might readily mistake the one for the other. They are however to be distinguished by the crocus having only three stamens, one style, and an inferior ovary, while the Colchicum has six stamens, three styles, and a superior ovary—distinctions of no little importance when the poisonous qualities of Colchicum, in which the crocus does not at all participate, are considered.

For medicinal purposes the rootstocks of Colchicum should be collected at Midsummer, and they should be used immediately; for at that time the peculiar principles which they contain are in the greatest state of concentration. If they are employed at a time when the plant is in a state of growth, especially when it is coming into flower, those principles are partly lost and decomposed by the growth of the plant, and there is no certainty as to the quantity of Colchicia that a given weight of the rootstocks will yield.

Other species of Colchicum are cultivated for the sake of their flowers, but they are of no medicinal importance, and are very badly distinguished from each other by botanists.

Three different parts of *C. autumnale* yield an active principle used in medicine, but they respectively contain it in the greatest intensity at different seasons of the year; the cormus (incorrectly called root or solid bulb) having it in perfection about June or July, the flowers in September, and the seeds the following spring. The cormus and seeds are most frequently employed in Britain; but should the proper period (Midsummer) for collecting the cormi be neglected, the flowers may be substituted, though they can only be put to immediate use, as they do not keep well. The cormi are found at various depths under ground; when very deep they are not so good, being the produce of old exhausted plants. Each cormus is about the size of a hazel-nut or walnut, ovate or heart-shaped, consisting of a white fleshy succulent substance, which, when cut across, exhibits roundish plates. It is somewhat flatter on one side, on which also may be discovered a groove, in which is lodged the germ of the flower-stem of the following year. The recent cormus has a nauseous radish-like odour; when dried, no odour; the taste is sweetish-bitter, leaving an acrid sensation in the throat.

The seeds, which should be collected in May, are small, globose, about the size of a grain of millet, of an obscure fawn-colour, opaque, rough, and wrinkled, with a white hilum at the base, very hard, tough, and difficult to reduce to powder. The relative proportions of the constituent ingredients of the cormus differ greatly, according to the season of the year when it is taken up for examination, as Stolze's analyses demonstrate. The active principle of Colchicum was long considered to be the same as that of Veratrum, and hence called Veratria; but Geiger and Hesse have shown that it is different, and have termed it Colchicia. The seeds contain this principle, and likewise some thick oil. Colchicum imparts its active principle partially to water, but more so to acetic acid, proof spirit, and wine. A sirup is sometimes formed of it, but it does not keep well.

COLE, COLESEED. [BRASSICA.]

COLEOPTERA (κολεόπτερα), a name first applied by Aristotle ('Hist. Anim.' i. &c.), and now universally adopted, to designate one of the orders into which Insects are divided, the species of which order are commonly known by the name of Beetles.

Nearly all true Insects, or those Annulose Animals which have six legs, exhibit, in a more or less developed state, four wings, or members, which, although they may not enable the animal to fly, occupy the same situation, and are analogous to those which in many insects are true organs of flight.

These members are modified in various ways to suit the habits of the species or of the groups in general; but in those insects whose habits are of a nature not to require the power of flight they are very seldom entirely wanting, being found either in a rudimentary state, or modified in their structure so as to perform some other office. In those instances where the wings are only rudimentary, we cannot often assign any positive use for them; we can only perceive that the affinities of the individuals exercise an influence in these respects—that is to say, those species which belong to groups where the individuals generally possess perfect wings, will often possess these members in a rudimentary state, when from their habits they do not require the power of flying. It appeared necessary to make these few general remarks before proceeding to give the distinguishing characters of a Coleopterous Insect, in order that the nature of these characters and the departures from them might be understood; for it is difficult to give a strict definition of any group of animals.

The insects, then, which constitute the order *Coleoptera* may be characterised as having four wings, of which the two superior are not suited to flight, but form a covering and protection to the two inferior, and are of a hard and horny or parchment-like nature, and when closed, their inner margins, which are straight, touch and form a longitudinal suture (*fig.* 16, *c*); the inferior wings, when not in use, are folded transversely under the superior, and are membranous. From this character of having the wings in a sheath, the term *Coleoptera* was applied, it being composed of the two Greek words *κολεός*, a sheath, and *πτερά*, wings. The superior wings, which form the sheath, are generally called elytra.

The principal exceptions to this general rule are as follows:—those beetles which have no under-wings, or have them in a rudimentary state, as in *Carabus cancellatus*, and those in which the elytra are soldered together at the suture, in which case we believe no under wings are ever found. Another species of *Carabus* (*C. violaceus*) and many among the *Heteromera* afford examples of this exception. There are several beetles in which the elytra do not close at the suture, and in which the under-wings are not protected by them. Such is the case in the genera *Sitaris*, *Ripiphorus*, and others, in which the wing-cases, or elytra, are somewhat pointed; and in the genus *Molorchus*, among the *Cerambycidæ*, the wing-cases are very short, and the wings are not folded beneath them when at rest. In the *Staphylinidæ* the wing-cases are also very short, but the under-wings, by a series of folds, are, when not in use, entirely concealed beneath them; and as in this tribe the elytra form a straight suture when closed, the only exception consists in the greater number of folds in the under-wings.

Numerous other exceptions might be noticed, but we shall merely mention the genus *Meloe*, where one elytron partly folds over the other; the families *Lampyridæ* and *Telephoridæ*, in which the elytra are comparatively soft and flexible; and the glow-worm, the female of which beetle has neither elytra nor wings.

The larvæ of Coleopterous Insects are generally composed of thirteen distinct segments, the head included. They are almost always of an elongate cylindrical or slightly depressed form; the body is often soft and fleshy, and of a white colour: in these the head is always of a firmer texture, being of a horny nature. The principal parts of the mouth are the same, as to number, as in the perfect insect, although the parts are (as far as our observations go) always differently formed. The head is furnished with two antennæ, which are generally minute, and composed of four joints; and ocelli, or simple eyes, are, on each side, situated near the base of the antenna. The body is furnished with six legs, which are attached to the first three segments, or those next the head, a pair to each: the legs are small and usually terminated by a simple claw. Sometimes, in addition to the ordinary legs, the larva is furnished with false legs (often termed pro-legs); these are fleshy tubercles which the animal can protrude at pleasure, and are used to propel the body. Some larvæ have only two of these pro-legs, which are attached to the apex of the terminal segment of the abdomen, or placed beneath that segment; and in the larvæ of the species of *Cerambycidæ* each segment of the body is thickened in the middle both above and below: these parts the animal has the power of protruding considerably, by which means it is enabled to thrust itself forwards or backwards in the holes in the trunks or boughs of trees which are formed by its feeding upon the wood.

The larvæ of groups (generally believed to be natural) very closely resemble each other, though those of different groups are sufficiently distinct; hence a knowledge of the larvæ is of great use in determining the natural affinities of species when their families or sections are not well ascertained.

We select as an illustration of the principal characters of a Coleopterous larva, that of one of the *Lamellicornes*, a group which comprises the common Cockchafer, and where the larvæ generally, if not always, have their body bent under at the apex.

Fig. 1, Larva of a Coleopterous Insect; *a*, natural size; *b*, leg; *c*, antenna; *d*, mandible; *e*, maxilla. Fig. 2, Pupa state of the same insect. Fig. 3, natural length of the pupa.

We shall now proceed to the pupa state of Coleopterous Insects. Those larvæ that live in the ground generally prepare for the pupa state by removing the soil which surrounds them so as to form an open oval space: others form a species of cocoon around them, constructed of particles of earth, and other substances within reach, joined together by a kind of web or glutinous substance. Wood-feeding larvæ, or those that live in the trunks or bark of trees, for the most part assume the pupa state without such preparation.

Some larvæ which feed upon plants inclose themselves in a spherical cocoon; others again suspend themselves by the tail, and hang from a leaf or stalk of the plant. In one instance we have known the animal to assume the pupa state within the skin of the larva. The pupæ of Coleopterous Insects are what is termed incomplete, that is, all the parts of the perfect insect are distinctly visible, the legs, antennæ, wings, &c., being each inclosed in a separate sheath, and not as in the pupa or chrysalis state of moths and butterflies, where all the parts are soldered together, or as in the pupæ of the *Hemiptera* (bug-tribe), or *Orthoptera* (locust-tribe), in which stage the insect is active, and in some instances cannot be distinguished from the perfect insect. This character of incompleteness in the pupa is therefore one of great importance, and is generally added to the definition of a Coleopterous Insect, for there are no other insects which, in the pupa state, are incomplete, and which in the imago state could be confounded with the *Coleoptera*.

Having traced the beetle through the larva and pupa states, we arrive at the last or imago state, the perfect insect.

Beetles belong to the *Mandibulata*, which forms the first of the two great sections into which Insects are divided: a section, the individuals of which are distinguished by their possessing distinct mandibles; and as the Insects of the order *Coleoptera* possess the mandibles and all other parts of the mouth so well developed, they have by many been placed at the head of the Insect-Tribe. We imagine, however, that the reasons stated for so doing are not sufficient.

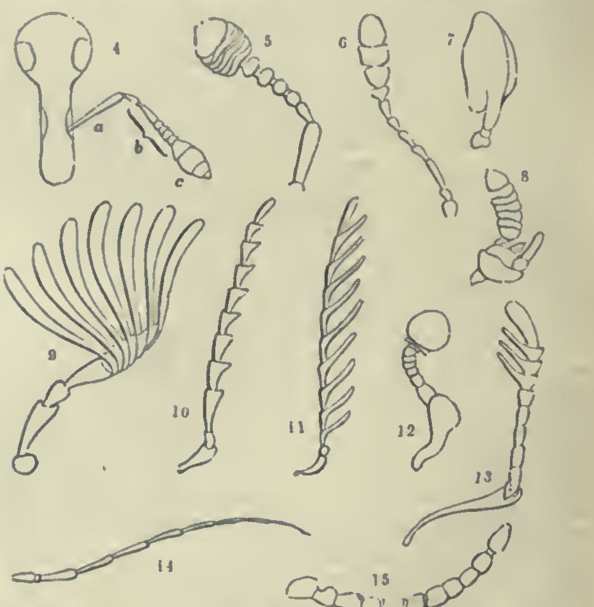
The anatomy of Insects is given under the article INSECTA. We shall therefore at present confine ourselves to the external parts of a beetle, and to those only which it is essential to know, in order to understand the description of those insects.

When we look at a beetle, we perceive that it is composed of three distinct parts, the foremost of which is the head; the next is called the thorax; and the last the abdomen.

The head is furnished with two eyes, two antennæ, and the various parts of the mouth, called the trophi. The eyes are situated on each side of the head, and are generally prominent, and always convex masses composed of an immense number of lenses arranged closely together, so that their interstices form hexagons. These are technically termed compound eyes, and are of a circular or oval form, frequently kidney-shaped, and in some instances (as in the genus *Tetrops* among the *Cerambycidæ*) they are completely divided.

The antennæ in Coleopterous Insects have their origin generally near the eyes, and are situated for the most part either between them or before them. They are generally composed of eleven joints; in many however this number cannot be traced, whilst in some few there appear to be twelve. The form of the antennæ is extremely variable, and will be best understood by an inspection of the following illustrations, among which will be found most of the more common forms, and some of the more extraordinary.

Fig. 4 represents the head (with one antenna attached) of one of the *Curculionidæ*, a large tribe of beetles, in which the antennæ are what is termed geniculate: that is, they have the terminal joints kneed, or bent at an angle with the basal joint. In describing beetles of this tribe the antenna is generally divided into three parts. The long basal joint (*a*) is called the scapus, the several following joints (*b*) are termed the funiculus, and the terminal joints which form the nob (*c*) clava. *Figs.* 5 and 12 represent antennæ which are termed capitate, or which have the terminal joint or joints suddenly enlarged and forming a knob. When the knob exhibits distinct articulations (*fig.* 5), the antenna is termed capitate with perfoliate knob; and when the knob does not exhibit articulations, or is composed of a single joint, it is said to be capitate with solid knob. Examples of the former will be found in the genus *Necrophorus*, and of the latter in the genus *Monotoma*. *Fig.* 6 represents an antenna which becomes gradually thicker towards the apex, and which is termed clavate. *Fig.* 7 is the antenna of one of a most extraordinary group of beetles, the *Pausidæ*, many of which insects have the knob of that member swollen or inflated. *Fig.* 8 is an auriculate antenna, and is so called from its having an ear-like appendage at its base. This description of antenna is found in the genera *Parnus* and *Gyrinus*. *Fig.* 9 represents the antenna of the common Cockchafer (*Melolontha vulgaris*). This form of antenna, which is termed lamellate, is found throughout the immense tribe of beetles called by Linneus *Scarabæus*, and which has received the name of *Lamellicornes* from this peculiar character.



It must be observed however that slight modifications are found. *Fig.* 10 is a figure of a serrate antenna. Antennæ are so called when they have the apex of the joints widened, so as to resemble the teeth of a saw. Examples may be found in the *Elateridæ* and *Buprestidæ*. Pectinate antennæ (*fig.* 11) are those in which the apex of the joints is produced on one side, and which somewhat resemble the teeth of a comb. There are many examples of this structure in the antennæ of the *Lampyridæ*, &c., and there are some in which the joints are elongated on each side: these are termed bipectinate. *Fig.* 13 is what is called a fissate antenna (the joints on one side divided as by incisures). This form of antenna is found in the genus *Lucanus*. *Fig.* 14 represents a very common form of antenna (where it is slender and tapering gradually to the apex); it is termed setaceous, and most of the *Carabidæ* and *Cerambycidæ* will afford examples. The antennæ termed filiform somewhat resemble the last, but the joints are all of equal thickness throughout. The last description of antennæ which we shall notice are those termed moniliform. (*Fig.* 15.) Here all the joints are oval or round, and resemble a necklace of beads. Examples are found in many of the species of the section *Heteromera*.

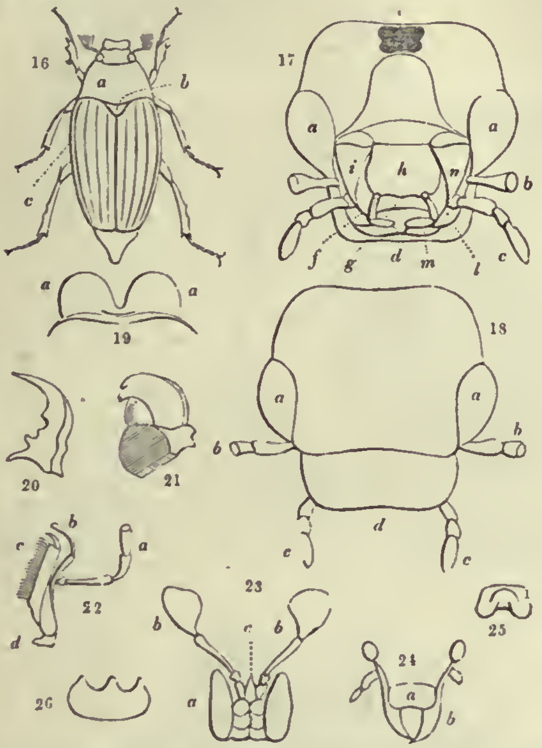
We now come to the parts which constitute the mouth of a beetle; these, it is scarcely necessary to say, are situated in the fore part of the head: they consist of a labrum, or upper lip; two mandibles, or jaws; two maxillæ, or under-jaws; and a labium, or under lip. These are the six principal parts. We shall however also notice the portions called the mentum, or chin, and the clypeus, since they are frequently mentioned in descriptions.

The labrum is a moveable plate, often on the same plane with the fore part of the head, which it terminates, and generally covers the base (at least) of the mandibles above; hence it is often called the upper lip, forming as it does the upper boundary of the mouth.

This portion, although of various forms, is less liable to variation than most of the other parts of the mouth. The most common form perhaps is somewhat quadrate, or broader than long, as in *fig.* 24, *a*.

Upon referring to the article CARABUS, it will be seen that that genus and some other closely-allied genera are separated chiefly on account of the difference in the form of this member. In one it is described as bilobate; by this is meant that the labrum is notched in the middle, so that the two side-pieces form lobes. (*Fig.* 25.) When the labrum is not thus notched, but presents an even anterior margin, it is described as entire. In one of the other genera (*Procrustes*), where the labrum is described as trilobate, the only difference consists in its having two notches on the anterior parts, and is thus separated as it were into three lobes.

The clypeus is the part to which the labrum is attached, and which is usually on the same plane with it. The term clypeus will seldom be found in descriptions, excepting in giving the characters of those beetles which belong to the *Lamellicornes*, a tribe in which this part is greatly developed (*figs.* 17 and 18, *d*), and where the labrum is hidden beneath it.



Under the labrum the mandibles (mandibulæ) are situated. These, as their name implies, are the organs of manducation; they move horizontally, and are most commonly of a shape more or less approaching to a triangle. Their form however varies according to the food of the insect.

Generally speaking, in beetles which feed upon vegetable substances the jaws are broad, obtusely pointed at the apex, and have moreover a broad flat surface at their base (often with little sharp ridges), which somewhat resembles a molar tooth of herbivorous quadrupeds. (*Fig.* 21.) In those species whose habits are carnivorous the jaws are longer and less stout, have the apex acutely pointed, and several sharp tooth-like processes on their inner side. (*Fig.* 20.)

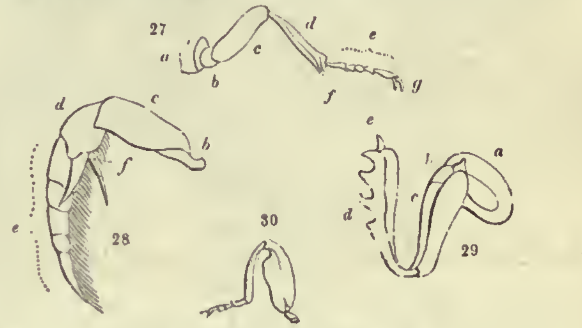
Next in succession follow the maxillæ, or under jaws (*fig.* 17, *n*, and *fig.* 22): these organs are situated beneath the mandibles, and, like them, move horizontally. A typical maxilla consists of several parts, the principal of which are—the hinge (cardo), a piece situated at the base of the maxilla (*fig.* 22, *d*); the maxillary palpus (*fig.* 22, *a*), an articulated organ generally composed of four joints; the outer lobe (lobus superior), which in beetles of carnivorous habits is a two-jointed process (*fig.* 22, *b*) situated between the maxillary palpus and the inferior lobe (lobus inferior), which last portion constitutes the inner part of the maxilla, and is often formed like the blade of a knife, and furnished generally with a series of bristles or hairs on the inner edge. (*Fig.* 22, *c.*) The maxillæ seem to be used with the labium in directing the food during manducation, and the bristles on the inner edge appear to serve as a kind of strainer through which the juices are pressed, for we observe that solid substances are seldom swallowed by insects in their imago state.

The labium, or under lip (*fig.* 17, *h* and *g*, and *figs.* 23 and 26), is a moveable organ which serves to close the mouth beneath, and is generally divided by a transverse suture, in which case the lower portion constitutes the mentum, or chin. The tongue (*fig.* 23, *c*), which may be considered as a portion of the labium, in Coleopterous Insects, is usually situated at the apex of that member, or emerging from it. The labial palpi (*fig.* 23, *b*, *b*, and *fig.* 17, *f*) are two articulated organs usually springing from the summit of the labium on each side.

Having now briefly noticed the head and its parts, we come to the thorax. On this portion it will be unnecessary to dwell: we need only mention that the thorax in insects is composed of the three first segments of the body, which in the larva state are usually distinct; these are termed the prothorax, mesothorax, and metathorax; and it generally happens that in the perfect insect one of these segments is greatly developed at the expense of the other two, particularly on the upper surface of the body; such is the case in the Beetle Tribe, where the first portion or prothorax (*fig.* 16, *a*) and the small plate (*fig.* 16, *b*), which is a part of the mesothorax, are all that is visible from above when the elytra are closed. Some few entomologists, therefore, in describing Beetles, call the part (*fig.* 16, *a*) the prothorax, but it is most commonly called the thorax. The small plate (*fig.* 16, *b*) above referred to is called the scutellum, and is usually of a triangular form.

To the thorax are attached the legs and wings: the anterior pair of legs are attached to the prothorax; to the mesothorax the intermediate pair of legs and the anterior pair of wings, or elytra, as they are termed in the *Coleoptera;* and to the metathorax the posterior pair of legs and the hinder pair of wings. Of the wings enough has been said for the present.

The legs in Beetles vary according to their habits. Thus in some they are formed for running (*fig.* 27), in others for swimming (*fig.* 28); here they are very broad and flat: in others again their structure is suited to burrowing habits (*fig.* 29); and *fig.* 30 represents the hind leg of a beetle, which has the power of leaping to a great distance, where the thigh is very large.



A leg may be divided into five principal parts: the coxa, or hip (*a*, *figs.* 27 and 29), which is the first joint, or that joined to the body, where it plays in a socket; the next part, or second joint of the leg, is the trochanter (*b*, *figs.* 27, 28, and 29); the third is the femur, or thigh (*c*, *figs.* 27, 28, and 29); the fourth joint is called the tibia, or shank (*d*, *figs.* 27, 28, and 29); the fifth and last part is the tarsus (*e*, *figs.* 27, 28, and 29): this part in a great portion of the Coleopterous Insects is composed of five joints; in many a lesser number is found, but in none do they exceed five: the last joint of the tarsus is usually terminated by two hooked claws called unguiculi (*g*, *fig.* 27), and the apex of the tibia is furnished generally with two straight spines called the calcaria (*f*, *figs.* 27 and 28).

As regards the classification of the *Coleoptera*, as well as of insects in general, in almost every work which treats of the subject, a new method is proposed. We shall content ourselves however with noticing two—that which is most commonly adopted on the continent, and that which is followed by most entomologists of our own country: the former is the method proposed by Latreille, and the latter by Stephens.

In the classification of the *Coleoptera*, published by Mr. Stephens in his 'Systematic Catalogue of British Insects,' the various sections and subsections are as follows:—

Order, *Coleoptera*.

Sect. 1. *Adephaga.*	Sect. 3. *Helminthomorpha.*
Sub-Sect. 1. *Geodephaga.*	Sub-Sect. 1. *Rhinchophora.*
2. *Hydradephaga.*	2. *Longicornes.*
3. *Philhydrida.*	Sect. 4. *Anoplurimorpha.*
4. *Necrophaga.*	Sub-Sect. 1. *Eupoda.*
Sect. 2. *Chilognathomorpha.*	2. *Cyclica.*
Sub-Sect. 1. *Clavicornes.*	3. *Trimeri.*
2. *Lamellicornes.*	Sect. 5. *Heteromera.*
3. *Sternoxi.*	Sect. 6. *Brachelytra.*
4. *Malacodermi.*	

The arrangement of Latreille is founded upon the number of joints of the tarsi. He accordingly divides beetles into the four following great sections:—

Section 1. *Pentamera*, including all those Beetles which have five joints to their tarsi.

Section 2. *Heteromera*, Beetles with five joints to the tarsi of the two anterior pairs of legs, and four to those of the posterior pair.

Section 3. *Tetramera*, Beetles with only four distinct joints to all the tarsi.

Section 4. *Trimeri*, Beetles with only three distinct joints to the tarsi.

On comparing these two arrangements, it appears that there is considerable difference of opinion between the authors of them as to the value of certain groups. The *Trimeri*, according to Latreille, is made one of the four great sections, whilst Mr. Stephens makes the same group a sub-section of a tribe of not equal importance with Latreille's first division, the *Pentamera*.

These discrepancies probably arise from the want of some standard by which the importance of characters may be estimated. We find a great number of Insects possessing certain characters in common, but it often happens that we cannot ascertain what influence these characters have on the habits and economy of the individuals. In such instances, the most correct way perhaps would be to judge of the value of a character from its constancy; or, in other words, to consider that character of most importance, as regards classification, which is found in the greatest number of species, these species agreeing more or less in some other points.

In all groups of animals there are however certain typical characters to which all the species approach more or less, and which perhaps the greater portion actually possess. The typical characters of a group, and the departures from them, ought not therefore to be selected for constructing natural and equivalent groups. In the *Coleoptera*, for instance, the typical structure is to possess five joints to the tarsi; Latreille's first section (the *Pentamera*) consequently comprises at least half the species and several distinct groups, each of which is equivalent to one of his other sections.

It appears to us, being guided by the points above mentioned, that the order *Coleoptera* contains the thirteen following distinct sections, and that Latreille's groups are not natural:—

All the Tarsi with five joints.

Section 1. *Geodephaga*, M'Leay.
2. *Hydradephaga*, M'Leay.
3. *Brachelytra*, Latreille.
4. *Necrophaga*, M'Leay.
5. *Palpicornes*, Latreille.
6. *Lamellicornes*, Latreille.
7. *Sternoxi*, Latreille.
8. *Malacodermi*, Latreille.

Five joints to the Tarsi of the two anterior pairs of legs, and four to the posterior pair.

9. *Heteromera*, Latreille.

All the Tarsi with four joints.

10. *Rhyncophora*, Latreille.
11. *Longicornes*, Latreille.
12. *Cyclica*, Latreille.

All the Tarsi with three joints.

13. *Trimeri*, Latreille.

The number of species of Beetles in existence may probably amount to between 30,000 and 40,000.

The principal works on the *Coleoptera* are as follows:—Fabricius (J. C.), 'Systema Eleutheratorum;' Olivier (A. T.), 'Entomologie, ou Histoire Naturelle des Insectes,' five vols. folio, with coloured plates; Paykul (Gustavus), 'Fauna Suecica,' three vols.; Gyllenhal (L.), 'Insecta Suecica;' Schœnherr (C. J.), 'Genera et Species Curculionidum;' Dejean, 'Species Général des Coléoptères;' five volumes of this work are published, and contain descriptions of the genera and species of the *Carabidæ* and *Cicindelidæ*. Besides these, the works of Germar, Illiger, Sturm, Knoch, and Duftschmid may be consulted; and the *Coleoptera* of our own country will be found described in Stephens's 'Illustrations of British Entomology.' The works also of Curtis, Kirby and Spence, Westwood, Newman, and the Transactions of the Linnæan and Entomological Societies, may be consulted with advantage.

COLIBRI. [TROCHILIDÆ.]

COLIUS. [FRINGILLIDÆ.]

COLLEMACEÆ, an order in the Lichenal Alliance proposed by Dr. Lindley, having the following characters:—Nucleus bearing asci; thallus homogeneous, gelatinous, or cartilaginous. Dr. Lindley has given no arrangement of the genera and species of this order in his 'Vegetable Kingdom.' [LICHENS.]

COLLO'MIA (from κόλλα, glue), a genus of Plants belonging to the natural order *Polemoniaceæ*. It has a campanulate calyx, 5-cleft or somewhat 5-parted, the lobes lanceolate or linear, equal, entire; the corolla salver-shaped, with a slender exserted tube, and a spreading 5-parted limb; the segments oblong, entire; the stamens inserted towards the middle of the tube; the anthers ovate-roundish; the cells of the capsule 1-2-seeded. The species are annual herbs, with alternate leaves and dense heads of flowers. They are all natives of America.

C. linearis is an erect branched plant, clothed with glandular hairs; the leaves ovate-lanceolate, quite entire, opaque, reniform, the upper ones downy beneath; the calyx cup-shaped, 5-parted; corolla more than twice as long as the calyx; the cells of the capsule 1-seeded. This plant is a native of North America, from Lake Winnepeg to the western ocean. The corolla has a reddish tube and a rose-coloured limb. The seeds of this as well as the other species are covered with a testa, which is composed of a spiral tissue held together by inspissated mucus. On the seeds being placed in water the gum of the mucus is dissolved, and the spiral fibres start up on the surface of the seed.

The species of *Collomia* are showy plants, and may be easily cultivated in any common garden soil. The seeds should be sown in an open border in spring.

(Don, *Dichlamydeous Plants*.)

COLLOPHORA, a genus of Plants belonging to the natural order *Apocynaceæ*. One of the species, *C. utilis*, yields caoutchouc, or a substance analogous to it.

COLLURICINCLA. [LANIADÆ.]

COLLURIO. [LANIADÆ.]

CO'LOBUS, a genus of Quadrumanous *Mammalia* (Cheiropeds of Mr. Ogilby) established by Illiger and adopted by M. Geoffroy. The latter places the genus in the group of Singes Catarrhins, or Monkeys of the Old Continent; a group distinguished by having their nostrils separated by a very thin partition, and by possessing five molar teeth only on each side of the two jaws.

The genus has the following characters:—Facial angle from 40 to 45 degrees; muzzle short; face naked; body elongated and small; extremities slender; the anterior hands deprived of a thumb; the fingers rather short; the posterior thumb very distant from the fingers, and placed very much backwards; tail longer than the body, small, and tufted at the end; cheek-pouches; and callosities on the buttocks.

The *Colobi*, which are supposed to be inhabitants of the Coast of Guinea, seem to be in the Old World the representatives of *Ateles*, whose locality is South America.

C. polycomos, Geoffroy, is the *Simia polycomos* of Schreber; the *Simia comosa* of Shaw; the Guenon à Camail of Buffon; and the Full Bottom of Pennant. It is a very handsome species. The head and upper part of the body are covered with hair, falling over the shoulders and forming a kind of hood and pelerine, from whence it derives the name given to it by Buffon, while the resemblance of this chevelure to a wig determined Pennant to give it the English name above recorded. This ornament is composed of floating hairs, which are yellow mingled with black; the face is brown, and the rest of the body is covered with very short close hair of a jet-black, a colour which sets off the snow-white tail, which is much longer than the body and not prehensile. In this last particular, in the possession of cheek pouches, and in other characters, it differs from *Ateles*; while in some points, and especially in the absence of the thumb in the anterior hands, it resembles it much.

Full Bottom (*Colobus polycomos*).

It inhabits the forests of Sierra Leone, where the natives give it the name of the 'King of the Monkeys' (Roi des Singes), apparently, says Desmarest, on account of the beauty of its colours, and its 'camail,' which represents a sort of diadem. They attach great value to its fur, of which they make ornaments, and they apply it to various purposes.

C. polycomos, Schreber, with the head and shoulders covered with long coarse flowing hair, of a dirty yellowish colour, mixed with black; body, arms, and legs of a fine glossy blackness, covered with short hair; tail of a snowy whiteness, with very long hair at the end, forming a tuft. (Pennant.) Locality, Sierra Leone.

C. Ursinus, Ogilby, "with very long glossy black hair over the whole body and extremities, and a long snowy-white tail, tufted at the end;" described from two imperfect skins without heads or hands. It is probable that this animal is only a variety or identical with *C. polycomos*.

C. Guereza, Rüppell, with the head, face, neck, back, limbs, and basal half of the tail, covered with short black hair; the temples, chin, throat, and a band over the eyes, white; the sides, flanks from the shoulders downwards, loins and buttocks, clothed with long flowing white, which hangs down on each side like a loose garment; the tip of the tail tufted with dirty-white. Locality, Abyssinia. There is a specimen, one of Dr. Rüppell's, in the British Museum.

Colobus Guereza.

C. ferruginosus, Geoffroy. Crown black; back of a deep bay colour; outside of the limbs black; cheeks, under part of the body, and legs, very bright bay; tail black. Locality, Sierra Leone.

C. fuliginosus. Smoky-blue above, dirty yellowish-gray beneath; cheeks, throat, tail, and extremities, brick-red. (Ogilby.) Locality, the Gambia. Mr. Ogilby observes that the face is short, the head round, and the whole form and habit of the animal similar to those of the *Semnopitheci*. The teeth, he adds, are of the usual form and number, and there are large and very distinct cheek-pouches. "I was the more particular," says Mr. Ogilby, "in making this last observation, because the organs in question had not been previously recorded as existing in the *Colobi*, and because M. Geoffroy St. Hilaire, in his valuable lectures, of which it is a matter of great regret that so small a portion has been given to the public, even doubts their existence." In the 'British Museum Catalogue' this species is given as a synonym of the following:—

C. Temminckii, Kuhl, "with the hands, face, and tail, purplish-red; rest of the members clear-red; belly reddish-yellow; head, neck, back, shoulders, and outer face of the thighs, black." Habitation unknown. Described from a specimen formerly in Bullock's Museum, and now in that of Leyden.

COLOCASIA, a genus of Plants belonging to the natural order *Araceæ*. The species are excessively acrid; the leaves of *C. esculenta* excite a violent salivation and burning sensation in the mouth. Notwithstanding this property many of the species are used as food by the natives of the south of Europe. The leaves and roots of *C. esculenta*, *C. Himalensis*, *C. Antiquorum*, and *C. mucronata*, under the names of Cocoa-Nut, Eddoes, and Yams, when boiled or roasted, are common articles of diet in hot countries. Whole fields of *C. macrorhiza* are cultivated in the South Sea Islands under the name of Tara or Kopeh roots. In the Himalayas the species which is called *C. Himalensis* forms a chief portion of the food of the Hill Tribes. Medicinally the root is stimulant, diaphoretic, and expectorant. The whole of the species are remarkable for containing a milky juice. They are cultivated in Portugal, Greece, and Egypt.

COLOCYNTH. [CUCUMIS.]

COLON. The alimentary canal below the stomach is divided into the small and great intestines. The former consist of the duodenum, jejunum, and ileum; the latter of the colon and rectum. The Colon commences a little above the right groin, in the right iliac fossa [ABDOMEN], in the form of a dilated pouch, which is called the caput coli, or more commonly the cœcum, from its blind rounded extremity. The ileum opens obliquely into the left side of this pouch, its inner or mucous membrane projecting so as to form the ileo-cœcal valve, which, permitting the contents of the small intestine to pass into the Colon, suffices to prevent their return, except in peculiar cases of diseased action. Near the same part of the cœcum opens also a slender contorted intestine about two inches long, likewise blind, which is called the appendix vermiformis, from its resemblance in the human subject to a worm. The use of this appendage is unknown: in some animals, as the sheep, it is much larger, and is probably of more importance than in man. From the right iliac region the Colon passes upwards along the side to the under surface of the liver. Hence it turns to the left, stretching over the upper part of the belly just below and in front of the stomach, to which it is connected by the common attachment of both organs to the omentum, a loose pendulous membrane, formed by a double fold of the peritoneum, and spread like an apron in front of the small intestines. Having reached the opposite side of the abdomen, the Colon passes downwards to the left iliac fossa; thence, taking two sudden turns to the right and downwards, it descends into the pelvis over the last lumbar vertebra, and becomes continuous with the rectum. The double turn just mentioned is the sigmoid flexure; the transverse part is called the arch of the Colon; and the ascending and descending or lateral parts, as they lie immediately over the loins, are called the right and left lumbar portions. The central space thus nearly encircled by the Colon is occupied by the convoluted heap of small intestines. The length of the whole intestinal canal is six or seven times that of the body in man, the Colon constituting about a fifth part. In graminivorous animals its length is proportionably greater; in those which feed exclusively on flesh it is less.

The Colon is enveloped in the serous membrane called the peritoneum, which forms the external covering of all the abdominal viscera. [ABDOMEN.] This outer tunic passing entirely round it, meets behind, and forms a duplicature called the mesocolon, which attaches it, more loosely at the arch than at the sides, to the spine and loins, and serves as a medium for the passage of nerves and vessels, and the lodgment of absorbent glands. Between the peritoneal coat and the interior mucous lining there is a layer of muscular fibres, some of which encircle the bowel in scattered bands, and serve to diminish its calibre; others, more regularly arranged in three distinct longitudinal bands, contract its length; and their combined actions, taking place successively in different parts of the intestine, but on the whole propagated from above downwards, agitate its contents backwards and forwards, and urge them ultimately into the rectum.

The Colon is amply supplied with blood-vessels, nerves, lymphatics, and ducts, which pour out the mucus that lubricates the interior as well as various excrementitious matters here separated from the blood as being injurious or useless. The canal is not smooth and uniform like the small intestines, but bulges out between the bands of muscular fibre into various prominences more or less regular in their form, in which the fæces lodge for a time and become deprived of much of their moisture as they are rolled onwards by the peristaltic action. Hence arises their lobulated or globular form, more observable in some of the lower animals, as the horse and sheep, than in man. It is in the Colon that the fæces acquire their peculiar odour, which is not perceived above the ileo-cœcal valve. It is in this part of the alimentary canal that the fluid part of the food is chiefly absorbed, being no longer needed to keep the nutritive particles in suspension. The lymphatic vessels of the Colon are consequently found distended with a transparent fluid, and not the milk-like chyle absorbed by those of the small intestines. [LACTEALS; LYMPHATICS.]

COLOPHO'NIA (in French the wood is called Bois de Colophane), a genus of Plants belonging to the natural order *Burseraceæ*. It has an urceolar bluntly 3-lobed calyx; 5 roundish-ovate petals inserted under the disc, imbricated in the bud; 6 stamens, one-half shorter than the petals, equal in length to the calyx; the disc 6-lobed. It is to a genus thus defined that De Candolle refers the tree producing the Bois de Colophane of the island of Mauritius, and calls it *C. Mauritiana*. In his description of the tree he says the fruit is unknown. Lindley, in his 'Flora Medica,' gives *Colophonia Mauritiana*, De Cand., *Bursera paniculata*, Lam., *Amyris Zeylanica*, Retz., and *Balsamodendron Zeylanicum*, De Cand., as synonyms of *Canarium commune*. This last is described as a small tree, with 7-11 leaflets on long stalks, ovate-oblong, acute or shortly acuminated, quite entire, smooth; stipules oval; the panicles of flowers terminal, divaricating; the flowers 2-3 together, almost sessile, when young covered over by broad ovate concave silky bracteola; the calyx silky externally; the drupes oblong, black. The bark of this plant yields a limpid oil, with a pungent turpentine smell, which congeals into a buttery camphoraceous substance. It possesses the same properties as Copaiba. Don says:—"When the nuts are mature they contain a sweet kernel, which does not become rancid, and which resembles a sweet chestnut; they are eaten both raw and dressed by the inhabitants of the Moluccas, Banda, and New Guinea; and an oil is expressed from them, which is used at the table when fresh, and for lamps when stale; bread is also made from them, cakes, biscuits, &c., for the table. Eaten fresh they are apt to bring on diarrhœas and dysenteries, and to occasion an oppression at the breast." The same tree is also said to yield East Indian Elemi. It is a native of the continent of India and of the islands of the Eastern Archipelago. (Don, *Dichlamydeous Plants;* Lindley, *Flora Medica.*)

COLOPHONITE, a coarse granular variety of *Garnet*, presenting iridescent hues and a resinous lustre. [GARNET.]

COLOQUINTIDA. [CUCUMIS.]

COLOSSOCHELYS. [CHELONIA.]

COLTSFOOT, the common name of *Tussilago Farfara.* [TUSSILAGO.]

COLUBER. [COLUBRIDÆ.]

COLUBRIDÆ, a family of Snakes, the last of the sub-order *Colubrina* of Dr. J. E. Gray. The *Colubrina* include the families *Hydridæ* [HYDRIDÆ], *Boidæ* [BOIDÆ], and *Colubridæ*. This last family includes the genus *Coluber* of Linnæus, which comprised all the serpents, whether venomous or not, whose scales beneath the tail are divided into two, or, more properly speaking, arranged in pairs; but the term is generally applied by Cuvier and other authors to those serpents which have transverse plates on the belly, and the plates under the tail forming a double row, a flattened head with nine larger plates, teeth almost equal, and no poison-fangs. The following is Dr. Gray's definition of the sub-order *Colubrina*:—Jaws strong, both toothed, sometimes with some fangs in front or grooved teeth behind. Head moderate or indistinct; crown often covered with regular shields. The section of this order to which the *Colubridæ* belong have the belly covered with broad band-like shields; vent without any; spur-like feet; the tail conical and tapering. The only family in this section are the *Colubridæ*, which have the nostrils apical, lateral, open; the head generally shielded.

Laurenti placed the *Colubridæ* between the Rattlesnakes (*Caudisona*) and the Vipers. Scopoli's genera were those of Linnæus. Lacépède placed the *Colubridæ* at the head of his nine genera of Serpents, and next to them came the Boas and Rattlesnakes. Alexander Brongniart made them the last but one of his six genera of Ophidians, arranging them between the Vipers and the Boas. Latreille gave the genus a place between *Chersydrus* and *Dipsas* in his family of Anguivipères. Daudin comprehended 172 species under the genus. In the synoptical table of Duméril and Bibron, Cuvier is made to place it between *Dipsas* and *Cerberus*. Oppel subdivides his section (the second) the *Squammata* (Ecailleux) into seven families, of which the *Colubridæ* (Couleuvrées) are the last, coming immediately after the Pseudo-vipères. Merrem divided the Serpents into two sub-tribes: in the first sub-division, the *Innocui*, or serpents without venom, of the first tribe (*Gulones*), *Coluber* appears between *Scytale* and *Hurriah*. De Blainville separated the Serpents into *Dipodes* and *Apodes; Coluber* coming immediately after *Boa*, is placed in the innocuous division of these *Apodes*. Dr. Harlan made the Ophidians, his fourth order, contain six genera, and placed *Coluber* between *Ophisaurus*, his first, and *Vipera*, his third genus. Mr. Haworth arranged the genus *Coluber* between *Scytale* and *Dryinus*, among the True Serpents (*Apoda epalpebrata*, or serpents without eyelids), and under the innocuous branch of the *Gulonia*. Fitzinger (1826) placed the *Colubroïdes* between the *Pythonoïdes* and the *Bungaroïdes*, in his comprehensive third tribe *Monopnoa squammata*. Ritgen (1828) arranged the *Colubridæ* and the *Boidæ* under his *Macrostomata*, the third sub-partition of the first sub-division, *Holodontaspistes* (with entire teeth), of his third sub-order of Scaly Serpents. Wagler published in 1830 his 'Naturaliches System der Amphibean.' He makes his fourth order, the Serpents, consist of one family only, comprehending 97 genera, and places *Coluber* the forty-ninth between *Spilotes* (Wagler) and *Herpetodrys* (Boié).

In 1832 Professor John Muller, of Bonn, published his system: the Colubers are arranged by him immediately after *Dryinus*, as the last of the Isodonts, the third family of his second order, uniting the *Macrostomes*, which correspond to the *Heterodermes* of Duméril.

The species of the genus *Coluber*, as left by Cuvier, are very numerous, and their geographical distribution is very wide. The foreign species are some of them remarkable for their vivid colouring, and others for the regularity of the pattern, so to speak, with which they are marked. Others again are singularly slender in form, but none grow to a large size.

The harmless Common Snake or Ringed Snake (Neidr fraith, Neidr y tomenydd, of the Welsh, *Natrix torquata* of Gesner and Ray, *Coluber Natrix* of Linnæus) is the best example of the form. [NATRIX.]

COLUBRINA, a genus of Plants belonging to the natural order *Rhamnaceæ*. It has a spreading 5-cleft calyx; petals 5, obovate-convolute; stigmas 3. Fruit capsular, dehiscent, tricoccous, girded at the base by the calyx. The seeds are furnished with a short stalk. The species are shrubs with alternate, quite entire, or crenulated leaves, netted with distant feather-nerves, smooth but usually pubescent or rusty villous. The flowers are in axillary short crowded cymes, or in fascicles with simple peduncles.

C. fermentum, Fermented Snake-Wood, is a native of Guinea; the bitter bark of which tree is said to bring on violent fermentation in the liquors into which it is thrown. There are several other species described, natives of South America, Africa, and the East Indies. None of them are of any known use, and are not worth cultivation except in general collections.

COLUMBA. [COLUMBIDÆ.]

COLUM'BIDÆ, a natural family of Birds, comprising the Pigeons, Doves, and Turtles.

Aristotle mentions five, if not six, birds of this group—Περιστερὰ, Πελειὰς, Φάττα, Οἰνὰς, and Τρυγὼν,—entering at large into their organisation and habits. ('Hist.,' b. i. c. 1; b. ii. c. 15, 17; b. iii. c. 1; b. v. c. 13; b. vi. c. 1, 2, 4, and 8; b. viii. c. 3; b. ix. c. 7.) He also (b. viii. c. 3) speaks of a bird named Φάψ, which Athenæus ('Deipn.,' b. ix. c. 11) and others consider to be one of the *Columbidæ*, while others again hold a different opinion, inasmuch as Athenæus states that Aristotle has distinguished five species of Pigeons, and enumerates Φάψ as one, omitting Πελειὰς; and so Aristotle does (b. viii. c. 3), but he mentions Πελειὰς elsewhere (b. viii. c. 13), and it is clear to us from the context that *Phaps* signified one of the *Columbidæ*, Περιστεροειδεῖς. There is considerable doubt as to which of the species of pigeons Aristotle intended to designate by the terms above given, and some of them have been applied by modern ornithologists to signify forms which he probably never saw. Only two, or at most three, can be identified with anything like certainty. Pliny ('Nat. Hist.,' b. x. c. 34) writes 'De Columbis,' and (c. 35) 'De Palumbibus.' He enters moreover largely into their habits in other parts of his 'Natural History.'

Much doubt seems to have prevailed as to the proper place of the pigeons in the system. Belon collected the few species known to him under the titles Ramiers, Tourterelles, Bisets, Pigeons Fuyards, and Pigeons, among the birds "qu'on trouve viander indifféremment en tous lieux," placing them between the Torcou (*Jynx Torquilla*, Wryneck) and the Merle Bleu (Blue Thrush). Gesner arranged them between the Gallinaceous Birds and the Bustards; Aldrovandus placed them between the Domestic Cock and the Sparrow; Willughby between the Bustards and Thrushes, and Ray gave them the same place. Brisson, Pennant, and Latham insulated them in a particular order. Pennant also arranged them between the Gallinaceous and Passerine Birds, and Latham between the *Passeres* and the *Gallinæ*. Other authors placed them among the Gallinaceous Birds. Linnæus made them a genus of his order *Passeres*, arranging them between *Tetrao* (the Grouse and Partridges, &c.) and *Alauda* (the Larks). Cuvier placed them among the Gallinaceous Birds, next to the Tinamous (*Tinamus*, Latham; *Crypturus*, Illiger), making them the last of the order. In his arrangement the Echassiers (*Grallatores*, Wading Birds) form the order which immediately follows the Gallinacés. Lacépède had previously given them the first place in the last-mentioned family, as did also Duméril. Meyer had insulated them as his seventh order, coming between the *Chelidones* (Swallow Tribe) and his eighth order, *Gallinæ;* and Illiger had found a situation for them under his *Rasores* (the Rasorial Birds). Le Vaillant, who seems to have been the first who separated the *Columbidæ* into well-defined divisions, arranged them in three sections; the first containing the Colombes, Ramiers, and Tourterelles; the second the Colombars; and the third the Colombi-Gallines. Vieillot made them the last family but one (Colombins) of his second tribe (*Anisodactyli*), arranging them between his *Ophiophages* and *Alectrides*. M. Temminck classed them as his ninth order between the Chelidons and the Gallinacés. De Blainville's order *Sponsores*, or Les Colombins, contained these birds, and came between the *Saltatores* (*Passeres*) and the *Gradatores* (Pheasants or Partridges): in his amended method, as developed by M. Lherminier, they occupy nearly the same position between the *Passeres* and the Gallinaceous Birds. C. Bonaparte (Prince of Canino) assigns the same place to them. ('Specchio Comparativo.')

When he wrote the article 'Pigeon' in the 'Dictionnaire d'Histoire Naturelle,' M. Vieillot conformed to the opinion of Linnæus in placing these birds among the *Passeres*, because of its natural great analogy to the last-mentioned group, like nearly the whole of which the pigeons pair in the season of love, the male and female working jointly at the nest, taking their turns during incubation, and participating in the care of the young, which, among the true pigeons, are hatched blind, fed in the nest, which they do not quit till they are covered with feathers, and are supported by their parents some time after their departure from it, having no power to feed themselves. Such are the points of resemblance. Their dissimilarity consists in their mode of drinking and feeding their young, in the nature of their plumage, and the singularity of their courtship and of their voice—points of difference which also separate them from the true gallinaceous birds, with which, says M. Vieillot, they have no analogy in their instincts, their habits, or their loves. Nearly all the gallinaceous birds are polygamous, and lay a great number of eggs each time they incubate, which is rarely more than once a year in the temperate zones; while the true pigeons lay only two eggs each time, incubate frequently during the year, and are monogamous. Among the gallinaceous birds, as a general rule, the male does not solace the female at the time of building the nest and of incubation; the young run as soon almost as they are out of the egg-shell, quitting their nest, and seeking their own food immediately. Finally, a striking character removes the pigeons from the gallinaceous birds, and in M. Vieillot's opinion places them in the same natural group with the *Passeres*, namely, the possession of a posterior toe articulated at the bottom of the tarsus, upon the same plane as the anterior toes, touching the ground throughout its length in walking and embracing the roost in perching. On the contrary, in the gallinaceous birds, the hind toe is articulated upon the tarsus higher than the others, and only touches the ground with its claw, or at most with its first phalanx, and remains perpendicular when the bird is on the perch. Nevertheless it must be confessed that there are found among the pigeons species which participate in some degree with the gallinaceous birds in regard to their manners and gait (allures) or some exterior conformity. Such are the Colombi-Gallines, the Pigeon-Caille of Le Vaillant, to which must be added the Colombi-Gallines of M. Temminck, the Mountain-Partridge of Sloane, the Blue-Headed Pigeon, the Cocotzin, &c., all which have their feet more elongated than those of their congeners, with the wings of the partridges, that is to say rounded, and with the two first quills shorter than the third or fourth; but for the rest, all, with the exception of the Colombe-Galline of Le Vaillant, approach the other pigeons in their amours, their laying, and the bringing up of their young; and so it is of the birds which at Guadaloupe and Martinique bear the name of Partridge; and M. Vieillot quotes Dutertre, who says that "according to the common opinion of the inhabitants of Guadaloupe, there are three sorts of partridges, red, black, and gray, which have never passed in my mind for aught but turtles (tourterelles); for they have not the short quality of flesh belonging to our partridges, they have the straight bill, they perch and build their nests in trees, they only lay two eggs," &c. ('Hist. des Antilles,' tom. ii.) These facts, adds M. Vieillot, have been confirmed to me by the inhabitants of Martinique and Guadaloupe. Of all the pigeons and turtles, continues this ornithologist, which I have had occasion to study in the living state, the Cocotzins are those which appear to me to have the greatest relation to the partridges; their haunt is always in the fields and savannahs; there they seek their food, and never resort to trees; they raise themselves into the air like the partridges, and after a short flight alight upon the ground. For this reason the English and the inhabitants of the United States call it the Ground Dove. But the habit of frequenting the ground, &c. does not belong exclusively to the pigeons whose wings are formed as above stated; for, according to Latham, the *Columba Chalcoptera* (*Phaps*), which M. Temminck arranges with his *Columbæ* (Vieillot's first section), has the same habits, so that the English of Australia call it the Ground Pigeon. (Vieillot.)

"The family of *Columbidæ* (says Mr. Vigors, 'Linn. Trans.,' vol. xiv. p. 410), alternately arranged by systematic writers among the Perching and Gallinaceous orders, and not unfrequently grouped as a separate order between the two, at once indicates where the point of junction exists between them. These birds, although we have the high authority of Linnæus for uniting them with that division of our Perchers which forms his *Passeres*, I do not hesitate in arranging, conformably to the opinion of Messrs. Cuvier and Illiger, as a subdivision of the Gallinaceous Birds.

"In those particulars, where they respectively assume the character of each order, their affinity with the latter is considerably stronger than that which approximates them to the former. Their food and habits, their internal economy, and the formation of their bills, identify them with the *Rasores*; while, on the other hand, the characters which bring them near the *Insessores*, their divided toes and comparatively short legs, are weakened by the resemblance which those members bear to the same parts of the contiguous order in their general structure, and more particularly in the bluntness of the nails, so strongly indicative of the rasorial habits of the Gallinaceous Tribes, and so strikingly contrasted with the sharpness of the nails in the Linnæan *Passeres*. They are much more nearly allied to these latter tribes by their habits of perching and building their nests in trees or rocks, by the absence of the spur on the legs of the male, and by the inferior number of their tail-feathers."

In a note to that part of the text which alludes to the rasorial habits of the Gallinaceous Birds, the author cites the habits of *Columba Nicobarica*, *Columba carunculata*, and *Columba passerina*. Mr. Vigors accordingly places the *Columbidæ* in the aberrant group of his *Rasores*. "I have already observed, when speaking of the affinities," says that ornithologist in the paper above quoted, "which connect the orders of birds together, that the *Columbidæ* form the passage from the *Insessores* to the *Rasores* by their habits of perching and their powers of flight. The hind toe is articulated, as in the Perchers, and their tarsi are shorter, more particularly in the earlier groups, than those of the Gallinaceous Birds in general. The first group which we meet in this extensive family is the genus *Vinago* of M. Cuvier, the bills of which, stronger and more solid than they are usually found to be among the pigeons, unite them to *Penelope* and *Crax*, which form the opposite extreme of the present order, as well as to *Musophaga* and *Corythaix*, which approach, as we have seen, the whole of the groups before us, and connect them with the Perchers. From this genus *Vinago*, which seems confined to the southern divisions of the Old World, we may observe a series of groups leading gradually to the true *Columba*, of which genus the European species *Columba Œnas*, Linn., may be considered to form the type. Hence we are led by several intervening species to the Columbi-Gallines of M. Le Vaillant, which, still retaining the soft and flexible bill of *Columba*, approach the typical Gallinaceous Birds in their more elevated tarsi, and in their habits of living in company and seeking their nourishment chiefly on the ground. Among these may be noticed some forms, *C. Nicobarica*, Linn., and *C. carunculata*, Temm., for instance, which possess the feathered appendages, together with the naked face and caruncles of the Linnæan *Gallinæ*; and another group, the *Lophyrus* of M. Vieillot, which exhibits the size and general form of the same birds, as well as the singular plumes which frequently decorate their head. This last-mentioned genus, formed of the crowned pigeon of India, possessing the strongly-formed leg and foot of *Meleagris*, Linn., but without the spurs, while at the same time it retains the bill of *Columba*, may be observed to open the passage immediately from the present to the succeeding family" (the *Phasianidæ*).

The following remarks embody Mr. Swainson's views upon this interesting family:—"The extensive genus of *Columba*, like that of *Falco*, has been pronounced indivisible by an eminent ornithologist of the present day; who, from having made these birds his peculiar study, is in one sense pre-eminently qualified to give a decided opinion. The principle he has laid down, and on which this opinion consequently is founded, is, that whenever intermediate species are discovered which serve to unite two neighbouring genera, such genera should invariably be united." After stating that this theory has been refuted in the pages of the 'Zoological Journal,' Mr. Swainson thus continues: "It is admitted that there are certain peculiarities of form and of economy among the *Columbidæ*, which point out natural divisions. Some of these have been used for the construction of genera, by Messrs. Le Vaillant, Vieillot, and Cuvier, and of sections by M. Temminck; but the immense number of species already known, and the great influx of new ones, renders it essential that many others should be formed. As we labour under a comparative ignorance of the natural economy of the vast number of tropical species recently described, any attempt to throw the *Columbidæ* into their natural arrangement must be very imperfect. The basis of such a work must rest on their natural habits, their food, and their geographic distribution. Yet, as we see in other natural families that a peculiarity of economy is almost invariably accompanied by some corresponding modification of structure, we shall receive considerable assistance by accurately examining such variations. We may note the forms without being acquainted with their reference to the peculiar habits of the group; and although our inference in some cases may be erroneous, in others we shall not be far from the truth. The passenger-pigeons, for instance, have their first quill-feather as long as any of the others—a sure indication of that rapid and long-continued power of flight they are known to possess. The Columbi-Gallines of M. Le Vaillant are described as having naked and somewhat lengthened tarsi; a structure well adapted to those ambulating habits which bring some of them close to the *Phasianidæ*, Vigors, and others to the *Cracidæ*, Vigors. Another group, the Colombars of M. Le Vaillant (*Vinago*, Cuv., *Tréron*, Vieill.), have a strong hard bill; and their short clasping tarsi covered with feathers lead us to conclude they seldom perch upon the ground; in fact, Messrs. Le Vaillant and Cuvier both assert that these birds are only found in the tropical forests of the Old World. Apparently confined to the same regions, we see another group, wherein the bill partakes of that weak structure observed in the generality of pigeons, while the tarsi are thickly clothed with feathers, similar to the group last mentioned. These seem to be the principal divisions among the *Columbidæ*." In 1827 the same author characterised the genera *Peristera*, *Chæmepelia*, and *Ectopistes*; and in the 'Fauna Boreali-Americana,' under *Columba Ectopistes migratoria*, he has the following note:—"As ornithologists do not appear to be aware of the great difference which exists in the groups of this family in the relative structure of their feet, we shall here draw their attention to the principal groups. In the even-tailed wood-pigeons of Europe, North America, and the Old World, forming the restricted genus *Columba*, the external and internal anterior toes are equal. In the lovely genus *Ptilinopus*, Swainson, confined to the green pigeons of the Indian and Australian isles, and in that of *Vinago*, Cuv., formed by the thick-billed species of the same countries, the inner toe is much shorter than the outer; but in the sub-genus (?) *Ectopistes*, Swainson, and the small turtle doves, this proportion is reversed, the inner toe being the longest. In the beautiful genus *Peristera*, Swainson, which comprises all the bronze-winged pigeons of Australia and the ground-pigeons of America, the tarsi are more elevated, the hind toe shorter, and the inner toe is likewise the longest. We have been for some time engaged in analysing this family, with the view of ascertaining the relative value of all these groups." Dr. Ritgen (1828) makes the genus *Columba*, Linn., form the third family (*Herpochoropteni*) of his first tribe (*Choropteni*), of his second series (*Xerornithes*, or birds of the dry land) in his trichotomous system, as applied to birds.

P. J. Selby, Esq., in the 'Naturalist's Library' (1835), characterises the following genera, *Carpophaga*, *Phaps*, and *Geophilus*. He thus speaks of the classification:—"Of the sub-families or five typical forms of the *Columbidæ*, we can only speak with diffidence and uncertainty, as no analysis of the species sufficiently strict or extensive has hitherto been instituted, from whence conclusive deductions can be drawn. We shall only cursorily observe, that the arboreal pigeons, embracing *Vinago*, Swainson's genus *Ptilinopus*, our genus *Carpophaga*, and some other undefined groups, with feet formed expressly for perching and grasping, and through which, from their habits and form, the necessary connection with the insessorial order is supported, are likely to constitute one; the true pigeons, of which our ring-pigeon and common pigeon may be considered typical, a second; the turtles and their allies, with feet of different proportions from the preceding, and graduated tails, a third; the ground-pigeons, or Columbi-Gallines of the French naturalists, a fourth; and the fifth is not unlikely to be represented by Vieillot's genus *Lophyrus*, in which the deviation from the proper Columbine form is not to that of the typical *Rasores*, but to the *Cracidæ*, placed at the farther extremity, and, like the *Columbidæ*, another aberrant family of the Rasorial order."

Before speaking of the classification of the *Columbidæ*, one part of the internal organisation of the pigeon is worthy of special notice. The crop, in the state which is adapted for ordinary digestion, is thin and membranous, and the internal surface is smooth; but by the time the young are about to be hatched, the whole, except that part which lies on the trachea, becomes thicker, and puts on a glandular appearance, having its internal surface very irregular. In this organ it is that the food is elaborated by the parents before it is conveyed to the young; for a milky fluid of a grayish colour is secreted and poured into the crop among the grain or seeds undergoing digestion, and a quality of food suited to the nestling is thus produced. The fluid coagulates with acids and forms curd, and the apparatus forms, among birds, the nearest approach to the mammæ of warm-blooded animals [BIRDS]; hence no doubt the term 'pigeon's-milk.' The number of vertebræ amounts to 13 cervical, 7 dorsal, 13 sacral, and 7 caudal = 40 (Cuvier). The sternum is narrow, with a deep keel, the inferior border convex, and the anterior one curved forwards, thin, and trenchant; the manubrial process is strong and bifurcated, the costal processes short. The posterior margin is cleft by two fissures on either side of the mesial plane, the lateral and superior fissures being the deepest; the mesial ones are occasionally converted into a foramen. The costal surface of the lateral margin is, as in the gallinaceous birds, of very little extent. In the crown-pigeon the superior fissures are so deep and wide as to convert the rest of the lateral margin into a mere flattened process, which is dilated at the extremity. (Owen.)

The distribution of this family is very extensive, the form occurring almost everywhere, except within the frigid zones. The species are most abundant in Southern Asia and the Great Indian Archipelago.

The following definition includes the *Columbidæ*, to which we shall refer in the present article:—Bill moderate, compressed, covered at the base of the upper mandible with a soft skin, in which the nostrils are pierced, and more or less curved at the point. Feet with three divided toes in front, and one behind.

Vinago (Cuvier).—Bill comparatively large, strong, thick, and solid, compressed at the sides; the tip very hard, hooked, and inflated; the nostrils comparatively exposed, and with the swollen or projecting membrane but little developed. Tarsi short, partly clothed with feathers below the tarsal joint; sole wide, the membrane being extended, and the whole foot formed for perching and grasping; the outer toe longer than the inner, claws strong, sharp, and semicircular, "closely resembling in form those of the woodpecker or other scansorial birds." (Selby.) Wings of mean length, strong and pointed, second and third quills about equal, and the longest in the wing. Mr. Selby says, that in all the species submitted to examination the third quill has the central part of the inner web deeply notched, as if a piece had been cut out; and that the prevailing colours are green and yellow of different intensities, contrasted more or less in certain parts with rich purple and reddish-brown.

The species inhabit Intertropical Asia and Africa. They feed on berries and fruits. They are shy and timid, and inhabit the woods. Mr. Selby gives the following, on the authority of Mr. Neill, who, speaking of *Vinago sphenura*, says: "I had two, but both, I believe, were males. Both had a song, very different from the mere cooing of the ringdove. When they sang in concert, they gave the same little tune, but on different keys. After the death of one the survivor used to sing at command, or, at all events, when incited to it by beginning its tune."

V. aromatica. It is the *Columba aromatica* of Latham. "The Aromatic Vinago is of a mild and timorous disposition, and is generally seen in flocks or societies, except during the period of reproduction, when they pair, and retire to the recesses of the forest. The nest is simple, and composed of a few twigs loosely put together, and the eggs are two. . . . . The base or softer part of the bill is a blackish-gray, the tip yellowish-white, strong, much hooked, and bulging on the side. The forehead is of a bright siskin-green, the crown greenish-gray, the chin and throat gamboge-yellow, the remainder of the neck, the breast, belly, lower back, and rump, yellowish-green. The upper back or mantle, and a part of the lesser wing-coverts, are of a rich brownish red, and exhibit a purplish-tinge in certain lights. The greater wing-coverts and secondary quills are greenish-black, with a deep and well-defined edging of gamboge-yellow throughout their length. The tail has the two middle feathers wholly green, and slightly exceeding the rest in length; these are of a dark bluish-gray, with a dark central band. The under tail-coverts are yellowish-white, barred with green. The legs and toes are red, the claws pale gray, strong, sharp, and semicircular." (Selby; and see Temminck.)

Aromatic Vinago (*Vinago aromatica*).

It inhabits the continent of India, Java, and other adjacent islands.

The habits of this species are arborial. Mr. Selby, gives the following note which accompanied the skins of *V. militaris*, and *V. aromatica*. "Green Pigeon.—This beautiful bird has brilliant red eyes. Its feet are something like the parrot's, and it climbs in the same way as that bird. It is very difficult to find; for although a flock is marked into a tree, yet its colour is so similar to the leaf of the banyan (on the small red fig of which it feeds), that if a bird does not move you may look for many minutes before you can see one, although there may be fifty in the tree."

Ptilinopus (Swainson).—Wings moderate, first quill contracted towards the apex, third and fourth longest. Bill slender. Tarsi feathered.

Mr. Swainson says that in proposing the characters of this genus, he wishes them to be considered more as indicating a group, by which the genus *Tréron*, Viell. (*Vinago*, Cuv.), may be united to the naked-legged pigeons, than as being so rigidly framed as to exclude all other species which do not strictly present the same structure.

Mr. Selby, in the 'Naturalist's Library,' feels inclined to still further subdivide the group, restricting the genuine title of *Ptilinopus* to that group of smaller pigeons in which the first quill-feather becomes suddenly narrowed or attenuated towards the tip, and the tarsi are feathered almost to the division of the toes.

The species inhabit the Moluccas, the Celebes, and the islands of the Pacific (Selby.) Their habits are retired; they live in forest solitudes. Food, fruits and berries.

The following is a description of the genus as restricted by Mr. Selby:—Bill comparatively slender, the base slightly depressed, and the soft covering of the nostrils not much arched or swollen; the tip though hard is little inflated, with a gentle curvature; the forehead is rather low and depressed; the legs are short but strong; the tarsi clothed with feathers nearly to the division of the toes; the feet are calculated for grasping, and are similar in form to those of *Vinago*, the sides of the toes being enlarged by the extension of the lateral membrane, and the outer longer than the inner one; the wings are strong, and of moderate length, the first quill-feather considerably shorter than the second, and suddenly narrowed towards the tip—a peculiarity also possessed by several pigeons belonging to other distinct groups, and by which means the connexion is thus kept up between them. The third and fourth quills are nearly equal to each other, and are the longest in the wing. The tail is of proportionate length, and generally square at the end. Predominating colour like that of *Vinago*, green, varied in parts with yellow and orange, and in some, beautifully encircled with masses of purplish-red and vivid blue.

P. cyano-virens. It is the *Columba cyano-virens* of Lesson, who described it in the 'Voyage de la Coquille.' The bird is termed Manasope in the Papuan tongue, and inhabits, says Lesson, the profound and still virgin forests (encore vierges) of New Guinea. "It was in the neighbourhood of the harbour of Doréry that we procured the greatest number of individuals. Their low cooing was heard frequently from the large trees, and every thing indicated that they were common."

Ptilinopus cyano-virens.

Description.—Total length from the end of the bill to the extremity of the tail, 8 inches 6 lines (French); bill delicate and black; iris of a red-brown; tarsi short, and nearly entirely feathered; toes with a membranous border, and of a lively orange colour; head, rump, upper part of the body, wings, and tail, of an agreeable grass-green; a large patch (calotte) of a beautiful indigo-blue covers the occiput; elongated blue spots occupy the centre of the subalar feathers, which are bordered with a straight yellow line; the internal and hidden part of the same feathers is brown; the quills are entirely brown, and bordered at the external edge with a line of canary yellow; the tail is square and rectilinear; the feathers which compose it are fourteen in number, brown, their extremities white below, and of a green similar to that of the back above, passing into black in the middle, and each terminating within with a white spot; the two exterior ones are brown, bordered with yellow externally, as are the two or three next; the shaft is brown; the throat to half-way down the neck is ash-gray; the breast is grayish-green; the belly and the flanks are at first green mingled with some yellow borderings, and then comes a large patch of yellowish-white extending on each side so as to form a kind of girdle; the feathers of the thighs are green; those of the vent, white and pale yellow; the lower tail-coverts are yellow mingled with green. M. Lesson mentions another individual rather smaller, with some differences of plumage, which he supposes to have been either a female or a young one. Mr. Selby remarks upon the fact that no notice is taken of the form of the first quill-feather in this description, and regrets it, but entertains little or no doubt of its presence in nearly a similar form to that assumed by the rest of this group, of which *P. purpuratus* is the type.

Carpophaga (Selby).—"In this group," says Mr. Selby, "which is composed of birds of a much larger size than the preceding, the wings, though possessing the same relative proportions, have no emargination, or sudden narrowing of the tip of the first quill. Their tarsi also are not so thickly or entirely feathered; and their nostrils are placed nearer to the base of the bill. In some species, green, yellow, and purple are the prevailing colours; in others, a rich bronzed or metallic colour composes the upper plumage, exhibiting shades of deep green and purple, according to the light in which it is viewed, while in those which lead the way to the typical pigeons, the tints become less vivid and more uniform in their distribution. Their bill is considerably depressed at the base, the membrane in which the nostrils are placed but little prominent or swollen, the tip compressed and moderately arched, the tomia slightly sinuated. The forehead is low, and the feathers advance considerably upon the soft portion of the bill. In many of them a caruncle, or gristly knob, varying in size and shape according to the species, grows upon the basal part of the upper mandible during the season of propagation. This is supposed to be common to both sexes, as the female is described with it in Duperrey's 'Voyage.' After this epoch it is rapidly absorbed, and its situation scarcely to be observed upon the surface of the bill. The feet are powerful, and formed for grasping, the soles being flat and greatly extended. As in the other members of this group, the hind toe is fully developed and long, and the exterior longer than the inner toe. They inhabit the forests of India, the Moluccas, Celebes, Australia, and the Pacific Isles. Their food consists of fruits and berries. That of the precious nutmeg, or rather its soft covering, known to us by the name of mace, at certain seasons affords a favourable repast to some species, and upon this luxurious diet they become so loaded with fat as frequently, when shot, to burst asunder when they fall to the ground. And here we may remark on the remarkable provision nature has made for the propagation as well as the dissemination of this valuable spice; for the nutmeg itself, which is generally swallowed with the whole of its pulpy covering, passes uninjured through the digestive organs of the bird, and is thus dispersed throughout the group of the Moluccas and other islands of the east. Indeed, from repeated experiments, it appears that an artificial preparation analogous to that which it undergoes in its passage through the bird, is necessary to ensure the growth and fertility of the nut; and it was not till after many unsuccessful attempts had been made that a lixivium of lime, in which the nuts were steeped for a certain time, was found to have the wished-for effect, and to induce the germinating tendency. The fruit of the Banyan (*Ficus religiosa*), the sacred tree of the Hindoos, is also a favourite repast of all the pigeons of this group, as well as of the stronger-billed *Vinago*."

C. oceanica. It is the *Columba oceanica* of Lesson. This species, according to Lesson, is the Moulouesse, or Mouleux, of the natives of Oualan, and though it approaches the Nutmeg Pigeon, *Columba* (*Carpophaga*) *ænea*, very nearly, it differs from it in size, being one-third less, and in the distribution of some of its colours. "The Nutmeg Pigeon lives more particularly in the eastern Moluccas, and especially at New Guinea and Waigiou, while the Oceanic Fruit-Pigeon is abundant in the little isle of Oualan, in the midst of the great archipelago of the Carolines, and seems to exist in the Pelew Islands, where Wilson mentions it under the name of cyep." Lesson further observes, that it may be possibly spread over the Philippines, and at Magindanao.

Oceanic Fruit-Pigeon (*Carpophaga oceanica*).

Description.—Total length, 14 inches (French), including the tail, which measures five; the bill, an inch long, is black, strong, and surmounted at its base by a rounded and very black caruncle; the feet are very strong and of a bright orange colour; the tarsi are feathered nearly down to the toes, which have a well-developed border; the wings are pointed, and only one inch shorter than the tail, which is almost rectilinear. The feathers of the forehead, cheeks and throat, are whitish mixed with gray; the head and the back of the neck are of a deep slaty gray; the back, rump, wing-coverts, quills, and tail-feathers, are of a uniform metallic green, passing into brown on the interior of the great feathers; the breast and upper part of the belly are gray, with a tint of rust-colour; the lower part of the belly, the vent, the thighs, and the lower tail-coverts, are a deep ferruginous red; the tail-feathers on the under side are a bright reddish-green (vert rougeâtre clair). (Lesson.)

M. Lesson thinks that this, very probably, is the species mentioned by "the celebrated naturalist, Forster (and not Captain Forster, as the reading is, twice, in M. Temminck's work, tom. i. p. 89, 8vo), who observed in the Isle of Tanna, one of the New Hebrides (Cook's 'Second Voyage,' vol. iii. p. 179, 4to), a Nutmeg Pigeon of the same species as that which occurred at the Friendly Islands."

The caruncle shown in the cut is dissipated after the breeding season, leaving nothing but a slight cutaneous wrinkle. M. Lesson says that the bird feeds on a berry which is very abundant in the small Isle of Oualan, and that it is not disturbed by the natives.

Mr. Selby gives as a form apparently belonging to this division of the *Columbidæ*, the following species: *Columba Phasianella* (Temm.), the structure of the bill being, as he observes, intermediate between that of *Vinago* and *Columba*, and the feet formed upon the same plan as those of the rest of the *Ptilinopinæ*.

Description.—Length from 14 to 16 inches, the tail being seven, and rather more. Wings short, reaching, when closed, about an inch and a half beyond the root of the tail, rounded, and with the third quill longest; the first and fourth being equal to each other. Bill, measuring from the forehead, nearly three quarters of an inch long; the tip of the upper mandible moderately arched, and with a notch; that of the lower angulated and strong; throat, yellowish-white; head, sides, and front of the neck, and whole of the under plumage orange-brown; hinder part of the neck changeable rich violet-purple, with brilliant gold reflections; back, wing-coverts, and the rest of the upper plumage, deep reddish-brown, shot with bronze in some lights; tail graduated or cuneiform, the two middle feathers brown, the lateral marked obliquely with a black bar; feet and naked part of legs reddish-brown; sole of the hind and inner toes much expanded.

Young differing from the adult in having the neck dirty reddish-brown, with narrow bars of black; belly of a pale reddish-gray, minutely and darkly speckled; back inclining to hair-brown; and smaller wing-coverts deeply edged with orange-brown.

M. Temminck first described the species in the 'Linnæan Transactions,' from an Australian specimen. It has since been observed in most of the Philippine and Molucca Islands, Java, &c.

Columba Phasianella is an inhabitant of the woods. Its food is said to consist of a kind of pimento and of other aromatic berries, swallowed entire. The flesh is dark, but its flavour is stated to be excellent.

Columba Phasianella.

Mr. Selby makes the group to contain *Columba Macroura*, Auct.; *C. nuchalis*, Wagler; and *C. Reinwardtii*, Temm. "Of its precise situation," says Mr. Selby, "in the circle of the *Columbidæ*, we speak with some degree of doubt, not having had an opportunity of instituting so strict an analysis of the species as the subject requires; but we believe it will be found to enter among the *Ptilinopinæ*, or arboreal pigeons, as the feet and tarsi of its members are similar in form to those of that division, the latter being very short and partly plumed below the joint, the former with the exterior toe longer than the inner, and the hinder toe fully developed; the sole of the foot, by the extension of the membrane, is broad and expansive, and the claws are arched and strong, all of which are characters evidently showing these members to be expressly adapted for perching and prehension, and not for gressorial movements. The bill also in one species (*C. Reinwardtii*) approaches in point of strength nearly to that of *Vinago*, and in all of them the tip of both mandibles is hard and firm, the upper one with a visible emargination and moderately arched. Their habits and mode of life are also nearly allied to the other arboreal species, being the constant inhabitants of the woods, and subsisting upon the fruits and berries of various trees and shrubs. M. Temminck, in his description of this species, says that it possesses a structure and form precisely similar to that of the *C. migratoria* of North America. To this we cannot subscribe, seeing that its essential characters, as above described, are different, and that the only point of resemblance consists in the length of the tail. Indeed, so far removed do we think it from the American group, that we cannot consider it as its analogue in the Asiatic regions where it resides."

Columba, Auct.—Most ornithologists are agreed that the sub-family *Columbinæ* contains the type of the form of the *Columbidæ*, and that we are to look among the species of our own country for that type. The Ring-Pigeon, Cushat or Queest (*C. Palumbus*), the Wood-Pigeon (*C. Œnas*), and the Rock-Pigeon or Biset (*C. livia*), are considered to be the forms in which the peculiarity of structure and habits of the family are most perfectly developed, and of these *C. Palumbus* is generally taken as the typical point of comparison. The *Columbinæ* are distinguished by a bill of moderate strength, with a hard tip, bulging and somewhat arched. The nostrils are partly clothed by a soft membrane, and the orbits of the eyes are more or less denuded of feathers. The feet may be called both gressorial and insessorial; for they are so organised, that the action of walking or perching may be performed at pleasure, for the back toe is moderately long, and the claws are so formed and placed as not to interfere with terrestrial progression, while they are at the same time calculated for arboreal prehension. In the types the exterior and interior toes are of equal length. The wings are fully developed and somewhat pointed; the second and third quills are the longest. The tail is generally square, and moderately long.

"In those species," says Mr. Selby, in the work above quoted, "which are the media of connection with other groups, the above characters become partially modified, as we see exemplified in the species nearest allied to the *Ptilinopinæ*, or arboreal pigeons, their feet losing the true character of that of the common pigeon, and assuming more of the grasping form than that fitted for progress upon the ground."

The species are very numerous, and spread over every quarter of the globe.

"The prevailing colour of the pigeons is bluish-gray, of various intensities and shades, frequently embellished upon the neck with feathers having a metallic lustre and peculiar form, and which exhibit various tints of colour according to the light in which they are viewed. They are naturally birds of a wild and timid disposition (though one species has been partly reclaimed), and usually live congregated in extensive flocks, except during the season of reproduction, when they pair. Most of the species seek their food upon the ground. This consists of the different *Cerealia*, as also acorns, beech-mast, and other seeds, and occasionally of the green and tender leaves of particular plants. Their flesh is sapid and nutritious, being of a warm and invigorating nature. Their flight is powerful, very rapid, and can be long sustained, and many species are in the habit of making distant periodical migrations. They are widely disseminated, species of the genus being found in every quarter of the globe, and in all climates, except the frozen regions of the two hemispheres. They build in trees or holes of rocks, making a shallow nest of small twigs loosely put together. Their eggs are never more than two in number, their colour a pure white; they are incubated alternately by both sexes, and are hatched after being sat upon from eighteen to twenty-one days. The young, upon exclusion, are thinly covered with down, which is rapidly succeeded by the proper feathers." (Selby.) The apparatus for preparing the food for the nestlings has been before adverted to.

C. spadicea. Mr. Selby places this species as connecting the arboreal species with the typical pigeons, but arranges it under the *Columbinæ*, not without doubt, "for although it presents characters in some of its members approaching those of the pigeons, it cannot be denied that, in its general appearance, and the metallic lustre of its plumage, it also shows evident marks of a near affinity to several species of the genus *Carpophaga*, and it might perhaps with equal propriety be placed at the extremity of that group;" and regrets the little information extant of its peculiar habits and mode of life, which would have assisted in forming a more satisfactory conclusion as to its proper position. He adds, that from the form and size of the feet we may judge that its habits are more those of an arboreal than terrestrial bird, though its claws want the great curvature of those of the *Ptilinopinæ*, and show its capability of occasionally resorting to the ground for food. M. Lesson, who killed many individuals of this brilliant pigeon, described by Latham and figured by Temminck, says that its flesh is excellent, and that it is very abundant in the woods about the Bay of Ipiripi, or the Bay of Islands. The first which he procured was killed and sent to the expedition by one of the officers of the Coquille; and Toui, chief of the hippah of Kaouera, near which she was moored, brought them frequently on board. He adds, that the individual described by Latham as the Chestnut-Shouldered Pigeon came from Norfolk Island, not far from New Zealand, and that M. Temminck indicates the Friendly or Tonga Islands as its native country. This locality M. Lesson, from whom the following description is taken, seems to doubt.

Total length, 16¼ inches (French)—English authors give it as from 19 to 20 inches; tail 6 inches, nearly rectilineal, and slightly notched; bill rather swollen near the point of the lower mandible, of a brilliant carmine at its base as well as the feet, the tarsi of which are feathered almost to the toes. The eyes are surrounded with a bright-red membrane, and the iris is of the same colour. All the upper parts of the bird, the back, the rump, the wings, and the throat, are of a changeable hue, in which are mingled rosy copper-reflections running into brilliant and iridescent tints, but becoming more sombre upon the great quills. The plumage of the breast, belly, vent, and tarsi are pure white. The upper part of the tail is brown, slightly tinged with greenish; and below it is brown, which is deepest within and at the extremity.

Columba spadicea.

C. dilopha. "In this curious species," says Mr. Selby, "besides the occipital crest, an ornament which is found in many other birds, there is an additional one in front, composed of long recurved and lax feathers, which not only occupy the forehead, but also the superior part of the soft or basal portion of the bill. This double crest gives the head of the pigeon a character unlike any of its congeners, and more resembling that of some of the crested *Phasianidæ* or *Cracidæ*, with which an analogical relation is thus sustained. In other respects

Columba dilopha.

its characters agree with those of *C. spadicea*, the proportion of the wings and the form of the feet being nearly the same. Temminck, who first described it, observes, "Cette nouvelle espèce a le plus de rapports dans toutes ses formes avec la *Columba spadicea*, et toutes les deux sont très peu différentes de notre Ramier d'Europe."

The size of this bird is nearly that of *C. spadicea.* Wings long and powerful, reaching when closed beyond the middle of the tail, second, third, and fourth feathers longest and nearly equal, fifth shorter than the first. Bill rich orange, tip of under mandible obliquely truncated, tip of upper mandible compressed, somewhat arched, culmen rounded. Frontal crest beginning on the upper part of the bill immediately behind the horny tip and above the nostrils, composed of long curved feathers, soft and loose in texture, and bluish-gray tinged with rufous in colour, pointing backwards. Occipital crest rich rufous, bounded on each side from the posterior angle of the eye by a streak of glossy black, decumbent, composed also of long soft feathers with open barbules, each feather widening towards the tip. Side and front of neck and breast pale gray, black at the base of the feathers, which is hid. The feathers here are trifid at the end: on the back of the neck they are acuminated, but not distinctly divided as upon the breast. Back, scapulars, and wing-coverts deep bluish-gray, the feathers darker at the margin; quills and secondaries bluish-black; under plumage gray. Tail square, basal part and narrow band pale gray tinged with reddish, tip and broad intermediate bar black; length 7 inches. Naked parts of tarsi and toes crimson-red; hind toe strong, with a broad flat sole, and exceeding the tarsus in length; nails long and somewhat curved. It is found in Australia and Java.

C. Palumbus, the Cushat. It is the Ramier of the French; Torquato, Ghiandaria, &c., of the Italians, according to Belon; Colombaccio, Palombo, Piccione da Ghianda of the same, according to Prince Bonaparte; Ringdufwa of the 'Fauna Suecica;' Wild-Taube and Ringel-Taube of the Germans; Ring-Dove, Queest, and Cushat of the British; Ysguthan of the Welsh, and in Belon's opinion the Φάττα of the Greeks.

The Cushat most probably sat for the pretty picture of Virgil's 'aëriae palumbes.' It is considered the type of the *Columbinæ*. Instances have been known of its laying in aviaries, and Mr. Selby states that a pair of ring-pigeons in one of the aviaries of the Zoological Gardens "built their nest in a tree or shrub contained within it, and that the female laid two eggs, which unfortunately were destroyed by some accident during incubation. This fact shows that under favourable circumstances, and when the habits of the bird are attended to, a progeny may be obtained."

C. Œnas. It is the Palombella, Palombella di Macchia, Piccione Topacchio of the Italians; Le Pigeon Sauvage of Brisson; Stock-Dove and Wood-Pigeon of the British. Mr. Selby observes, "Near as it approaches the common pigeon in size and form, no mixed breed that we are aware of has ever been obtained between them, although repeated attempts to effect an intercourse have been made. This in our mind appears a strong and convincing proof that all the varieties generally known by the name of Fancy Pigeons have originated from one and the same stock, and not from crosses with other species, as some have supposed, the produce of which, even could it be occasionally obtained, we have no doubt would prove to be barren, or what are generally termed mules."

C. livia. This—the Pigeon Privé of Bélon; Le Pigeon Domestique, Le Biset, and Le Rocheraye, of Brisson; Coulon, Colombe, Pigeon, of the French; Palombella, Piccione di Torre, Piccione di Rocca, of the Italians; Feld-Taube, Haus-Taube, Hohl-Taube, Blau-Taube, and Holtz-Taube, of the Germans; Wild Rock-Pigeon of the British; Colommen of the Welsh—is the stock from which ornithologists generally now agree that the domestic pigeon and its varieties are derived. "Under this species," writes Mr. Selby, "we include not only the common pigeon, or inhabitant of the dove-cot, but all those numerous varieties, or, as they are frequently termed, races of domesticated pigeons, so highly prized, and fostered with such care and attention by the amateur breeder or pigeon fancier; for, however diversified their forms, colour, or peculiarity of habit may be, we consider them all as having originated from a few accidental varieties of the common pigeon, and not from any cross of that bird with other species, no signs or marks whatever of such being apparent in any of the numerous varieties known to us. In fact, the greater part of them owe their existence to the interference and the art of man; for by separating from the parent stock such accidental varieties as have occasionally occurred, by subjecting these to captivity and domestication, and by assorting them and pairing them together as fancy or caprice suggested, he has at intervals generated all the various races and peculiar varieties which it is well known when once produced may be perpetuated for an indefinite period, by being kept separate from and unmixed with others, or what by those interested in such pursuits is usually termed 'breeding in and in.' Such also, we may add, is the opinion of the most eminent naturalists as to their origin, and it is strongly insisted on by M. Temminck in his valuable work the 'Histoire Générale Naturelle des Pigeons.' Indeed the fact that all the varieties, however much they may differ in colour, size, or other particulars, if permitted, breed freely and indiscriminately with each other, and produce a progeny equally prolific, is another and a convincing proof of their common and self-same origin; for it is one of those universal laws of nature, extending even to plants, and one which if once set aside or not enforced would plunge all animated matter into indescribable confusion, that the offspring produced by the intercourse of different species, that is, distinct species, is incapable of further increase. That such an intercourse may be effected is well known to all; but it is generally under peculiar or artificial circumstances, and rarely when the animals, birds, or whatever they may be, are in their natural state, and in a condition to make their own election. It is seen in the crosses obtained in a state of confinement between the canary and goldfinch, linnet, &c.; in the hybrids between different species of *Anatidæ*, when domesticated or kept in captivity; in the cross between the pheasant and common fowl, &c. . . .

"The bastard produce of the common wild turtle (*Turtur communis*) with the turtle of the aviary (*Turtur risorius*) has been proved by frequent experiments to be barren, although the two species from whence it originates appear to be closely allied, and a mixed breed is easily procured; and such, we have no hesitation in saying, would be the event if a cross could be obtained between the common pigeon and the ring pigeon, the wood pigeon, or any other species." These observations are well worthy of attention. The assertion respecting the bastard produce of the turtles, made above, is corroborated by Messrs. Boitard and Corbié in their 'Histoire des Pigeons de Volière,' and the principle is further confirmed by the experiments of Mauduyt, Vieillot, and Corbié.

The varieties of this bird produced under the fostering hand of man, the tumblers, croppers, jacobines, runts, spots, turbits, owls, nuns, &c. &c., would fill a volume. Our limits will not permit us to figure or describe them. The Carrier however demands notice. In one of his odes (Εἰς Περιστερὰν) Anacreon has immortalised it as the bearer of epistles. Taurostheues sent to his expectant father, who resided in Ægina, the glad tidings of his success in the Olympic games on the very day of his victory. Pliny ('Nat. Hist.,' book x. 37) speaks of the communication kept up between Hirtius and Decimus Brutus at the siege of Mutina (Modena): "What availed Antony the trench and the watch of the besiegers; what availed the nets (retia) stretched across the river, while the messenger was cleaving the air (per cœlum eunte nuntio)." The Crusaders employed them, and Joinville records an instance during the crusade of Saint Louis. Tasso 'Gierusalemme Liberata,' cant. xviii. sings of one that was attacked by a falcon and defended by Godfrey,

> "Che dal colle ad un filo avinta pende
> Riachiusa carta, e sotto un' ala ascosa."

which 'carta' Godfrey of course reads, and is put in possession of all the secrets. In the same way Ariosto (cant. xv.) makes the 'Castellan di Damiata' spread the news of Orrilo's death all over Egypt. Sir John Maundeville, knight, warrior, and pilgrim, who penetrated to the border of China in the reigns of our Second and Third Edward, thus writes: "In that contree and other contrees bezonde thei han a custom, whan thei schulle usen werre, and whan men holden sege abouten cytee or castelle, and thei withinnen dur not senden out messagers with lettere fro lord to lord, for to aske sokour, thei maken here letters and bynden them to the nekke of a *Colver*, and letten the Colver flee; and the Colveres ben so taughte that thei fleen with the letters to the very place that men wolde sende hem to. For the Colveres ben norysscht in tho places where thei ben sent to; and thei senden hem thus for to beren here letters. And the Colveres retournen azen where as thei ben norisscht, and so they don comonnly."

The Carrier however gradually sank, in this country at least, to the bearer of the intelligence of the felon's death at Tyburn—Hogarth's print will occur to every body: it became the messenger from the race-course and prize-ring, and was also largely used in stock-jobbing transactions. The invention and application however of the electric telegraph has to a considerable extent superseded the use of the Carrier-Pigeon.

Some idea of the astonishing fecundity of the domesticated pigeon may be derived from the assertion of Biberg, who observes that if you suppose two pigeons to hatch nine times a year they may produce in four years 14,760 young.

In its wild state the Rock Pigeon is widely distributed; the rocky islands of Africa and Asia, and in the Mediterranean, abound with them. Virgil's beautiful simile in the Fifth Æneid evidently relates to this species:—

> 'Cui domus et dulces latebroso in pumice nidi.'

In the Orkneys and Hebrides it is said to swarm. "It is also met with upon the northern and western coasts of Sutherland, the perforated and cavernous rocks which gird the eastern side of Loch Eriboll, and those of the limestone district of Durness, furnishing suitable places of retreat; and again upon the eastern coasts of Scotland it is seen about the rocky steeps of the Isle of Bass and the bold promontory of St. Abb's Head." (Selby.)

C. livia in its wild state has the following characters:—Bill blackish-brown; the nostril membrane red, sprinkled as it were with a white powder. The irides pale reddish-orange. Head and throat bluish-gray. Sides of the neck and upper part of the breast dark lavender-purple, glossed with shades of green and purplish-red. Lower part of breast and abdomen bluish-gray. Upper mandible and wing-coverts blue-gray. Greater coverts and secondaries barred with black, so that there are two broad and distinct bars across the closed wings. Lower part of the back white; rump and tail-coverts bluish-gray. Tail deep gray, with a broad black bar at the end. Legs and feet pale purplish-red. Wings when closed reaching within half an inch of the end of the tail. (Selby.)

Wild Rock-Pigeon (*Columba livia*).

Turtur (*Ectopistinæ*, Selby).—Bill more slender than that of the pigeons. Tip of the upper mandible gently deflected, that of the lower scarcely exhibiting the appearance of an angle. Tarsi rather shorter than the middle toe. Feet formed for walking or perching; inner toe longer than the outer. Front of tarsi covered with broad imbricated scales. Wings—first quill a little shorter than the second, third longest of all. Tail rounded or slightly graduated. (Selby.)

T. risorius. It is the *Columba risoria* of authors; *T. torquatus Senegalensis*, Brisson; Tourterelle à Collier, Buffon; probably the Turtle of the Scriptures, and still plentiful in Egypt and other eastern countries, where it is often kept in confinement. The relics of Greek and Roman art give a very fair representation of this species; but Bélon and others seem to be of opinion that the *T. communis*, Common Turtle Dove, was the Τρύγων of the Greeks.

Turtur risorius.

The following is a description of a wild specimen from Southern Africa:—Length about 10 inches. Chin whitish; from the corners of the mouth to the eyes a narrow streak of black. Forehead pale bluish-gray; crown darker; cheeks, neck, breast, and belly, gray, tinged with vinaceous or pale purplish-red; the hind neck with a demi-collar of black; some of the side feathers of the collar tipped with white. Back, scapulars, and rump, pale clove-brown, with a greenish tinge. Margins of wings, greater coverts, and under wing-coverts, blue-gray. Greater quills hair-brown, delicately edged with grayish-white. Vent and under tail-coverts white. Legs and feet gray; inner toe a little longer than the outer. (Selby.)

In its natural state this species haunts the woods, where it breeds, making a nest like that of the common turtle, and lays two white eggs. It seeks its food in the open grounds, and subsists upon grain, grass-seeds, and pulse, &c. Its trivial name is derived from a fanciful resemblance to the human laugh in its cooings. (Selby.)

A race between the common turtle and this species has been obtained; but the mules are stated to have been invariably barren.

T. communis (Linnæus), the Turtle Dove (*Columba turtur* of authors), is found in Great Britain. It occurs only as a summer visiter coming from Africa.

Mr. Selby provisionally places the *C. lophotes* of Temminck under this genus.

Ectopistes (Swainson).—Bill slender, notched. Wings rather elongated, pointed; the first and third quill equal; the second longest. Tail rounded, or curvated. Feet short, naked; anterior scales of the tarsi imbricate; lateral scales very small, reticulate.

E. migratoria. It is the *C. migratoria* of authors, the Passenger Pigeon of Wilson, Audubon, and others. Our limits not allowing us to give a detailed history of any length of the habits of more than one species, we have selected Wilson's graphic account of this elegant bird as the most striking:—

Passenger Pigeon (*Ectopistes migratoria*).

"The roosting-places are always in the woods, and sometimes occupy a large extent of forest. When they have frequented one of those places for some time, the appearance it exhibits is surprising. The ground is covered to the depth of several inches with their dung; all the tender grass and underwood destroyed; the surface strewed with large limbs of trees, broken down by the weight of the birds collecting one above another; and the trees themselves, for thousands of acres, killed as completely as if girdled with an axe. The marks of their desolation remain for many years on the spot; and numerous places could be pointed out where, for several years after, scarcely a single vegetable made its appearance. When these roosts are first discovered, the inhabitants, from considerable distances, visit them in the night with guns, clubs, long poles, pots of sulphur, and various other engines of destruction. In a few hours they fill many sacks and load horses with them. By the Indians a pigeon-roost or breeding-place is considered an important source of national profit and dependence for that season, and all their active ingenuity is exercised on the occasion. The breeding-place differs from the former in its greater extent. In the western countries, namely, the states of Ohio, Kentucky, and Indiana, these are generally in back woods, and often extend in nearly a straight line across the country for a great way. Not far from Shelbyville, in the state of Kentucky, about five years ago, there was one of these breeding-places, which stretched through the woods in nearly a north and south direction, was several miles in breadth, and was said to be upwards of forty miles in extent. In this tract almost every tree was furnished with nests wherever the branches could accommodate them. The pigeons made their first appearance there about the 10th of April, and left it altogether with their young before the 25th of May. As soon as the young were fully grown, and before they left the nests, numerous parties of the inhabitants from all parts of the adjacent country came with waggons, axes, beds, cooking-utensils, many of them accompanied by the greater part of their families, and encamped for several days at this immense nursery. Several of them informed me that the noise was so great as to terrify their horses, and that it was difficult for one person to hear another speak without bawling in his ear. The ground was strewed with broken limbs of trees, eggs, and young squab pigeons, which had been precipitated from above, and on which herds of hogs were fattening. Hawks, buzzards, and eagles were sailing about in great numbers, and seizing the squabs from the nests at pleasure, while, from twenty feet upwards to the top of the trees, the view through the woods presented a perpetual tumult of crowding and fluttering multitudes of pigeons, their wings roaring like thunder, mingled with the frequent crash of falling timber; for now the axemen were at work, cutting down those trees that seemed to be most crowded with nests, and contrived to fell them in such a manner, that in their descent they might bring down several others; by which means the falling of one large tree sometimes produced 200 squabs, little inferior in size to the old ones, and almost one heap of fat. On some single trees upwards of 100 nests were found, each containing one squab only; a circumstance in the history of this bird not generally known to naturalists. It was dangerous to walk under these flying and fluttering millions, from the frequent fall of large branches, broken down by the weight of the multitudes above, and which in their descent often destroyed numbers of the birds themselves; while the clothes of those engaged in traversing the woods were completely covered with the excrements of the pigeons.

"These circumstances were related to me by many of the most respectable part of the community in that quarter, and were confirmed in part by what I myself witnessed. I passed for several miles through this same breeding-place, where every tree was spotted with nests, the remains of those above described. In many instances I counted upwards of ninety nests on a single tree; but the pigeons had abandoned this place for another, sixty or eighty miles off, towards Green River, where they were said at that time to be equally numerous. From the great numbers that were constantly passing over our heads to or from that quarter, I had no doubt of the truth of this statement. The mast had been chiefly consumed in Kentucky; and the pigeons, every morning a little before sunrise, set out for the Indiana territory, the nearest part of which was about sixty miles distant. Many of these returned before ten o'clock, and the great body generally appeared on their return a little after noon. I had left the public road to visit the remains of the breeding-place near Shelbyville, and was traversing the woods with my gun, on my way to Frankfort, when about ten o'clock the pigeons which I had observed flying the greater part of the morning northerly, began to return in such immense numbers as I never before had witnessed. Coming to an opening by the side of a creek called the Benson, where I had a more uninterrupted view, I was astonished at their appearance: they were flying with great steadiness and rapidity, at a height beyond gunshot, in several strata deep, and so close together that, could shot have reached them, one discharge could not have failed of bringing down several individuals. From right to left, as far as the eye could reach, the breadth of this vast procession extended, seeming everywhere equally crowded. Curious to determine how long this appearance would continue, I took out my watch to note the time, and sat down to observe them. It was then half-past one; I sat for more than an hour, but instead of a diminution of this prodigious procession, it seemed rather to increase, both in numbers and rapidity; and anxious to reach Frankfort before night I rose and went on. About four o'clock in the afternoon I crossed Kentucky River, at the town of Frankfort, at which time the living torrent above my head seemed as numerous and as extensive as ever. Long after this I observed them in large bodies that continued to pass for six or eight minutes, and these again were followed by other detached bodies, all moving in the same south-east direction, till after six o'clock in the evening. The great breadth of front which this mighty multitude preserved would seem to intimate a corresponding breadth of their breeding-place, which, by several gentlemen who had lately passed through part of it, was stated to me at several miles."

Wilson then enters into a rough calculation of the numbers of this mass, and he comes to the conclusion that its whole length was 240 miles, and that the numbers composing it amounted to 2,230,272,000 pigeons, observing that this is probably far below the actual amount. He adds, that allowing each pigeon to consume half a pint of food daily, the whole quantity would equal 17,424,000 bushels daily. Mr. Audubon confirms Wilson in every point, excepting that he very properly corrects that part of the narrative which would lead to the conclusion that a single young one only is hatched each time. The latter observes that the bird lays two eggs of a pure white, and that each brood generally consists of a male and female.

Description.—Wings long and acuminate, having the second quill-feather exceeding the others in length. The tail is greatly cuneiform or graduated, and consists of twelve tapering feathers. Bill black, and like that of the turtle. Legs purplish-red, short, and strong. Iris bright orange-red, the naked orbit purplish-red. Head and cheeks pale bluish-gray. Fore-neck, breast, and sides brownish-red, with a purplish tinge. Abdomen and vent white. Lower part and sides of neck purplish-crimson, reflecting tints of emerald green and gold. Upper plumage deep bluish-gray, some of the scapulars and wing-coverts spotted with black. Greater coverts gray, tipped with white. Quills blackish-gray, their exterior webs bluish-gray. Tail with the two middle feathers black, the other five on each side gray at the base, with a black bar on the interior arch, and passing into white towards the extremities.

The female is rather smaller, and has the colours of her plumage much duller than those of the male, though the distribution is the same. (Selby.)

The Passenger Pigeon inhabits the North American continent, between the 20th and 62nd degrees of north latitude. Mr. Eyton has figured one as a visitant to our shores, on the authority of Dr. Fleming, who, in his 'History of British Animals,' says that one was shot in the parish of Mouymeal, Fifeshire, on the 31st December, 1825. Mr.

Yarrell also records the capture of another specimen at Royston, in Cambridgeshire.

Mr. Selby refers provisionally *Columba Capensis*, Auct., *C. Macquarrii*, Lesson, and *C. venusta*, Temm., to his group of *Ectopistinæ*, and thinks that by these and some other nearly allied forms a passage to the next group, *Peristerinæ*, the Ground-Doves, is effected.

Family *Peristerinæ* (Selby).—Distinguished from the preceding groups by their terrene habits, and their evident approach in many points to the more typical *Rasores*, or Gallinaceous Birds. In these the bill is rather slender, frequently sub-emarginate, and the tip of the upper mandible gently deflected; the wings are generally short and rounded, and in many instances concave, as in the partridge, grouse, &c. The legs are considerably longer than in the typical pigeons, the tarsus usually exceeding the middle toe in length, and the feet better adapted for walking than grasping; the claws are obtuse and slightly arched. The hallux is shorter, and its relative position different from that of the arboreal species. Their plumage is plainer and more uniform in tint than that of some of the preceding groups, though it is still brilliant in those species which connect them with other forms. They live almost entirely upon the ground, and many of the species run with great celerity, on which account they have been called Partridge Pigeons. Their flight, which is usually low, is effected with greater exertion than that of the pigeons, and is never long sustained. (Selby.)

Mr. Selby observes that this division contains a great number of species, and is of opinion that when better investigated it will be found divisible into a variety of minor groups or genera. He places under it *Phaps*, *Chamæpelia*, and *Peristera*. This group is distinguished by a longer bill, very faintly emarginate, and by its tarsi, which are moderately long and naked, with the frontal scales divided into two series, and the sides and hinder part reticulated with minute scales. Another group, he adds, seems indicated by certain Asiatic species, conspicuous for the rich metallic green of the plumage of their backs, resembling therein some of the *Ptilinopinæ*. The tarsi of these are destitute of scales, except a few indistinct ones in front, just above the toes. The bill is rather long, and destitute of a notch. They live mostly on the ground, but their flight is powerful. Mr. Selby takes *Columba superciliosa* of Wagler as the type of this last-mentioned group.

Phaps (Selby).—Bill moderately long, rather slender; upper mandible gently deflected at the tip, and with the indication of a notch or emargination. Wings of mean length; second and third feathers longest, and nearly equal. Tail slightly rounded. Legs—tarsi as long as the middle toe, the front covered with a double row of scales, sides and back reticulated with small hexagonal scales. Hind toe short; inner toe exceeding the outer in length. Claws blunt, slightly arched. Type, *Columba chalcoptera*, Latham. *C. elegans*, Temm.; and *C. picata*, Wagler, belong to this group. (Selby.)

P. chalcoptera. It is the *C. chalcoptera*, Latham; the *C. Lumachelle* of Temminck; Bronze-Winged Ground-Dove.

Bronze-Winged Ground-Dove (*Phaps chalcoptera*).

Size about that of *C. Œnas*. Total length about 15 inches. Bill, from edges of the gape, hardly an inch; black anteriorly; reddish near the base. Forehead, stripe below the eyes, and throat, white; crown brown, tinged with reddish, filleted with dusky red; cheeks and sides of neck bluish-gray; bottom of neck in front and breast purplish-gray. Belly and vent gray, with a pale purple tinge. Back, scapulars, rump, and upper tail-coverts, brown tinged with greenish in some lights, the border of each feather paler. Wing-covers bluish-gray, but the outer webs of every feather have a large ovate spot, producing various tints of metallic brilliancy according to the direction of the light. Quills brown above, with the inner surface of the webs, the axillary feathers, and under wing-coverts bordered rather deeply with pale orange-red. Tail slightly rounded, bluish-gray, with a black band. Legs red; two rows of scales in front, the sides reticulated.

It is an inhabitant of Australia and islands in the Pacific; in the neighbourhood of Sydney from September till February.

It haunts dry and sandy places, where it is generally seen on the ground, and occasionally perched upon the low branches of shrubs. Nest inartificial, in holes of low trees or decayed trunks near the ground, sometimes on it. Eggs two, white. These birds go in pairs generally; their cooing is loud, and has been compared, when heard at a distance, to the lowing of a cow.

Chamæpelia (Swainson).—Bill slender, entire. Wings rounded, the first quill short, third, fourth, and fifth nearly equal and longest; the webs on both sides slightly emarginate. Tail rounded. Feet rather short; the sides of the tarsi feathered. Types, *Columba passerina*, Linn.; *C. squamosa*, Temm. (Swainson).

C. Talpicoti. It is the *Columba Talpicoti* of Temminck, the species which Mr. Selby considers to be the type. Length 6¼ inches, adult male; forehead, crown, and nape of neck, ash-gray; cheeks and throat pinkish-white; upper plumage entirely brownish-orange, with the exception of a few transverse streaks of black upon the exterior webs of some of the wing-coverts nearest the body; under plumage deep vinaceous-red; axillary feathers and part of under wing-coverts black; tail with the two middle feathers brownish-orange, the remainder brownish-black, with reddish-brown tips, moderately curved; bill and orbits bluish-gray; legs and toes pale red, the outer side of the tarsus with a row of small feathers down the line of junction between the acrotarsia and paratarsia; quills broad, the fourth with a large projecting notch towards the middle of the inner web. The female has the crown of the head of a sordid gray; the upper plumage of a wood-brown, tinged with red; the scapular and wing-coverts marked as on the male; under plumage dirty gray, tinged with pale purplish-red. (Selby.)

Chamæpelia Talpicoti.

This bird inhabits Brazil, Paraguay, and other districts of South America. It haunts open grounds near woods, where it roosts and breeds upon the underwood, but never far from the ground, where it is active, and feeds upon the smaller cerealia, berries, &c. Generally observed in pairs, sometimes in families of four or six, never in large flocks. Does not fly from the face of man, but affects the confines of houses and farm-yards. Easily kept and propagated in aviaries.

Peristera (Swainson).—Bill slender, sub-emarginate. Wings rounded, the first quill short and abruptly attenuated, second and fifth equal, third and fourth equal and longest. Tail rounded. Feet strong, naked, somewhat lengthened; anterior scales of the tarsi imbricate, lateral scales none. Type, *Columba cinerea*, Temm. (Swainson).

P. tympanistria. It is the *Columba tympanistria* of Temminck. Length about 9 inches; upper plumage brown, slightly tinged with gray on the neck; large spots of shining dark green on the outer webs of three or four of the greater wing-coverts; middle tail-feathers brown; the two exterior on each side gray, with a broad black bar near the tip; inner webs of greater quills deep brown; forehead, streak over the eye, and under plumage, pure white; under wing-coverts and sides pale orange-brown; under tail-coverts brown; bill and legs gray, the latter with a reddish tinge.

It inhabits South Africa, where it is said to haunt woods. The species does not seem to be common.

Geophilus (Selby).—Mr. Selby, speaking of *Columba cyanocephala*, Wagler, *Turtur Jamaicensis*, Brisson; *Columba carunculata*, Wagler; and *Columba Nicobarica*, Latham, *Columba Gallus*, Wagler, says—

Peristera tympanistria.

"Whether they will form a separate division, or the three first will enter among the *Peristerinæ*, and the *Lophyrus* alone remain a representative of another group, we are unable to determine, not possessing sufficient materials to institute so strict an analysis as is necessary, or to trace out with precision the direct affinities of those species, and the situation they hold in respect to the other groups of the *Columbidæ*, as well as those of the adjoining families. The three first we have provisionally included in the genus *Geophilus*. In their form and habits they approach still nearer to the typical gallinaceous birds than the species we have just been describing. Their tarsi are long, and covered with hexagonal scales; their tail short, and rather pendent; their wings concave, short, and rounded; and their body, as compared with the typical pigeons, thick and heavy. A striking departure from the general economy of the *Columbidæ* is further observed in their mode of propagation, the number of the eggs they lay each hatching not being confined to two, as is seen to prevail in the groups already described, but extending to eight or ten, which are incubated upon the ground, and the young, like those of the true gallinaceous birds, are produced from the egg in such a state as to be able immediately to follow the parent, which broods over and attends them like the partridge or domestic fowl. They live entirely upon the ground, except during the hours of repose, when they sometimes retire to bushes, or the low branches of trees. They walk and run with great quickness, like the *Gallinæ*, and in fact appear to be the forms which immediately connect this family with the *Pavonidæ* and *Tetraonidæ*. Although for the present we have placed the first three under the same generic head, yet from their distinct geographical distribution, and the difference observed in the bill of the first, it is more than probable that a further division will be required."

G. carunculatus. It is the *Columba carunculata* of Temminck; the Colombe Galline of Le Vaillant. Size about that of the Common Turtle, but with the body stouter and more rounded. Base of the bill and forehead covered with a naked red wattle; another wattle of the same hue depends from the chin, and branches of it extend upwards towards the ears. Plumage of head, cheeks, neck, and breast, purplish-gray; back, scapulars, and wing-coverts, pale gray; feathers bordered with white. Belly, upper and under tail-coverts, flanks, and under wing-coverts, white. Tail short, rounded, deep ruddy-brown, except the outer feather on each side; these have the outer web white. Legs covered with hexagonal scales, purplish-red. Iris with a double circle, yellow and red. The female has no wattle, and her colours are less pure. (Le Vaillant.)

It inhabits South Africa, where it was discovered in the Great Namaqua country by Le Vaillant, who gives the following account of its habits and affinities:—"To the pigeons its affinity is shown by the form of the bill and the plumage; while it differs from them in the pendent wattle, elongated tarsi, rounder body, less graceful form, tail, which it carries hanging down like that of a partridge, and rounded wings; points which bring it near to the *Gallinæ*." A passage is thus formed by it, in his opinion, between those birds and the pigeons. The nest, composed of twigs and the dried stems of grasses, is formed in some slight hollow of the ground, and there the female lays six or eight reddish-white eggs, which are incubated by both the parents. The young are hatched clothed with down of a reddish-gray, run immediately and follow their parents, which keep them together by a peculiar oft-repeated cry, and brood over them with their wings. Their first food consists of the larvæ of ants, dead insects, and worms, which the parents point out to them. When strong enough to find their own food, they live on grain of different sorts, berries insects, &c., and keep together in coveys, like the partridge and other *Tetraonidæ*, till the pairing-time.

Geophilus carunculatus.

If the wattles of the last-named species recall to the observer the same parts so highly developed in the gallinaceous birds, the species which we next present will remind him of the hackles which ornament the *Gallinæ*.

G. Nicobaricus. It is the *Columba Nicobarica* of Latham, the *C. Gallus* of Wagler. Length hardly 15 inches; bill slender, about 1¼ inch long, tip but little bent downwards; the tail pure white, the quills deep blackish-blue, with varying tints of green; all the rest of the plumage rich metallic green, shooting, according to the light, into the variegated tints of golden-green, bronze, bright copper-colour, and deep purplish-red; neck-feathers long, narrow, and pointed, like those of the domestic cock; barbules towards the tip silky and distinct; tail short, pendent, nearly square; wings, when closed, reaching nearly to the termination of tail; legs strong, moderately long, black, covered with hexagonal scales; nails yellow, gently curved, blunt. Upon the base of the upper mandible of the male a round fleshy tubercle (probably apparent in the breeding season only). The female resembles the male in colour, but her neck-feathers are not so long, and she has no tubercle.

Geophilus Nicobaricus.

It inhabits the isles of Nicobar, Java, Sumatra, and many of the Moluccas. Authors differ about its habits, some asserting that its nest is placed on the ground, and that the female lays several eggs, the young running as soon as hatched; but Mr. Bennett, who saw them in Mr. Beale's aviary at Macao, says that they were usually seen perched upon the trees, even upon the loftiest branches, and adds, that they build their rude nests and rear their young upon trees, similar to all the pigeon tribe.

Lophyrus (Vieillot).—Bill moderate, rather slender, and slightly gibbous towards the tip; upper mandible channeled (sillonnée) on the sides, inclined towards the point; nostrils situated in a groove; wings rounded. (Vieillot.)

L. coronatus. It is the *Columba coronata* of Latham; *Phasianus cristatus Indicus*, Brisson; *Columbi Hocco*, Le Vaill.; Colombe Galline Goura, Temm.; Great Crowned Pigeon, Edw. A species surpassing in size all the other *Columbidæ*. Total length from 27 to 28 inches; bill two inches long, black, tips of mandibles thickened, that of the upper one somewhat deflected; head with a large elevated semicircular compressed crest of narrow straight feathers, with decomposed or rather disunited silky barbules, always erect; crest and body below grayish-blue; feathers of back, scapulars, and smaller wing-coverts, black at the base, rich purple-brown at the tips; greater coverts same colour, but centrally barred with white, forming a single transverse band across the wings when closed; quills and tail deep gray, the latter terminated with grayish-blue; legs gray; tarsi 3¼ inches in length, covered with rounded scales not closely set, with a white border of skin round each; toes strong and somewhat short, scales placed as in the *Columbinæ*.

Great Crowned Pigeon (*Lophyrus coronatus*).

This bird is found in many of the islands of the great Indian group. Not rare in Java and Banda, abundant in New Guinea and in most of the Moluccas. Nest built in trees; eggs two; cooing of the male hoarse, accompanied by a noise somewhat like that of a turkey-cock when strutting. Food—berries, seed, grain, &c. Flavour of the flesh said to be excellent.

"In this magnificent and beautiful bird," says Mr. Selby, "we observe a combination of form different from that of the ground-pigeons so lately described; for, instead of the marked affinity to the typical rasorial families, the *Pavonidæ* and *Tetraonidæ*, so decidedly exhibited by these species, both in their mode of life and in their deviation from the usual Columbine figure, we have, in the present instance, an approximation of structure much nearer that of some of the *Cracidæ*, another tribe of birds which constitutes an aberrant family of the Rasorial Order; and it is on this account we think that this bird cannot well be placed in the same division with the ground-doves, but must constitute the type of a separate group."

Fossil Columbidæ.—Dr. Buckland enumerates the bones of the pigeon among the remains in the cave at Kirkdale, and figures a bone which he says approaches closely to the Spanish runt; but Professor Owen, in his 'British Fossil Mammals and Birds,' is silent on this subject.

COLUMBINE. [AQUILEGIA.]

COLUMBITE, a Mineral into the composition of which the metal Columbium enters. Columbium on its first discovery was also called by chemists Tantalum, and this mineral has also been called *Tantalite*.

Columbite occurs in rectangular prisms, more or less modified, also massive. It is of an iron-black or brownish-black colour, often with a characteristic iridescence on a surface of fracture; the streak dark brown, slightly reddish; lustre submetallic, shining; opaque; brittle. The hardness is 5 to 6; the specific gravity 5·3 to 6·4.

According to Dana the composition of an American specimen was as follows:—

Columbic with Niobic Acid	80·1
Protoxide of Iron	12·6
Protoxide of Manganese	6·0
Oxide of Tin	·1
Oxides of Copper and Lead	·4

Bavarian specimens contain Pelopic acid, which, according to Rose, accounts for their high specific gravity, which ranges from 5·7 to 6·4.

This mineral is infusible alone before the blowpipe, but on mixture with borax in fine powder it fuses slowly but perfectly, forming a dark green glass, which indicates the presence of iron.

Columbite is found in granite at Bodenmais in Bavaria, also in Bohemia. It occurs in the United States in feldspathic or albitic rocks, at Middletown and Haddam, Connecticut, at Chesterfield and Beverley, Massachusetts, and at Acworth, New Hampshire. *Ferro-tantalite* is a Columbate of Iron.

(Dana, *Mineralogy.*)

COLUME'LLA, the central part or axis in the theca of a moss, around which the spores are arranged, without having any definite connection with it. Also the axis of any kind of fruit when separate from the carpels: in the latter case it is a hardened state of the growing point.

COLUMELLIACEÆ, a natural order of Exogenous Plants with epipetalous stamens, sinuous anthers bursting longitudinally, and

Columellia oblonga.

1, a flower seen from above; 2, the ovary, style, and stigma; 3, the half-ripe fruit; 4, the fruit opening, with the calyx adhering; 5, the pericarp separated from the calyx; 6, valves of the pericarp; 7, one valve and seeds.

unsymmetrical flowers. They are evergreen shrubs or trees. The leaves opposite, without stipules, entire or serrated; the flowers yellow and terminal; calyx superior, 5-parted; corolla rotate, 5-8-parted, with an imbricated æstivation; stamens 2, inserted in the throat, alternate with the segments of the corolla; anthers roundish, 3-lobed, bursting externally, each consisting of three pairs of narrow somewhat sinuous cells, which open longitudinally, and which are placed upon a solid fleshy connective. The affinities of this order are very doubtful. Professor Don, who first noticed the order, places it near the Jasmines. It differs however materially from them, and may almost be described as a form of monopetalous *Onagraceæ*. Dr. Lindley, in this uncertainty, leaves it by the side of *Berberaceæ* and *Cinchonaceæ*; to either of which, and especially to the latter, it may be compared. The species hitherto discovered are from Mexico and Peru. They are not known to possess any useful properties.

COLUMNARIA. [MADREPHYLLLÆA.]

COLUMNEA, a genus of Plants belonging to the natural order *Gesneraceæ*. One of the species (*C. scandens*) is called by the French colonists Liane à Sirop, because its flowers secrete a large quantity of honey.

COLUMNI'FERÆ, an old name for Plants belonging to the natural order *Malvaceæ*. [MALVACEÆ.]

COLUTE'A, a Papilionaceous genus of Exogenous Plants, consisting of hardy shrubs, with pinnated leaves and inflated membranous pods, which explode when suddenly compressed, and which look like vegetable bladders, whence the common English name of Bladder-Senna. The species have yellow or yellow and red flowers of some beauty; and are all found in the South of Europe, in Palestine, and in the Himalaya Mountains.

COLY'MBIDÆ, a family of Swimming Birds (*Natatores*), having a smooth, straight, compressed, and pointed bill.

Willughby assigned the family a place in his fifth section ('Whole-Footed Birds, with Shorter Legs'), under the name of "Douckers or Loons, called in Latine *Colymbi*," and he divided them into "Cloven-Footed Douckers that have no Tails," the Grebes, and the "Whole-Footed Douckers with Tails," the true Divers. The following is Willughby's description 'of Douckers in general:'—"Douckers have narrow, straight, sharp-pointed bills, small heads, and also small wings; their legs situate backwards, near the tail, for quick swimming and easier diving; broad flat legs, by which note they are distinguished from all other kinds of birds; broad claws, like human nails. Of these Douckers there are two kinds; the first is of such as are cloven-footed, but fin-toed, having lateral membranes all along the sides of their toes, and that want the tail; the second is of those that are whole-footed and caudate, which do nearly approach to those birds we call *Tridactylæ*, that want the back toe. These are not without good reason called 'Douckers,' for that they dive much, and continue long under water, as soon as they are up dropping down again."

Ray, in his 'Synopsis,' arranges the Cloven-Footed and Whole-Footed *Colymbi*, Grebes, and Divers, under his 'Palmipedes Tetradactylæ digito postico soluto, et primò rostro recto angusto acuto, Brachypteræ et Urinatrices, *Colymbi* dictæ.' He also includes the genus *Mergulus*. [AUK.]

Linnæus placed both the Divers, properly so called, and the Grebes under his genus *Colymbus*, which stands in his system under the order *Anseres*, between the genera *Phaëton* (Tropic Birds), and *Larus* (Gulls).

Pennant followed Brisson in separating the Grebes from the Divers. The first he placed next to the Coots, and immediately before the Avosets; and the Divers between the Guillemots and the Gulls.

Under the term 'Plongeurs, ou Brachyptères,' Cuvier arranges those *Palmipedes*, "a part of which have some relation to the Water-Hens. The legs placed more backward than in any of the other birds, render walking a difficult operation, and oblige them, when on land, to keep themselves in a vertical position. As the greater part of them are, besides, bad flyers, inasmuch as some of them cannot fly at all on account of the shortness of their wings, they may be regarded as almost exclusively attached to the surface of the waters. In accordance with this destination their plumage is more close-set, and sometimes it even offers a smooth surface and silvery hue. They swim under the water, aiding themselves with their wings, nearly as if they were fins. Their gizzard is sufficiently muscular, their cæca are moderate, and they have each a peculiar muscle on each side of their lower larynx." The following are the genera comprehended under this family by Cuvier:—the Grebes, Brisson (*Podiceps*, Latham; *Colymbus*, Brisson and Illiger); the Divers (Plongeons), properly so called (*Mergus*, Brisson; *Colymbus*, Latham; *Eudytes*, Illiger); the Guillemots (*Uria*, Brisson and Illiger); the Auks (Pingouins), *Alca* of Linnæus; the Penguins (Manchots), *Aptenodytes* of Forster, consisting of the sub-genera *Aptenodytes*, Cuvier; *Catarrhactes*, Brisson; and *Spheniscus*, Brisson.

Temminck places the Grebes (*Podiceps*) next to the *Phalaropes*, at the end of his fourteenth order, the *Pinnatipedes*, or Fin-Footed Birds; and the Divers (*Colymbus*, Latham) between the Pelicans and the Guillemots in his fifteenth order, the *Palmipedes*.

Mr. Vigors makes his fifth order of birds (*Natatores*) comprise the following families:—

Anatidæ, Leach.
Colymbidæ, Leach.
Alcadæ.
Pelecanidæ, Leach.
Laridæ, Leach.

Or, with reference to the typical groups—

Normal Group.

With short wings, which are sparingly feathered, and with feet placed behind the equipoise of the body . .	*Colymbidæ*. *Alcadæ*.

Aberrant Group.

With longer and well-feathered wings, and feet especially placed within the equipoise of the body . .	*Pelecanidæ*. *Laridæ*. *Anatidæ*.

M. Lesson, in his 'Manuel,' makes the *Colymbidæ* (Plongeurs, ou Brachyptères, Cuvier; *Urinatores*, Vieillot) the first family of the sixth order of birds, Les Palmipèdes (*Natatores* of Illiger and Vieillot); and the family comprises the genera *Podiceps*, Latham; *Colymbus* (part), Linnæus; and *Cephus*, Cuvier.

The Prince of Canino places *Podiceps* under his order *Anseres* in the family *Lobipedes*, and *Colymbus* under the same order in his family *Pygopodes*.

In the 'Fauna Boreali-Americana,' *Podiceps* is placed at the head of the order *Natatores*, and is immediately succeeded by *Sterna* (the Terns): the position of *Colymbus* is between *Pelecanus* and *Uria*, which last-mentioned genus concludes the order.

Podiceps.—Bill longer than the head, robust, slightly compressed or nearly cylindrical, subulated, straight, entire, pointed; upper mandible straight, or hooked at the point; nostrils oblong, half-closed. Wings short, the first three quills of equal length and longest. Tail none. Toes bordered with large fimbriations; hallux pinnated.

Head and Foot of the male Eared Grebe; summer plumage. The head from Mr. Gould's 'British Birds;' the foot from a specimen in the Museum of the Zoological Society.

The species of *Podiceps* are called Grebes. They haunt the sea as well as the rivers, are excellent swimmers, and dive frequently, as all who have watched the Dabchick or Little Grebe (*Podiceps minor*), and have been amused by its quickly-repeated plungings, well know. They feed on small fishes, frogs, crustaceans, and insects, and their nests, formed of a large quantity of grass, &c., are generally placed among reeds and carices, and rise and fall with the water.

The geographical distribution of this genus is very wide. Five European species are enumerated, and the foreign species are very numerous. The form seems capable of adaptation to great varieties of climate. In the 'Tables' published in the 'Introduction to Fauna Boreali-Americana,' we find *P. cornutus* and *P. Carolinensis* among the birds which merely winter in Pennsylvania, and migrate in summer to rear their young in the Fur Countries; and *P. cristatus*, *P. rubricollis*, and *P. cornutus* in the list of species common to the Old World and to the Fur Countries. Sabine gives a description of a mature individual of *P. rubricollis* killed at Great Slave Lake, and of a specimen of *P. Carolinensis* killed at the same place, both in Sir John Franklin's first expedition and in May 1822; and Sir John Richardson notes *P. cristatus* as having been killed on the Saskatchewan, and *P. cornutus* at Great Slave Lake ('Fauna Boreali-Americana'). *P. Chilensis* and *P. Americanus* are natives of the warm parts of America; the first, as its name implies, having been found in the Bay of Concepçion, and the second on the Brazilian waters (Rio Grande and S. Paulo).

P. occipitalis (Lesson) may be taken as an example. This Grebe, according to M. Lesson, is remarkable for the delicate tints of its plumage, which is slate-gray (gris ardoisé) above and of a satiny white below. The cheeks and forehead are of a light gray; a bundle of loose plumes (plumes effilées) springs behind each eye, and is prolonged backwards and on the sides of the neck. A calotte of deep black rises from the occiput, and is prolonged on the posterior part of the neck half-way down it. The throat is of a pearled-gray, which becomes lighter, so that the front of the neck and the sides are of a pure white, as well as the rest of the lower part of the body. The back and wings are of a deeper slate-colour, and this tint, mingled however with white, prevails on the feathers of the rump. The tarsi, toes, and the considerably large membranes which fringe them, are greenish. The bill is short and black. The iris is of a most lively red, so brilliant as to call forth from Père Dom Pernetty, whose Petit Plongeon à Lunettes it is, the expression that "diamonds and rubies have nothing to offer equal to the fire of the eyes of a species of Plongeon which is frequently found on the edge of the sea." The total length of this Grebe is 11 inches and 2 or 3 lines; from the forehead to the point of the bill, 8 lines; tarsi, 17 lines; external toe, 2 inches.

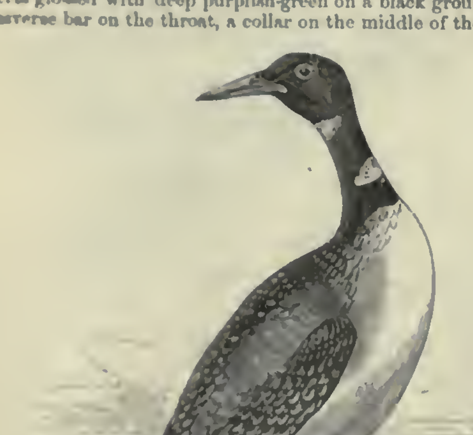
The British species of this genus given by Yarrell in his 'British Birds,' are—*P. cristatus*, the Great-Crested or Great-Tippet Grebe; *P. rubricollis*, the Red-Necked Grebe; *P. cornutus*, the Sclavonian, Dusky, or Horned Grebe; *P. auritus*, the Eared Grebe; and *P. minor*, the Little or Black-Chin Grebe, Dabchick, and Didapper.

Colymbus.—It is the *Mergus* of Brisson; *Urinator*, Lacépède; and *Eudytes*, Illiger. Bill moderate, strong, straight, very much pointed, compressed; nostrils concave, half closed. Wings short; the first quill the longest. Tail short, rounded. Three front toes very long, entirely palmated; hind toe bordered with a small supple membrane.

The Divers bear a close resemblance to the Grebes, from which they differ but little, excepting in their palmated feet. On the water they are at their ease: on land, they, as well as the Grebes, are awkward and beset with difficulties in their locomotion.

They principally inhabit the northern latitudes, where they nestle in the wildest and most desert spots. In the 'Tables' in 'Fauna Boreali-Americana,' we find *C. glacialis* and *C. septentrionalis* in the list of species which merely winter in Pennsylvania and migrate in summer to rear their young in the Fur Countries, and *C. septentrionalis* in the list of birds (migratory) detected on the North Georgian Islands and adjoining seas (lat. 73° to 75° north), on Sir Edward Parry's first voyage. *C. glacialis* and *C. septentrionalis* occur in Sabine's list of Greenland Birds; and *C. glacialus*, *C. arcticus*, and *C. septentrionalis* in Sir John Richardson's list of species common to the Old World and to the Fur Countries.

C. glacialis, the Great Northern Diver. Head, neck, and upper tail-coverts glossed with deep purplish-green on a black ground. A short transverse bar on the throat, a collar on the middle of the neck, interrupted above and below, and the shoulders white, broadly striped on the shafts with black. Whole upper plumage, wings, sides of the breast, flanks, and under tail-coverts, black; all, except the quills and tail, marked with a pair of white spots near the tip of each feather: the spots form rows, and are large and quadrangular on the scapulars and interscapulars, round and smaller elsewhere; smallest on the rump. Under plumage and inner wing-coverts white, the axillaries striped down their middles with black. Irides brown. Bill compressed, strong, tapering; its rictus quite straight; its contour very slightly arched above; lower mandible channeled beneath, appearing deepest in the middle; its gonys sloping upwards to the point; margins of both mandibles, but particularly of the lower one, inflected. Inner wing-coverts very long. Tail, of twenty feathers, much rounded. Total length 36 inches; extent of wing 48 inches. Sir John Richardson, whose description this is, observes, that specimens in mature plumage vary considerably in total length, upwards of an inch in length of wing, and more than half an inch in the length of the tarsus.



Great Northern Diver (*Colymbus glacialis*).

The young of the year differ considerably from the old birds. The head of the young, the occiput, and the whole posterior part of the neck are of an ashy-brown; on the cheeks are small ashy and white points; throat, front of the neck, and other lower parts, pure white; feathers of the back, of the wings, of the rump and flanks, of a very deep brown in the middle, bordered and terminated by bluish-ash; upper mandible ashy-gray, lower mandible whitish; iris brown; feet externally deep brown; internally, as well as the membranes, whitish. In this state Temminck says that the bird is the *Colymbus Immer*, (Gmelin, 'Syst. Lath. Ind.'); Le Grand Plongeon of Buffon (but the plate enl. 914 represents a young individual of *Colymbus arcticus*); Mergo Maggiore o Smergo ('Stor. deg. Uec.'), with a good figure. He thinks that the Imber Taucher of Bechstein ('Naturg. Deut.') is probably a young of this species on account of its large dimensions, and remarks that under the name of *C. Immer* the young of this species are often confounded with those of *C. arcticus*.

At the age of a year, according to the same author, the individuals of both sexes show a transverse blackish-brown band towards the middle of the neck, about an inch in length, forming a kind of collar; the feathers of the back become of a blackish tint, and the small white blotches begin to appear. In this state it is the Grand Plongeon of Brisson (vol. vi. p. 105, pl. 10, f. 1), a very exact figure.

At the age of two years the collar is more defined: this part, the head, and the neck are varied with brown and greenish-black feathers; the numerous blotches on the back and wings become more prevalent, and the band under the throat, and the nuchal collar also, are marked with longitudinal brown and white lines.

At the age of three years the plumage is perfect.

According to Montagu, *Colymbus glacialis* is the *Colymbus maximus caudatus* of Ray; *Mergus major nævius* and *Mergus nævius* of Brisson; L'Imbrim of Buffon; Greatest Speckled Diver or Loon of Willughby; and Northern Diver of Pennant ('Brit. Zool.'): and the female is *Colymbus Immer* of Linnæus; *Colymbus maximus Gesneri* of Ray; *Mergus major* of Brisson; Le Grand Plongeon of Buffon; Ember Goose of Sibbald; and Imber Diver of the British Zoology. It is the *Colymbus torquatus* of Brunnich; the Schwarzhalsiger See-Taucher, Eis-Taucher, Grosse Halb-Ente, and Meer-Noering, of the Germans; Brusen of the Norwegians; Turlik of the Greenlanders; Eithinnew-Moqua of the Cree Indians; Talkyeh of the Chipewyans; Kagloolek of the Esquimaux; Inland Loon of the Hudson's Bay residents; and Trochydd Mawr of the Welsh: it is provincially called by the British Gunner and Greater Doucker.

Fish is the principal food of this species, and the herring in particular; the fry of fish, crustaceans, and marine vegetables. It nestles in small islands and on the banks of fresh waters, and the female lays two eggs of an Isabella-white, marked with very large and with small spots of a purplish-ash. Sir John Richardson gives the following description of its manners:—"Though this handsome bird is generally described as an inhabitant of the ocean, we seldom observed it either in the Arctic Sea or Hudson's Bay; but it abounds in all the interior lakes, where it destroys vast quantities of fish. It is rarely seen on land, its limbs being ill fitted for walking, though admirably adapted to its aquatic habits. It can swim with great swiftness, and to a very considerable distance under the water; and when it comes to the surface, it seldom exposes more than the neck. It takes wing with difficulty, flies heavily, though swiftly, and frequently in a circle round those who intrude on its haunts. Its loud and very melancholy cry, like the howling of the wolf, and at times like the distant scream of a man in distress, is said to portend rain. Its flesh is dark, tough, and unpalatable. We caught several of these birds in the fishing-nets, in which they had entangled themselves in the pursuit of fish." The species is sometimes taken even in the south of England. Montagu mentions one which was kept in a pond for some months. In a few days it became extremely docile, would come to the call from one side of the pond to the other, and would take food from the hand. The bird had received an injury in the head, which had deprived one eye of its sight, and the other was a little impaired; but, notwithstanding, it could, by incessantly diving, discover all the fish that were thrown into the pond. When it could not get fish it would eat flesh; and when it quitted the water, it shoved its body along upon the ground like a seal, by jerks, rubbing the breast against the ground; and returned again to the water in a similar manner. In swimming and diving the legs only were used, and not the wings, and by their situation so far behind, and their little deviation from the line of the body, it is enabled to propel itself in the water with great velocity in a straight line, as well as turn with astonishing quickness. In the winter of 1813-14, according to Mr. Graves, during the intense frost, two fine individuals were taken alive in the Thames below Woolwich, and were kept in confinement for some months. They eagerly devoured most kinds of fish or offal. At the approach of spring they began to show great uneasiness in their confinement, though they had the range of an extensive piece of water, from whence they ultimately escaped in the month of April. The distance of the river from the pond in which they were confined was several hundred yards, but they made their escape; and two birds resembling them in colour were seen on the river in that neighbourhood for several days after they were missed; and though repeatedly shot at, they escaped by diving.

They are found in the arctic seas of the New and Old World; very abundant in the Hebrides, Norway, Sweden, and Russia; accidental visiters along the coasts of the ocean. The young in winter are very rare on the lakes of the interior, in Germany, France, and Switzerland; the old birds are never seen there. (Temminck.) It is a rather rare visitant to these islands, especially to the southward.

C. arcticus, the Black-Throated Diver, the Lesser Imber, Plongeon à Gorge Noire of the French. In habits and appearance this bird is like the last. It is more rare in this country.

C. septentrionalis, the Red-Throated, or Speckled Diver, is the most common species in Great Britain.

Lesson arranges the genus *Cephus*, Mœhring, Cuvier (*Colymbus*, Linn.; *Uria*, Temm.; *Mergulus*, Ray, Vieillot), under the *Colymbidæ*, observing that it forms the passage from the Divers to the Auks. [Auk.]

COLYMBUS. [Colymbidæ.]

COLZA. [Brassica.]

COMARUM, a genus of Plants belonging to the natural order *Rosaceæ*. It has a concave 8-10-parted calyx in two rows, the five exterior sepals being smallest; 4-5 petals; the receptacle ultimately large, fleshy, spongy, and persistent; the style lateral near the summit of the nut, the seed ascending. There is but one species of this genus, *C. palustre*, Marsh Cinquefoil. It has an ascending stem, is about one foot high, has pinnate leaves, dark purple flowers, and numerous carpels seated on the dry spongy receptacle. This plant is a native of Great Britain. It is found in marshes and peaty bogs. In Scotland the fruit is called Cow-Berries. The roots dye wool of a dirty red colour, and possess a sufficient amount of tannin to render them available for making leather. In gardens it will grow in any moist soil, and may be increased by dividing at the root.

COMATULA, Lamarck (*Alecto*, Leach), a genus of Radiated Animals. Linnæus appears to have confounded the form with the other Star-Fishes; for it is only noticed by him as a species of his genus *Asterias*. Neither Gmelin nor Pennant disturbed this arrangement. M. de Fréminville ('Nouv. Bull. des Sciences') seems to be the first who formed a genus for it, under the name of *Antedon*. Leach characterised it generically under the name of *Alecto*. Lamarck makes it the first genus of his first family (Les Stellérides) of his order of Echinodermatous *Radiaria*, placing it immediately before *Euryale*. Cuvier arranges the genus under his Échinodermes Pédicellés; observing, that it is near to the division of the *Euryales* and *Comatulæ* that the *Encrinites* ought to have their position. Miller is of opinion that *Comatula* presents a conformity of structure with that of the Pentacrinite almost perfect in every essential part, excepting that the column is either wanting or reduced to a single plate; and M. de Blainville makes it come under his first section (Free Asterencrinideans) of his third family (Asterencrinideans) of his third order (Stelleredians) of his first class (Cirrhodermarians) of his first type (Actinozoarians) of Zoophytes.

The genus is thus characterised by M. de Blainville:—Body orbicular, depressed, membranous; protected above by an assemblage of calcareous pieces, of which one is medio-dorsal, with one or two rows of accessory articulated simple rays, and provided on its circumference with five great rays, deeply bifid and pinnated, commencing with three basilary pieces. Mouth rather anterior, isolated, membranous, at the bottom of a star formed by five bifurcated channels. A large pseudo-anal orifice at the fringed extremity of a visceral sac.

The following details of structure are given by the same author. The body of *Comatula* is almost entirely membranous below; above, on the contrary, it is protected by a sort of cupule, which is thick, and composed of calcareous pieces, articulated and held together by a very delicate and hardly distinct skin. This cupule is formed by a centro-dorsal part, in which two pieces placed one over the other enter. It is round the first that the auxiliary rays are articulated, and to the second the great rays are joined by means of their basilary part.

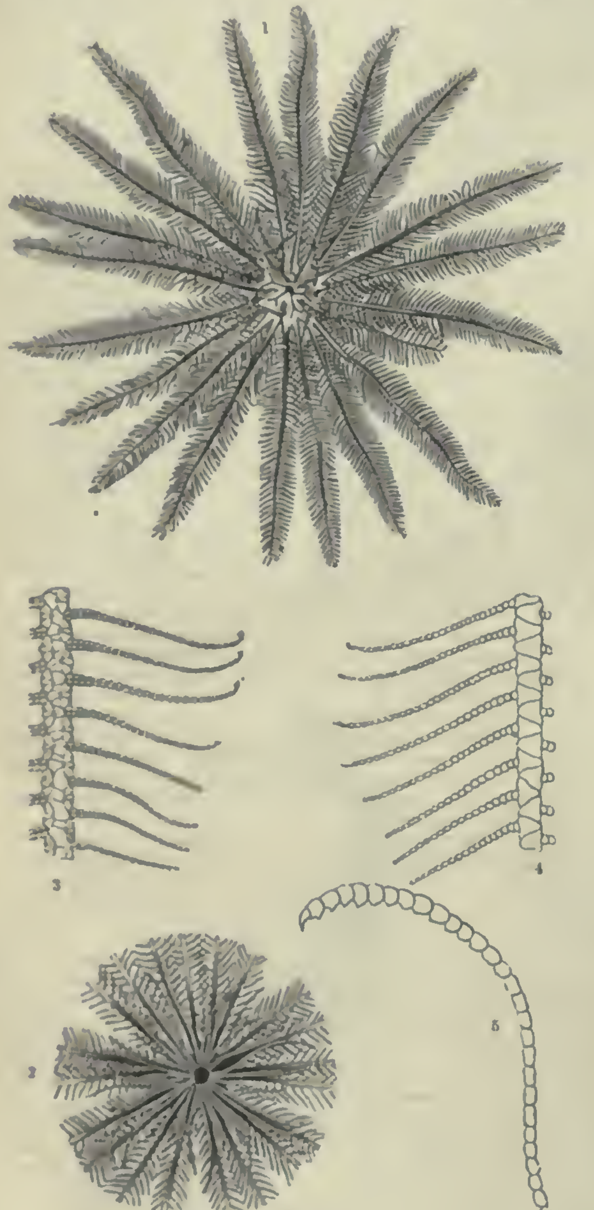
The auxiliary rays, whatever may be their number, for they may form one or two rows, are always simple; that is, they are composed of simple articulations joined end to end, of which the last is attenuated and curved into a hook. (*Fig. 5.*) They are never pinnated, and it would appear that they are not provided with any suckers.

The great rays enter by their base into the composition of the cupule or cell in which the visceral mass is contained. Each of them is formed by a simple basilary part, and another much more extended, divided, and pinnated. The basilary part is composed of three joints, a first articulated with the centro-dorsal piece, a second intermediate, and a third terminal, with which the two principal divisions of the rays are joined, and which on that account is shaped into an angle at its summit. The joints of this basilary part not only articulate with each other, but laterally they touch the corresponding parts of the two neighbouring rays. By such a disposition, becoming more and more complex, it is that the heads of *Encrinites* and the genera allied to them are formed. With regard to the pinnated or complex part of the ray, it is at first constantly double, that is, formed of two digitations, which are themselves often subdivided in a variable manner; so that sometimes the *Comatula* bears a resemblance to a great figure of a sun: each subdivision is composed of joints in general but little elongated, which augment but little in number in a given space in proportion as they approach towards the extremity. Their most remarkable points are, that they alternately differ a little in length, and that the longest carry, right and left, on their internal surface, compressed triangular pinnules nearly cirrhous at their extremity, and also composed of a great number of short articulations. The result is, that when the animal is dead the digitation resembles the leaves of the *Mimosæ*, because the pinnules in repose cling one to another like the folioles of sensitive plants throughout the length of the rachis when they are closed. But the principal character which distinguishes the great rays from the accessory ones is, that through the whole length of the axis and pinnules the buccal or labial channel, fleshy and provided with sucking cirrhi serving the animal to seize its prey, is continued. In following out these channelings (espèces de sillons), the number of which is in proportion to that of the digitations of the ray, we arrive, by means of a channel from each, and occupying its base, at the centre of a sort of star with thick fringed borders, and finally at the mouth, which is at the bottom. The star formed by the junction of the channels of the rays is not symmetrical, that is, its branches are very unequal; some, which we shall call the anterior ones, being shorter than the others, or posterior ones. The result is, that the mouth is not at the centre of the star, but much nearer one side than the other; it is difficult to be seen, which is not the case with another orifice which we shall presently discuss, and which M. Lamarck seems to have taken for it. The mouth is deeply buried in the star of the channelings, is round, unarmed, and leads immediately into the stomach. What is remarkable in this last is, that its parietes are thick, and especially that it is not simple. It is in fact full of lacunæ, or rather it forms a sort of cavernous tissue, enveloped on all sides by a yellow granulated matter of some volume, which must be the liver. The result of this disposition of stomach and liver is a considerable visceral mass, which occupies the excavated part of the calcareous cupule, and which is attenuated by degrees as it retires backwards, where it terminates in a soft and obtuse point. All this mass projects in the interior of a large cavity, of which it remains to speak. This cavity, entirely membranous—at least below, for above and on the sides it is doubled by the solid parts—surrounds the visceral mass, and detaches it from all the rest of the animal, except towards the mouth, where it is continued. The internal orifice M. de Blainville was unable to discover. It is perfectly smooth, but it is prolonged externally into a sort of bladder (vessie), the base of which is behind, and whose truncated summit is forward. This free summit passes even a little beyond the mouth as it advances below it. It is pierced by a large gaping orifice, provided with a circular row of tentaculiform papillæ.

In the 'Descriptive Catalogue of the Museum of the College of Surgeons' (Physiological Series, vol. i.), there is a notice regarding *Alecto glacialis* (No. 435, A), which imports that the alimentary canal is continued in a spiral direction from the sub-central opening at the convergence of the radiated canals to the opening at the extremity of the fleshy tube which projects forwards by the side of the mouth, forming a second distinct orifice or anus. Professor Owen at first followed Lamarck in considering this tubular orifice as the mouth; but after dissecting a specimen carefully, and considering the analogy of *Alecto* with the other *Asteriæ*, he regarded it as the superadded orifice, and the sessile orifice at the convergence of the canals or channels as the normal orifice, and consequently the mouth. He is of opinion that this tubular orifice cannot be the opening of the oviducts, because the ovaries are situated in membranous expansions on the inside of the pinnules of the rays, as has been described in another part of the 'Physiological Catalogue.' That the tubular cavity should be a locomotive organ he considers most improbable, to use no stronger term; indeed the animal is so well provided with moveable rays, that such an adaptation would be superfluous. Whether or not some respiratory actions are effected by the fleshy tube and receptacle is another question, requiring observation on the currents, &c., while the animal is living, for its solution.

Péron states that these *Radiata* suspend themselves by the small arms from fuci and polyparies, and in that position watch for their prey, which they entrap in their spreading arms.

Comatula rosacea, Link, Rosy Feather-Star. The whole animal is of a deep rose-colour dotted by brown ovaries and fringed by transparent cirrhi. Professor E. Forbes, in his 'History of British Star-Fishes,' says: —"The history of this creature is one of the little romances in which natural history abounds, one of those narrations which while believing we almost doubt, and yet while doubting we must believe, it being the only Crinoid animal at present inhabiting our seas, at one time so full of those beautiful and wonderful creatures, presenting points of great interest not to the zoologist only but also to the geologist." In the year 1823 Mr. J. V. Thompson discovered in the Bay of Cork a singular little pedunculated animal, which he called *Pentacrinus Europæus*, and which proved to be the young of the *Comatula*, and gave rise to much interest and discussion both at home and abroad, for it was the first animal of the Encrinite kind which had been seen in the seas of Europe, and the first recent *Encrinite* that had ever been examined by a competent observer in a living state. In 1836 Mr. Thompson published a memoir in the 'Edinburgh New Philosophical Journal,' maintaining the proposition that his *Pentacrinus Europæus* was only the young of *Comatula*; that the Feather-Star commenced life as an *Encrinite*, and thus as it were changed its nature from a pseudo-polype to a star-fish. He then compares the youngest *Comatula* he had met with, with the oldest *Pentacrinus*, and shows the gradual progression



1, *Comatula Adeonæ*, three-fourths of the natural size, lower side; 2, upper side of the same; 3, part of the under side of a ray magnified; 4, upper side; 5, one of the dorsal rays magnified, showing the hook or anchor. De Blainville.

of form during the development of the latter towards the adult state of the former. Since that time other naturalists have testified to this observation of Mr. J. V. Thompson; it is confirmed by Professor E. Forbes, Dr. Ball of Dublin, and the late Mr. W. Thompson of Belfast.

C. Adeonæ of Lamarck has the following characters:—10 pinnated, slender, penniform rays; pinnules lanceolate, complicatedly canaliculate below; 20 dorsal cirrhi.

It inhabits the seas of Australia, where Péron and Lesueur found it hooked on to an *Adeona*. It is small, delicate, with 10 very slender feathery rays, and only 3 inches in diameter. The pinnules are lanceolated, and folded in two, as it were, below, longitudinally.

The species of *Comatula* are widely spread. The Rosy Feather-Star is found on many parts of the British Coast. Two species are given as British in most works on zoology, *C. rosacea* and *C. barbata*. They are evidently the same animal of different ages or in different states of preservation: they are both identical with the *C. Mediterranea* of Lamarck. A Feather-Star is a very different animal when preserved in spirits with its expanded fins from what it appears when dried. In the Museum of the College of Surgeons there are two specimens from the Society Isles, one brought up from a depth of 226 fathoms, in 80° 26′ N. lat., 12° 30′ E. long. (H.M.S. Dorothea, Captain Buchan, R.N.); and the same species (*Alecto glacialis*) from 250 fathoms, 80° 26′ N. lat., 11° 32′ E. long. (H.M.S. Trent, Lieutenant Franklin, R.N.).

The species probably are tolerably numerous. Dr. Leach records three species, two in the British Museum, Lamarck eight, and De Blainville nine. Many of the species are of comparatively large size. [ECHINODERMATA.]

Fossil Comatulæ.

Goldfuss enumerates four species from Solenhofen (Oolitic group). There are none in any of the British strata.

COMBRETA'CEÆ, an order of Polypetalous Exogenous Plants, with 1-celled inferior fruit, the seeds of which are solitary or nearly so, and pendulous, the stamens definite in number, and the cotyledons convolute. It cannot be doubted that this order has a near relation to *Myrtaceæ* and especially to *Punica*. Dr. Lindley considers it to be in closer alliance with *Lauraceæ* and *Compositæ*.

Combretum coccineum.

a, Flower; *b*, flower opened to show the insertion of the eight stamens; *c*, pistil; *d*, stamen; *e*, fruit; *f*, horizontal section of fruit; *g*, seed; *h*, embryo.

The species known as Myrobalans are tropical shrubs or trees, with alternate or opposite leaves destitute of stipules, and long slender stamens. The order does not contain any plants of much importance for their useful properties. Some of them are astringent and used for tanning, and the kernels of others are eatable; they are chiefly valued for their brightly coloured showy flowers, especially in the genus *Combretum*.

COMEPHORUS, a genus of Fishes belonging to the family of Gobies. There is only one species, which is found in the fresh-water lake of Baikal. It is not taken by the fishermen, but is found dead on the shores after the severe storms to which that lake is frequently exposed. The fish is about a foot in length, and of a soft greasy texture. It is collected and pressed for oil, but is not eaten.

COMFREY. [SYMPHYTUM.]

COMMELYNA. [COMMELYNACEÆ.]

COMMELYNA'CEÆ, a very small order of Tripetaloideous Endogens, consisting of Plants with sheathing leaves, white or most frequently blue flowers inclosed in a green spathe, and a single 3-celled ovary terminated by a single style. They are moreover remarkable for their pulley-shaped (or trochlear) embryo lying in a particular cavity of the albumen. None of the species are European, nor of any known use. Many of them are common Indian weeds; others are handsome American herbaceous plants. The common Spiderworts are a good type of the order. They are in many respects allied to the Lilies. Brown compares them with Rushes. They may also be compared with Alismads. Lindley places them between *Liliaceæ* and *Bromeliaceæ*. There are 16 genera of this order and about 260 species.

Spiderwort (*Tradescantia Virginiana*).

a, Calyx, stamens, and pistil; *b*, stamen magnified; *c*, jointed hair from the filaments of the stamen; *d*, pistil; *f*, fruit; *g*, horizontal section of the seed-vessel; *h*, *i*, sections of seed; *k*, embryo; *l*, seed germinating.

COMMIA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has diœcious flowers. The staminiferous flowers are formed of bracts united into an amentum; the stamens are numerous and united into a single column. The pistiliferous flowers are racemose, the calyx is 3-parted, the styles 3, the capsule 3-lobed.

C. Cochinchinensis is a small tree with a resinous juice. It has alternate entire smooth leaves. The male flowers are amentaceous, the catkins consisting of imbricated 1-flowered scales, axillary and short; the female flowers racemose, terminal, and small. This tree yields a gum which possesses emetic and purgative properties. It is recommended in cases of dropsy, but has not been introduced into European practice. It is a native of Cochin China.

COMMINGTONITE, a Mineral belonging to the Silicate of Iron series. It is a compound of silica, iron, manganese, and soda.

COMOCLA'DIA (from κόμη, hair, and κλάδος, a branch), a genus of Plants belonging to the natural order *Anacardiaceæ*. It has hermaphrodite or monœcious flowers; a 3-4-parted permanent calyx, 3-4 long petals; 3-4 short stamens; a single ovary with no style, and a single stigma; an ovate 1-celled, 1-seeded drupe; the seed somewhat pendulous from a curved funiculus originating at the base of the cavity; no albumen.

C. dentata, Tooth-Leaved Maiden-Plum, has pinnated shining leaves, green above, with a round rachis 6 inches long, 6-10 leaflets on each side, with an odd one oblong, acuminate, spiny-toothed, veiny, and somewhat downy at the back. This plant is a tree reaching a height of about 30 feet. It is a native of the woods of Cuba and St. Domingo, where it is called Guao. It has an erect not much branched stem. A milky juice exudes from it, which is glutinous, and becomes black by exposure to the air. It stains linen and the skin black, which cannot be washed out of the former, and only comes off from the latter by the exfoliation of the cuticle. It is believed by the natives of Cuba that it is death for persons to sleep under this tree, especially if they are fat or of a full habit of body. It is, undoubtedly, a poisonous tree, although nothing is recorded of its mode of action on the system.

C. integrifolia has stalked leaflets, lanceolate, quite entire, smooth. It is a tree 20 feet high, with small scentless deep red flowers. The berries are black and succulent, and may be eaten with impunity, but are not pleasant to the taste. The wood is hard, of a fine grain, and reddish colour. The tree gives out a watery juice, which is slightly glutinous, and grows black on exposure to the air. Like the juice from the last, it stains linen and the skin indelibly. It is a native of Jamaica.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

COMPO'SITÆ, the largest known natural order of Plants. It consists of Monopetalous Exogens with syngenesious stamens, and an erect solitary ovule in a simple 1-celled inferior ovary, the style of which is divided into two arms; the flowers are always arranged in dense heads, or capitula, and are surrounded by one or more external rows of bracts forming an involucre. Professor Lindley regards it as an alliance of several natural orders. It consists of herbs, shrubs, or trees, found in all parts of the world, but assuming an arborescent character only in warm latitudes: they occur in every conceivable variety of situation, are often exceedingly similar to each other in appearance, and have always been, from the birth of botany as a systematic science, the puzzle and reproach of systematists. Every succeeding writer, with a few exceptions, rendered the subject more complicated and difficult, till Cassini, a Frenchman, of good powers of observation, much patience in investigation, and a clear head, with the command of the rich materials included in the Paris herbaria, set steadily about a re-formation and re-examination of the whole order. In 1832 Lessing gave the world a synopsis of the genera of *Compositæ*, in which for the first time a clear, compendious, intelligible view of the order was systematically taken. Subsequently De Candolle, the celebrated botanist of Geneva, achieved the difficult task of systematising the *Compositæ* in an unexceptionable manner in his great work, 'Prodromus Systematis Naturalis Regni Vegetabilis.'

The old and generally adopted plan of breaking up *Compositæ* into primary divisions is that of Jussieu, which may be explained thus:— Every head of flowers, or florets, as they are technically named, has a central part, or disc, and a circumference, or ray: of these florets some are regularly tubular, with their limb cut into four or five segments; others are slit up on one side, opened flat, and turned towards the circumference of the head; the latter are named ligulate florets. When in a head of flowers all the florets are alike and ligulate, it belonged to the division *Cichoraceæ* (*fig. a*), as in the dandelion; if the florets of the disc were tubular, and those of the circumference only ligulate, it was referrible to *Corymbiferæ* (*fig. b*), as in the marigold; and when all the florets are alike tubular, both in the disc and ray (*fig. c*), it belonged to *Cynarocephalæ*, provided the involucre was at the same time stiff and ovate, as in the thistle. The latter character was necessary in order to distinguish *Cynarocephalæ* from those *Corymbiferæ* in which the ray is not developed, as common groundsel. To these three divisions a fourth has in later times been added under the name of *Labiatifloræ*, in consequence of the florets having distinctly two lips of unequal size. (*Figs. d* and *e.*)

These divisions have however been thought objectionable on several accounts, and De Candolle, following Cassini and Lessing, has trusted more to modifications of the style; the result of which is the following arrangement of the order in eight tribes:—

* *Tubulifloræ;* namely, with the hermaphrodite florets regularly tubular, and 5-toothed, seldom 4-toothed.

Tribe 1, *Vernoniaceæ*. Style of the hermaphrodite flowers cylindrical, its arms usually lengthened and subulate, rarely short and obtuse, always equally hispid in about all the length. The true stigma ending short of the middle of the arms of the style. A part of the rayless *Corymbiferæ*. (*Fig.* 1.)

Tribe 2, *Eupatoriaceæ*. Style of the hermaphrodite flowers cylindrical, with long somewhat club-shaped arms, which are covered externally near the end with papillose down. The true stigma but little prominent, and usually ending short of the middle of the arms of the style. A part of the rayless *Corymbiferæ*. (*Fig.* 2.)

Tribe 3, *Asteroideæ*. Style of the hermaphrodite flowers cylindrical, with linear arms, rather flat externally, and towards the end equally and finely downy. The true stigma produced about as far as the origin of the external down. A part of *Corymbiferæ*. (*Fig.* 3.)

Tribe 4, *Senecionideæ*. Style of the hermaphrodite flowers cylindrical, with linear arms having a pencil of hairs at the point; either truncated, or produced beyond the pencil into a short cone, or a long narrow hispid appendage. The true stigma broad and prominent as far as the pencil. A part of *Corymbiferæ*. (*Fig.* 4.)

Tribe 5, *Cynareæ*. Style of the hermaphrodite flowers thickened and knobby towards the upper end, and often pencilled at the knob,

the arms either distinct or grown together, and downy externally. Tho true stigma not prominent, reaching the apex of the arms, and then becoming confluent. All the *Cynarocephalæ*. (*Fig.* 5.)

* * *Labiatifloræ*; namely, with the hermaphrodite florets usually 2-lipped.

Tribe 6, *Mutisiaceæ*. Style of the hermaphrodite flowers cylindrical at the upper end, or rather knobby, the arms usually obtuse or truncated, very convex on the outside, and at the upper part covered with minute even down, or naked. (*Fig.* 6.)

Tribe 7, *Nassauviaceæ*. Style of the hermaphrodite flowers never knobby and thickened; the arms linear, rather loug, truucated, and pencilled at the point only. (*Fig.* 7.)

* * * *Liguliflorœ*; namely, with all the flowers hermaphrodite and ligulate.

Tribe 8, *Cichoraceæ*. Style cylindrical at the upper end, with rather long arms, which are somewhat obtuse and equally hairy; the true stigma terminating short of the middle of the arms. (*Fig.* 8.)

De Candolle estimates *Compositæ* at one-tenth of the whole vegetable kingdom. They are in some cases soporific, as lettuce and succory; in others they are diuretic, as various conyzas; some are tonic and stomachic, as wormwood and chamomile. Common artichokes with their succulent receptacles, and Jerusalem artichokes with their succulent tubers, are the only esculents. Many are beautiful objects to look upon, and are amongst our choicest garden flowers, as dahlias, marigolds, coreopsis, asters, &c.

For further information on this order see—ACHILLEA; ANTHEMIS; ARNICA; ARTEMISIA; ASTER; BARKHAUSIA; BELLIS; BIDENS; CALENDULA; CENTAUREA; CHRYSANTHEMUM CICHORACEÆ; CICHORIUM; CINERARIA; CONYZA; CORYMBIFERÆ; CREPIS; CYNARA; CYNARACEÆ; DAHLIA; DIOTIS; CARLINA; ERIGERON; EUPATORIUM; FILAGO; HELMINTHIA; HIERACIUM; HYPOCHŒRIS; INULA; LACTUCA; LAPSANA; LEONTODON; LINOSYRIS; SONCHUS; MULGEDIUM; PETASITES; PICRIS; PRENANTHES; PYRETHRUM; SENECIO; SOLIDAGO; OPORINIA; TANACETUM; THRINCIA; TRAGOPOGON; TUSSILAGO.

COMPOUND FLOWERS are the flower-heads of *Compositæ*; they are masses of small flowers collected upon a depressed axis, or receptacle, and surrounded by an involucre of floral leaves or bracts.

COMPT'ONIA, a genus of Plants belouging to the natural order *Myricaceæ*, named after Henry Compton, bishop of London, by whom the fine collection of plants attached to the episcopal palace at Fulham was formed. The male flowers have cylindrical loosely imbricated catkins, with deciduous 1-flowered bracts; 2 sepals; 6 stamens, adhering in pairs: the female flowers have ovate densely imbricated catkins, with 1-flowered bracts; 6 sepals, larger than the bracts; 2 capillary styles, and a 1-seeded nut. There is only one species, the *C. asplenifolia*, Sweet Fern. It is a small bush from 3 to 4 feet in height, yielding a powerful aromatic fragrance when rubbed between the fingers. It has long linear pinnatifid leaves, brown and rather downy on the under side, shining on the upper. It is a native of the woods and mountains of the United States, where it is a favourite domestic remedy for the cure of diarrhœa. It possesses tonic and astringent properties. It is a handsome shrub, and will thrive in a peat soil or sandy loam, and may be propagated by layers or suckers. It was called *Liquidambar asplenifolium* by Linnæus, but differs very much from that genus in its characters and properties. (Lindley, *Flora Medica*; Loudon, *Encyclopædia of Plants.*)

COMPTONITE, a Mineral, also called *Thomsonite*. Trimetric. In right rectangular prisms. Usually in masses having a radiated structure within, and consisting of long fibres or acicular crystals. Also amorphous. Cleavage parallel to the diagonal planes of the primary form. Fracture uneven, conchoidal. Hardness, scratches fluor-spar. Colour snow-white; lustre vitreous, inclining to pearly; transparent to translucent. Specific gravity, 2 to 4·7. Composition:—

Silica	38·3
Alumina	30·7
Lime	13·5
Soda	4·5
Water	13.0

It intumesces and becomes opaque, but the edges merely are rounded at a high heat. When pulverised it gelatinises with nitric or muriatic acids. It is distinguished from *Natrolite* and other *Zeolites* by its difficult fusibility. It occurs in Amygdaloid near Kilpatrick, Scotland; in Lavas at Vesuvius; in Clinkstone in Bohemia; also at Pelter's Point in Nova Scotia, in Trap.

CONCHA'CEA, a family of *Mollusca* in M. De Blainville's arrangement of the Animal Kingdom. The following is his definition of the family:—"Mantle closed before (en avant), above, and behind, where it is prolonged by two tubes more or less long, extensile, and either separated or united; abdomen constantly provided with a foot of slightly variable form, serving for locomotion. Shell nearly always regular, entirely closed, equivalve; umbones curved forward; hinge dorsal, complete—that is to say, with teeth and a ligament; this last either external or internal, short, and swollen (bombé); two distinct muscular impressions united below by a ligule more or less large, and very often inflected or returning backwards (rentrée en arrière).

"All the animals of this family live plunged more or less deeply in the sand or in the mud, but they are still able to come out of it sometimes."

M. Rang thus modifies De Blainville's definition, principally for the introduction of *Iridina* (which according to the observations of M. Deshayes could no longer be retained among the *Submytilacea*) and *Gratelupia*, a fossil species.

"Mantle closed, furnished with a considerable antero-inferior opening, for the passage of a foot, and presenting two posterior tubes more or less elongated, extensile, united or separated longitudinally, the lower one serving for respiration, and the upper one for dejections. Shell equivalve, generally regular, rarely gaping; umbones more or less curved forwards; hinge almost always with teeth; ligament short and swollen, internal or external; muscular impressions very distinct; united by a pallial impression more or less excavated posteriorly.

"Animals marine, rarely fresh-water."

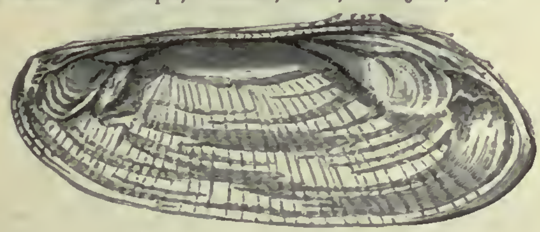
Cuvier, in his last edition of the 'Règne Animal,' at the foot of his definition of the *Cardiacea*, the fourth family of his Testaceous *Acephala*, has the following note:—"M. de Blainville en fait la famille des *Conchacées*." The following is Cuvier's definition of his Cardiacés:—"Mantle open in front (par devant), and moreover with two separate openings, one for respiration and the other for the excrements, which are prolonged into tubes sometimes distinct, sometimes united into a single mass. There is always a transverse muscle at each extremity, and a foot which most frequently serves for creeping. It may be regarded as a sufficiently general rule, that those which have long tubes live plunged in the mud or sand. One may recognise on the shell this condition of organisation by the more or less developed contour (contour plus ou moins rentrant), which the impression of the attachment of the borders of the mantle describes before uniting with the impression of the posterior transverse muscle."

These definitions appear contradictory, but in reality they are meant to convey the same ideas. The mouth is placed anteriorly, the foot is exserted inferiorly, and the tubes open posteriorly. The following is an arrangement of the genera:—

*

Hinge linear and toothless—freshwater. (Rang.)

Iridina.—Animal elongated, straight, rather thick on the back, thinner towards its inferior border; mantle delicate, terminated anteriorly by a thick border, open from the anterior muscle to two-thirds of the lower border for the passage of the foot; borders of the mantle united throughout the whole posterior part, whence spring two short and unequal tubes, with no retractor muscle to the siphons; foot compressed and sharp-edged. Shell, with an epidermis, nacreous or iridescent internally, tolerably thick, oval oblong, elongated, inauriculated, equivalve, inequilateral, the anterior end shorter than the posterior, a little gaping at either end; umbones small and projecting but little, slightly inclined; hinge very long, linear, attenuated towards the middle, often crenulated, as it were, throughout its length; ligament very long, marginal, external; muscular impressions very distinct. Example, *I. exotica*, Lam.; *I. elongata*, Sow.



Iridina exotica, one-third of natural size.

Lamarck gives the rivers of warm climates as the locality. The specimens were supposed to come from China. M. Caillaud found them in considerable abundance in the Nile; and from his specimens preserved in spirit M. Deshayes made his examination. Mr. G. B. Sowerby figures another species ('Zool. Journ.,' vol. i.), *I. Nilotica*, obtained from Sennaar by M. Caillaud, and sent to England by M. D'Audebard. It very much resembles the species given here as an example, but its hinge margin is not crenulated or dentated. M. Deshayes, in his last edition of Lamarck, makes it identical with *I. exotica*, Lam. and Desh., *Anadonta exotica*, Blainv., and Le Mutel, Adanson.

**

Hinge with Teeth.

a

Regular: Hinge-Teeth lateral and wide apart (marine).

Cardium [CARDIUM].—The species are numerous, and some grow to a very large size. M. Deshayes, in his edition of Lamarck, gives forty-eight, including *Hemicardium*, a form which Cuvier proposes to separate from the others, comprehending the species with compressed valves strongly carinated in the middle, observing that it is difficult to suppose that the animal is not modified in unison with this singular conformation. M. Rang corroborates Cuvier's observation, from the examination of many living individuals of *Cardium Cardissa*, the type; but M. Deshayes considers that the form can only be admitted as a section.

De Blainville divides the genus into the following sections:—

1. Species more or less gaping posteriorly, and with the ribs of the shell as large as the channelings. Example, *Cardium exoticum*.

2. Species not gaping, and with the ribs as large as the channelings. Example, *C. tuberculatum*.

3. Species not gaping, with the ribs larger than the channelings. Example, *C. edule*.

4. Smooth or almost smooth species. Example, *C. elongatum*.

5. Species whose anterior side is very short and nearly flat. Example, *C. hemicardium*.

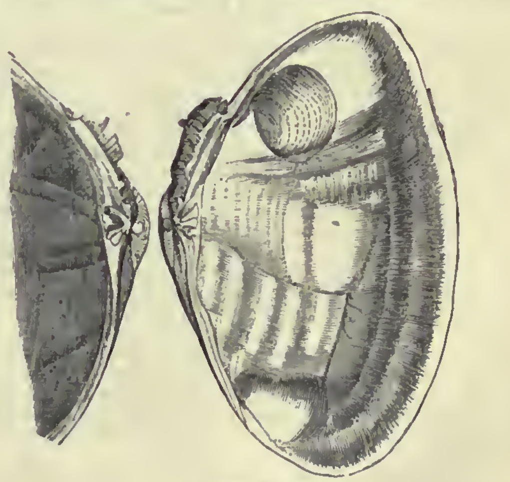
Several species have been added to this genus from the collection of Mr. Cuming.

The species of *Cardium* are found fossil.

1. Hinge of *Cardium elongatum*, natural size. 2. *Cardium* (*Hemicardium*) *Cardissa*, natural size; spotted variety.

Deshayes in his Tables gives fifty-three living species and thirty-nine fossil (tertiary), and *C. ringens*, *C. ciliare*, *C. echinatum*, *C. sulcatum*, *C. edule*, *C. tuberculatum*, and *C. planatum*, as both living and fossil species (tertiary). Of the recent species M. Deshayes, in his edition of Lamarck, where they are given as forty-eight, considers *C. Indicum*, *C. ringens*, *C. echinatum* (of which last he makes *C. tuberculatum* to be only a variety), *C. sulcatum*, and *C. edule* (common cockle) as identical with fossil species described by Brocchi and others under different names. The fossil species he makes amount to thirty. Of these he refers *C. echinatum* to its living analogue, *C. Burdigalinum* to the recent *C. Indicum*, *C. rhomböides* to the recent *C. edule*, and considers *C. diluvianum*, Lam., as identical with *C. hians*, Brocchi. The fossils occur in nearly all the fossiliferous strata from the Supracretaceous to the Grauwacke group, and appear to be most abundant in the Crag, London Clay, and Greensand and the contemporaneous beds.

Capsa.—Animal with the mantle considerably open at its ante-inferior border for the passage of a compressed and very large foot:



Capsa Braziliensis.

tubes separated and of considerable length, with tentacular papillæ at their orifices. Shell transverse, equivalve, inequilateral, not gaping;

cardinal teeth diverging from a point close to the umbo, no lateral teeth in one valve, in the other one distinct bifid cardinal tooth, and two distant very obsolete lateral ones; ligament external on the anterior side of the umbones; a large sinus in the pallial impressions.

The species are found in temperate and warm seas. They bury themselves at a small depth in the sand, where they are said to lie with the posterior part upwards to facilitate the influx of the water for respiration. The genus has been found in sandy mud and soft mud, at depths varying from five to twelve fathoms from the surface of the sea.

Mr. G. B. Sowerby has added a new species, *C. altior*, brought home by Mr. Cuming. ('Zool. Proc.')

Donax.—Animal rather compressed, more or less triangular, having the mantle bordered with tentacular appendages; labial appendages large; mouth small; branchiæ very unequal, on the same side; foot compressed, trenchant, angular; tubes separate and elongated, returning into a sinus of the mantle.

Shell more or less triangular and compressed, always longer than it is high, regular, equivalve, very inequilateral, posterior side shorter than the anterior; umbones but little prominent, and nearly vertical; hinge composed of two cardinal teeth, sometimes upon both valves, sometimes upon one only, and one or two lateral teeth more or less distant; ligament external, short and swollen; muscular impressions rounded, united by a pallial impression, which is straight and very much excavated posteriorly.

The species are widely extended. De Blainville says that they occur in all parts of the world. They plunge themselves in sand and sandy mud, where the animal lies with the short side of the shell uppermost, at a depth ranging from the surface of the sea to ten fathoms.

The species are numerous. M. Deshayes in his Tables enumerates twenty-nine living, and in his edition of Lamarck thirty of these. He considers *D. pubescens*, Linn., as having been established on a young individual of *D. scortum*; *D. granosa*, Lam., as a variety of *D. cuneata*;

Donax scortum.

D. triquetra, as approaching nearer to the *Cythereæ* than the *Donaces*; *D. ringens*, as belonging to the genus *Capsa*, Lam., if Lamarck's characters are rigorously followed; *D. cardioides* (the animal), as a proper subject for study, as it is very probable that it does not belong to the *Donaces*; the pallial impression is not notched posteriorly, and the hinge comes nearer to that of *Cardium medium* than those of the *Donaces*; and *D. Meroe* and *D. scripta*, as having more of the characters of *Cythereæ* than *Donaces*. Forbes and Hanley give the following species as British:—*D. anatinus*. It has the inner margin crenulated, and the hinge with lateral teeth. It is the *D. trunculus* of Linnæus. It is very common on all our shores. *D. politus* has the inner margin entire. It is the *D. complanatus* of Montagu, and is one of the most beautiful of our native shells. It is never common, and is much prized by collectors. It is found on the south coasts of England, and at Bantry Bay in Ireland.

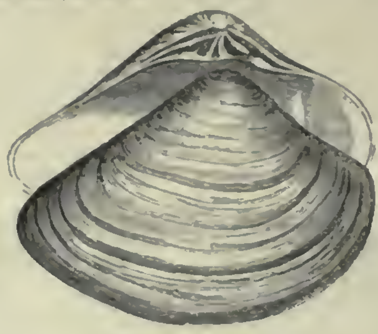
Lamarck divides the species into two sections: first, those which have the internal border of the valves entire or nearly so; second, those that have the internal border distinctly crenulated or dentated.

De Blainville separates them into five divisions, according to the shape, sculpture, and markings of the shell. His fifth division is the genus *Capsa* of Lamarck.

Mr. G. B. Sowerby, in his 'Genera of Shells,' says, "Of fossil species there are very few: Brocchi mentions two, and we possess a small one from Bordeaux, but we believe they are very scarce." De Blainville quotes Defrance for seventeen, three of which are analogues, one at Loignan, near Bordeaux, one in Italy, and a third in the environs of Paris. Deshayes in his Tables gives fifteen fossil (tertiary), and one only (*D. elongata*) as both living and fossil (tertiary). In his edition of Lamarck, the last-mentioned species is passed without any notice of its occurring in a fossil state; but *D. trunculus* is noticed as fossil, and Brocchi, 'Conch.,' t. ii., p. 537, No. 1, is quoted: nine fossil species only are given. The fossils are said to have occurred principally in the blue marls of the south of France, &c., the beds at Bordeaux and Dax, and in the oolitic group.

Gratelupia.—Shell subtrigonal, equivalve, regular, nearly equilateral, a little attenuated at its posterior part, and presenting at the postero-inferior border a slight sinuosity; umbones very small, not projecting, hardly inclined forwards; hinge with three cardinal diverging teeth in each valve, and from three to six cardini-serial teeth, lamellar, with finely dentelated edges, converging towards the summits, and situated a little below them, under the ligament; a single lateral tooth, anterior, beneath the lunule, in the left valve, corresponding with a hollow similarly situated in the right valve; ligament external, long, swollen, passing beyond the serial teeth; muscular impressions nearly equal, oval, united by a pallial impression largely and very deeply excavated posteriorly.

This genus, founded by M. Charles des Moulins, was confounded with the Donaces by M. de Basterot. M. Rang, who agrees with M. des Moulins on the propriety of this separation, says that there is but one species, *G. donaciformis*, which is fossil. It is found in the marine beds of Mérignac (tertiary). Dr. Lea, in his 'Contributions to Geology,' describes and figures another species, *G. Moulinsii*, from Claiborne, Alabama (America), here copied.



Gratelupia Moulinsii.

Tellina.—Animal generally very much compressed, considerably elongated; mantle moderately open at its antero-inferior part, and bordered with tentacular appendages; branchiæ unequal, on both sides; foot very much compressed, trenchant, and pointed before; tubes very much elongated, separated, and capable of being returned into a fold of the mantle.

Shell generally elongated, and very much compressed, equivalve, regular, sometimes slightly inequilateral; the anterior side not being always much longer than the posterior one, which is often angular, with a flexuous and irregular bend or fold at its lower border; umbones very small; hinge with three cardinal teeth, and two lateral ones which are often distant, with a hollow at their base in each valve; ligament posterior, swollen and elongated; a very small second ligament near the umbo; muscular impressions rounded; pallial impression straight, and very deeply excavated.

Lamarck makes the forms of *Tellina* and *Tellinides* distinctly generic. Mr. G. B. Sowerby follows Lamarck's arrangement, observing that of the *Tellinæ* there are many species, some of a form very much elongated in a transverse direction, as *T. rostrata*, *T. Spengleri*, &c.; others of an oval shape, some of which are rough on the outside, *T. linguafelis*, for example; others, again, nearly orbicular, *T. scobinata*, *T. carnaira*, &c.; a very few have one valve more flat than the other, *T. opercularis*, for instance: while both valves are remarkably deep in others, as in *T. lacunosa*. Of *Tellinides*, he says that the number of shells that may be ranged under it is rather considerable, although Lamarck has mentioned only one.

Both M. de Blainville and M. Rang think that these two forms belong to one genus, and M. Deshayes is of the same opinion.

The species are found in almost all seas, but more particularly in those of warm climates, where, like the *Donaces*, they live plunged in the sands and sandy mud; *Tellina* having been found in the former at depths varying from the surface of the sea to seventeen fathoms, and *Tellinides* in sandy mud at depths ranging from five to sixteen fathoms. Mr. G. B. Sowerby observes that they are commonly the prey of *Aporrhaides*, *Buccina*, and other carnivorous *Trachelipods*, which pierce the shell to devour the inhabitant.

The species are very numerous. M. Deshayes, in his Tables, makes the number of living species sixty-eight, and that of *Tellinides*, one. In his edition of Lamarck (1835), he records sixty-two only, the number of species of *Tellinides* being still one. Of these, he considers some as repetitions or varieties (*Tellina unimaculata*, *T. sulphurea*, for example, the first of which he considers a white variety of *T. radiata*, and the second as identical with *T. latirostra*, the only difference being that of colour), and others as founded merely on the difference of age, *T. chloroleuca*, for example.

Lamarck divided the species into—

1. Those with the shell transversely oblong. Example, *T. radiata.*

2. Those with the shell orbicular, or rounded oval. Example, *T. scobinata.*

De Blainville divides the genus thus:—

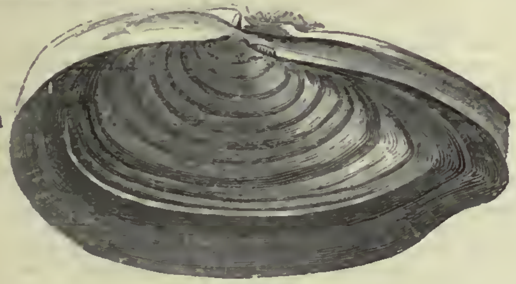
1. Subtriquetral species. Example, *T. bimaculata.*

2. Elongated species, but which have the posterior side shorter and narrower (plus étroit) than the anterior. Example, *T. radiata.*

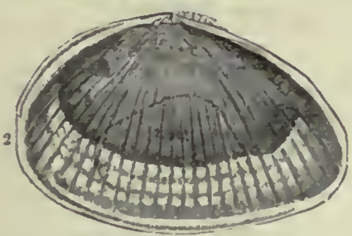
3. Oval, or suborbicular, and nearly equilateral. Example, *T. scobinata.*

4. Equilateral species, sufficiently elongated, almost without a flexuous fold; two divergent cardinal teeth, and two distant lateral ones, of which the anterior is but little distant from the umbo. (*Tellinides*, Lam.) [TELLINIDÆ.]

1



2



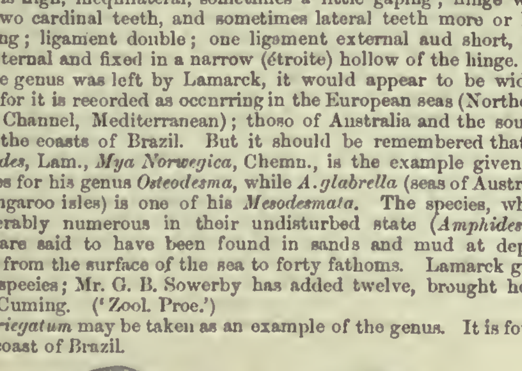
1. *Tellina rostrata.* 2. *Tellinides.*

The fossil species are recorded as occurring in the Supracretaceous group, in the Cretaceous group, and in the Oolitic group (Coralline Oolite, Yorkshire; Kimmeridge Clay; Bernese Jura). Sir R. Murchison mentions two species (probably) in the Salopian outlier of Lias.

Amphidesma.—Shell suboval or rounded, of little thickness, longer than it is high, inequilateral, sometimes a little gaping; hinge with one or two cardinal teeth, and sometimes lateral teeth more or less projecting; ligament double; one ligament external and short, the other internal and fixed in a narrow (étroite) hollow of the hinge.

As the genus was left by Lamarck, it would appear to be widely spread, for it is recorded as occurring in the European seas (Northern, English Channel, Mediterranean); those of Australia and the south; and on the coasts of Brazil. But it should be remembered that *A. corbuloides*, Lam., *Mya Norwegica*, Chemn., is the example given by Deshayes for his genus *Osteodesma*, while *A. glabrella* (seas of Australia and Kangaroo isles) is one of his *Mesodesmata.* The species, which are tolerably numerous in their undisturbed state (*Amphidesma*, Lam.), are said to have been found in sands and mud at depths varying from the surface of the sea to forty fathoms. Lamarck gives sixteen species; Mr. G. B. Sowerby has added twelve, brought home by Mr. Cuming. ('Zool. Proc.')

A. variegatum may be taken as an example of the genus. It is found on the coast of Brazil.



Amphidesma variegatum.

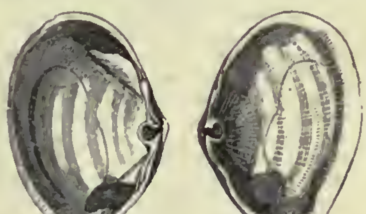
But few species have been found fossil.

Mesodesma (Deshayes).—Animal inclining to oval or subtrigonal, flattened; lobes of the mantle united for two-thirds of the posterior length, and provided, at their posterior extremity, with two short siphons prolonged within by a very delicate membrane; foot very much flattened, quadrangular, hidden in part by the branchiæ, which are short, truncated, and fixed (soudées) posteriorly, the external pair smallest and subarticulated. Shell oval, transverse or triangular, thick and ordinarily closed. Hinge with a spoon-shaped hollow, straight and mesial for the ligament, and, on each side, an oblong and simple tooth. (Deshayes.)

M. Deshayes remarks that the shells of this genus are easily recognised. The shell is always thicker than that of the *Mactræ*: they are more compressed, more completely closed (mieux fermées) and in this respect approach the *Crassatellæ.* The hinge is particularly remarkable; in the middle of the border and immediately below the umbo is placed a spoon-shaped triangular deep hollow, the border of which projects within the valves as in the greater part of the *Lutrariæ.* On each side of this spoon-like process, in which the ligament is inserted, is seen in each valve a large thick tooth, and behind is a hollow to receive the tooth of the opposite valve. Muscular impressions unequal; the anterior largest, elongated; the posterior somewhat rounded. The pallial impression in the species which approach the *Mactræ* has a moderate posterior sinuosity which diminishes more and more in proportion as the species have more resemblance to the *Crassatellæ.* The sinuosity exists however in all the species of the genus.

Cumingia (G. B. Sowerby).—A genus which should be placed near to *Amphidesma.* It is remarkable for the dissimilarity of the hinge of the two valves, one having a strong lateral tooth on each side of the ligament, and the other being entirely destitute of lateral teeth. Having only met with a small West Indian species, we could not venture to consider this genus as established, until Mr. Cuming showed us several species in his rich collection of South American and Pacific shells, one of which is sufficiently large to show the characters distinctly. ('Genera of Recent and Fossil Shells,' No. 40.) Mr. Sowerby characterises the shell as inequilateral, equivalve, with the anterior side rounded and the posterior rather acuminated. A single small anterior cardinal tooth observable in each valve: one strong lateral tooth on each side of the hinge in one valve, but no lateral tooth in the other valve; ligament internal, and affixed to a somewhat spoon-shaped pit in each valve. Muscular impressions two in each valve, lateral and distant, the anterior irregular and oblong, the posterior rounded. A very large sinus in the muscular impression of the mantle.

The species are found in the tropical seas as far as is yet known, in clay, mud, and sand, in the fissures of rocks, at a depth varying from the surface of the sea to six fathoms. No fossil species known. Example, *Cumingia mutica* (Sow.).



Cumingia mutica.

Mactra.—Animal oval, somewhat thick, with the borders of the mantle thick and simple, furnished posteriorly with two tubes but little elongated and united; branchial laminæ small and nearly equal; foot oval, trenchant, very long, angular. Shell transverse, inequilateral, subtrigonal, sometimes a little gaping at the sides; umbones protuberant; hinge with one cardinal tooth, folded into the shape of the letter V, the point being nearest the umbo and the branches diverging from it; posterior to this and very close to it is a very thin sharp tooth; sometimes the branches of the folding tooth are separated at the base, forming two diverging teeth; ligamental pit immediately behind the angular tooth and projecting within the shell. Lateral teeth, two on each side in one valve, one on each side in the other, diverging from the umbones, and very near the margin, thin, mostly elongated, and the inner ones more prominent than the outer, but in some species very short, in the thicker species perpendicularly striated. Muscular impressions two, lateral, distant; pallial impression with a small sinus. Ligament consisting of two portions (as usual), one, by far the larger, internal; the other external. In some species the umbones are separated, and the ligament forms a deep pit extending both within and without to the point of the beaks: of this *M. Spengleri* is an example.

"This genus," says Mr. G. B. Sowerby, "contains a great number of species, some of which are handsome and others very singular shells; upon examining a number of species we think it might be desirable to divide it into several genera, because we find several distinct forms in it." It is found in Europe, East and West Indies, Africa, North America, &c., buried generally in sandy mud and sands at a depth varying from the surface of the sea to 12 fathoms.

The species are numerous. Deshayes, in his Tables, gives thirty-two living; in his edition of Lamarck thirty-three; but in his opinion one of these, *M. donacia*, is not a *Mactra* but a *Mesodesma*, and others are repetitions or varieties.

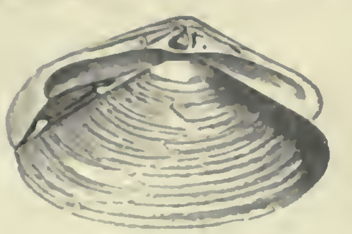
De Blainville thus divides the genus :—

1. Species whose cardinal teeth become nearly non-existent in consequence of the enlargement of the ligamental hollow. Example, *M. gigantea*.

2. Species all of whose teeth are very large, lamellar, and not striated. Example, *M. Stultorum*.

3. Thick and solid species without an epidermis; the lateral teeth finely striated; mantle pierced with two openings; but almost without tubes. Example, *M. trigonella*.

4. Very thick solid species striated longitudinally; cardinal teeth none or next to none; lateral teeth very thick, approximated, raised; an external ligament besides the internal one.



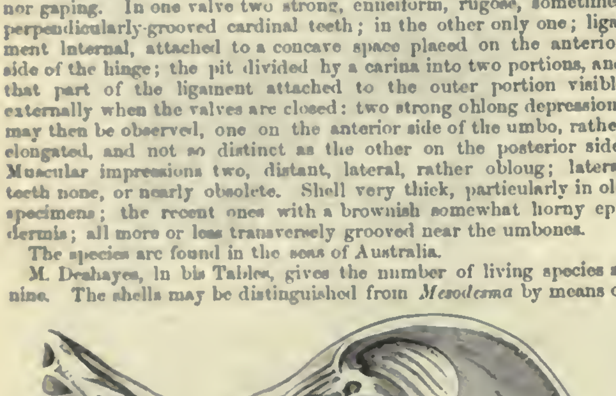
Mactra Brasiliana.

Mr. G. B. Sowerby says, "The fossil species are not numerous; they are only found in the tertiary beds, unless indeed some very singular fossils found in the secondary strata, particularly oolite, be truly referrible to this genus; of this however we cannot be certain, because we know not their hinges;" they will be found represented in Sowerby's 'Mineral Conchology.' De Blainville quotes M. Defrance for eighteen fossil species, one identical, one analogue in the Plaisantin, and another analogue "dans la Caroline du Nord." Deshayes in his Tables gives fourteen fossil (tertiary) and four as both living and fossil (tertiary): in his edition of Lamarck but three species are given as fossil only. Among the fossil shells from the borders of the Red Sea, collected by Mr. J. Burton and communicated by Mr. Greenough to Mr. Lyell, we find *M. Stultorum* with a (?). Mr. Lea gives three species, *M. dentata*, *M. Grayi*, and *M. pygmæa*, from the Claiborne beds. [MACTRIDÆ.]

Crassatella.—Shell equivalve, transverse, inequilateral, not attached nor gaping. In one valve two strong, cuneiform, rugose, sometimes perpendicularly-grooved cardinal teeth; in the other only one; ligament internal, attached to a concave space placed on the anterior side of the hinge; the pit divided by a carina into two portions, and that part of the ligament attached to the outer portion visible externally when the valves are closed: two strong oblong depressions may then be observed, one on the anterior side of the umbo, rather elongated, and not so distinct as the other on the posterior side. Muscular impressions two, distant, lateral, rather oblong; lateral teeth none, or nearly obsolete. Shell very thick, particularly in old specimens; the recent ones with a brownish somewhat horny epidermis; all more or less transversely grooved near the umbones.

The species are found in the seas of Australia.

M. Deshayes, in his Tables, gives the number of living species at nine. The shells may be distinguished from *Mesodesma* by means of



Crassatella Kingicola.

the pallial impression, which is always simple in the *Crassatellæ*, and always sinuous posteriorly in *Mesodesma*.

Mr. G. B. Sowerby, in his 'Genera,' mentions *C. tumida* and *C. compressa* from the Calcaire Grossier of the environs of Paris, and *C. sulcata* as very common at Hordwell, and as appearing to be characteristic of the London Clay. M. Deshayes remarks upon that shell, that Lamarck regarded the fossils at Beauvais and those living at Australia as analogues; but that he has satisfied himself that those fossils and *C. sulcata* are different species. *C. tumida*, he observes, approaches *C. Kingicola* nearer than any other.

De Blainville states that there are seven at least fossil in France, and that M. Defrance mentions twenty from the lower chalk with some doubt. In his Tables M. Deshayes gives twenty-four fossil species (tertiary): in his edition of Lamarck he records fourteen only. It appears in the catalogues in the Supracretaceous and Cretaceous groups.

Other genera belonging to De Blainville's *Conchacea* will be found under LITHOPHAGIDÆ, and the genera separated from *Venus*, or allied to that family, under VENERIDÆ.

CONCHI'FERA, Lamarck's name for that large class of Molluscous Animals which are protected by shells consisting of two principal pieces commonly known under the denomination of Bivalves. It comprises the whole of the Acephalous Mollusks of Cuvier, including the *Brachiopoda*. [BRACHIOPODA.]

Lamarck divided the class into two great orders, the *Dimyaria* (Dimyaires), or Conchifers, furnished with two adductor muscles, and the *Monomyaria* (Monomyaires), or Conchifers furnished with one adductor muscle only. M. Deshayes would separate the class into three sub-classes:—1, the *Polymyaria*, or *Brachiopoda*; 2, the *Dimyaria*; 3, the *Monomyaria*. He founds this order of arrangement on the principle that the organisation of the *Brachiopoda* is more simple than that of the other Conchifers, while that of the *Dimyaria* is somewhat less complex than that of the *Monomyaria*. The two last divisions are now more generally called *Lamellibranchiata*, from the fact that in nearly every case the branchiæ, or gills, occur in the form of four riband-shaped lamellæ, two of which are attached to each lobe of the mantle.

The following account of the structure of the *Conchifera* refers more especially to the *Lamellibranchiata* :—

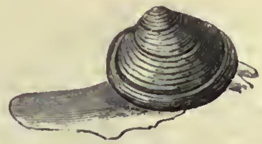
Digestive System.—Mouth without any hard parts, situated anteriorly: in the Dimyarians concealed between the foot and the anterior retractor muscle: in the Monomyarians under a sort of hood made by the mantle. Labial palps or lips flattened, sometimes truncated, sometimes laminated internally, more or less elongated, extending on either side. No salivary gland. Œsophagus varying in length and capacity, often wanting altogether both in Dimyarians and Monomyarians. Stomach sometimes, not often, lengthened and narrow, sometimes subcircular, generally pear-shaped; interior surface with irregular depressions, or biliary crypts. Intestine arising posteriorly, convoluted within the liver and ovary, and so brought towards the back and mesial line of the animal, and continued posteriorly to the vent, nearly of the same diameter all through. Rectum, which commences with the dorsal part of the intestine, shorter in the Monomyarians than in the Dimyarians: in the former it is convoluted behind the single central adductor, and terminates in a floating vent between the edges of the mantle; in the latter the vent is situated above the superior adductor. Liver very large, supported by muscular fibres, which traverse it, pouring the bile into the stomach by the biliary crypts.

Circulatory and Respiratory System.—Circulation, a simple circuit of two vascular systems, namely, a ventricle and an arterial system—a venous system and two auricles, the ventricle firmly and closely embracing the rectum, so that it appears to pass through it. The arterial system not complicated, the venous system upon a considerable scale of development. Circulating fluid nearly colourless, or white, scarcely tinged with bluish, slightly viscid, and with very little crassamentum. [BLOOD.] "Circulation then is an extremely simple function in the Conchiferous Mollusks; an aortic ventricle gives the blood impulse enough to carry it through the two systems of vessels, to expel it from the heart, and to carry it back again to the auricle. In other branchiferous animals the auricle is sometimes adapted to give the blood a new impulse when it is about to pass through the branchiæ; here, on the contrary, the auricles do not receive the blood until it has been exposed to the revivifying influence of the organs of respiration." (Deshayes.) The respiratory function is carried on by means of branchiæ variously disposed. They are all however disposed in a lamelliform manner.

The reproductive system consists simply of an ovary enveloped in the visceral mass. Taking the common oyster for example, it rests, a whitish mass of considerable size, upon the adductor, and may be seen through the mantle. It occupies the whole upper part of the mollusk, and creeps down along the sides and lower parts, being filled at the time of reproduction with a milky fluid, containing multitudes of small globules of a whitish colour. These are the eggs; and in many of the family they are not at the time of their exclusion abandoned at once, but are deposited between the two membranes of the branchial laminæ, where they undergo a kind of incubation. In some the shell is developed in the ovum before it quits this receptacle. This fostering of the eggs seems to be analogous to the gestation of the eggs in the *Crustacea* and the pipe-fishes. Sir Anthony Carlisle ('Hunterian Oration,' 1826) says, "Oysters are viviparous, and their young are found within the tracheal passages and between the folds of the coverlet (mantle) during the months of June and July in this climate. In its first state the oyster exhibits two semi-orbicular films of transparent shell, which are continually opening and closing at regular intervals. The whole brood are associated together by being involved in a viscid slime, and in that state called the 'spat,' it being common among viviparous animals of this kind to have their spawn posited in contact with the lungs. The involving slime serves as the first nutriment: and we may infer that the fœtal food so influenced by the gills is at the same time a respiratory supply to the imperfectly formed young." In the siphoniferous branch of the family the longer the siphons the larger, as a general rule, is the mass of the ovary: in those forms which have the siphons short and the foot comparatively large the ovary is comparatively small. As far as anatomy has hitherto detected this part of the organisation, here we have hermaphroditism in the true sense of the word. The whole business of reproduction is apparently carried on within the two valves of the shell without the aid of a second individual, as it is in a hermaphrodite flower. But it will occur to most observers that the *Conchifera* are gregarious; the Fixed Conchifers (Oysters, *Spondyli*, *Chamæ*, &c., for instance) eminently so; and it is by no means clear that this congregation may not be a necessary condition for the fecundation of the ova; and that there may not be a mutual diffusion of some influence analogous to that of the milt in fishes. M. Prevost, who made his experiments upon the *Uniones*, would make it appear that though there can be no union, still no propagation takes place without an assemblage of these animals upon the same spot.

The muscular system, as it regards motion, is two-fold; valvular and locomotive. The first consists in the adaptation of muscular fibre to the movement of the valves, and indeed this muscular apparatus may in some cases be made ancillary to locomotion, as in the Pectens, for example. The adductor muscles are attached to opposite points in each valve, and their office is to close the valves by their contractility, or suffer them to expand by their relaxation. In the greater number (*Dimyaria*) there are two; one anterior near the oval aperture, the other posterior. The *Monomyaria* have apparently one only; but Poli has shown that this muscle is in reality an approximation of two, and thence most probably arose the slight regard manifested by Cuvier for the division of Lamarck. The second or true locomotive organ is called the foot, and is formed of various layers of fibres, which by their counteraction bestow on it great power of motion when the organ is well developed. Though in some species merely rudimentary it is found in all the *Dimyaria*, not so in the *Monomyaria*, some of which are entirely without it. Its place may be defined by stating that the mouth is generally hidden between its base and the anterior adductor. Where well developed it is of various shapes, cylindrical, flattened, &c. In some it is a digging organ, or kind of ploughshare for making a furrow in the sand or mud wherein the animal means to lie hid; in others, as in the cockle, &c., it becomes a leaping organ, and enables the conchifer to clear a boat's gunwale when laid on the bottom boards. The foot is the instrument which produces the byssus. [BYSSUS.] The following is Deshayes's account of the structure:—"If the byssus and foot of a byssiferous mollusk be placed under a powerful lens, the last filaments of the byssus are first seen to be nearest to the base of the foot; and if the inferior edge of the foot be inspected, a fissure will be found running completely along it, at the bottom of which a brownish and semicorneous filament is often to be perceived: this is neither more nor less than a filament of the byssus prepared to be detached by the animal, in order to which the animal stretches forth its foot until it encounters the object upon which the other fibres of the byssus are fixed; to this it applies the point of the foot, which then secretes a small quantity of glutinous matter continuous with the silky filament lying along the bottom of the furrow of which we have spoken. When the pasty matter has acquired sufficient consistency, and is firmly fixed to the stone or other body at the bottom, the animal retracts its foot, and in doing so detaches the new fibre at the base of the pedicle. The mode in which the filaments of the byssus are formed is consequently entirely different from that in which hair or the horns of the higher animals are evolved, and it is easily understood when the intimate structure of the foot of the byssiferous mollusks is known, when we are aware that this organ consists in its centre of a pretty considerable fasciculus of parallel and longitudinal fibres. By a faculty peculiar to the class of animals that now engages our attention the fibres situated at the bottom of the groove of the foot become horny, and are detached in succession in the form of threads as they become consolidated." The siphons, which are the organs by which these animals take in and throw out water, are retracted by means of two lateral fan-shaped muscles, situated posteriorly.

Mantle and Cuticular System.—Two thin fleshy laminæ applied over the back of the animal, extending over its sides, and with its edges meeting along the anterior middle aspect of the body, covering, or closely in contact with, the whole interior surface of the shell, form the mantle, in the thickened edge of which is the principal apparatus that secretes the shell: there are also frequently rows of contractile tentacular cilia fringing it. The whole of these parts are exquisitely sensible, and highly contractile. The mantle becomes free at the origin of the branchiæ, and forms a cavity round the lower part of



Cycias cornea.

the animal, containing the visceral mass, the foot, for the extrusion of which there is an opening, and the branchiæ. This is the pallial sac, and is the area wherein the currents for respiration and nutrition are formed. The siphons, where they exist, project from the mantle, with which they are continuous. They are sometimes very long, and sometimes reduced to mere perforations; sometimes separate, and sometimes conjoined; but in any case the superior siphon is that destined for dejections, and is called the anal siphon, while the office of the lower one is to conduct the water to the branchiæ, whence it is termed the branchial or oral siphon. The structure of these posterior siphons or tubes is eminently contractile, and their apertures are fringed with a number of papillæ of great sensibility, capable of giving notice of the contact of any prejudicial foreign body. The retractor muscle is generally more or less developed according to the greater or less development of these parts.

The nervous system is very simple. Symmetrical in the *Dimyaria*, hardly symmetrical in the *Monomyaria*. They have no true brain. In the *Dimyaria* there is a ganglion above the œsophagus on each side of the mouth towards the labial palps, connected by a transverse filament, crossing the œsophagus. From these ganglions filaments are given off to the mouth, anterior adductor, &c.; and from their posterior edges two nervous branches go to the stomach, liver, and heart, ovary, and branchiæ. A branch of some volume goes down to the foot. The lateral filaments, after advancing along the internal surface of the posterior adductor, are conjoined into one or two ganglions larger than the anterior ones. These posterior ganglions give off the nerves to all the posterior parts; if the ganglions are much separated a nervous filament connects them. In the *Monomyaria* the system is less perfectly developed.

The senses of these animals are very limited; and indeed there is no good ground for attributing to the generality of them anything beyond a sense of touch and taste. That most of them may be conscious of the presence or absence of light is possible. "Not having any especial organs for seeing, hearing, or smelling," says Sir Anthony Carlise, speaking of the common oyster, in his 'Hunterian Oration' (1826), "the creature is limited to perceive no other impressions but those of immediate contact; and yet every part of its exterior seems to be sensible to light, sounds, odours, and liquid stimulants. It is asserted by fishermen that oysters, in confined beds, may be seen, if the water is clear, to close their shells whenever the shadow of a boat passes over them."

M. Deshayes goes so far as to say that no especial organ of sense can be detected among them, unless perhaps those of touch and taste; but we must not forget what have been called the eye-specks in *Pecten*, to the animal of which Poli gave the name of *Argus*, from the supposed number of its visual organs. The pectens are free swimmers, and, from their rapid and desultory motions, we have heard them termed the butterflies of the ocean. The manner in which these motions are executed, especially on the approach of danger, indicates the possession of a sense analogous at least to that of ordinary vision. These eye-specks may be seen in the pecten placed at short intervals round the thickened edge of the mantle, on the outworks, as it were, of the internal part of the animal fabric. "As locomotion so vision" is a general aphorism, not without its particular exception; for there is good reason for believing that *Spondylus*, which is a fixture in its adult state, is furnished with these visual specks.

The following arrangement of the *Conchifera* proposed by M. Deshayes, is published in the 'Cyclopædia of Anatomy and Physiology':—

CLASSIFICATION OF THE CONCHIFERA.

Families.

MOLLUSCA ACEPHALA BIVALVIA

- DIMYARIA ....
  - The lobes of the mantle united in a greater or less degree posteriorly ......
    - TUBICOLÆ ....: *Aspergillum*, *Clavagella* — *Fistulana*,
    - PHOLADARIÆ ....: *Septaria*, *Teredo*, *Teredina*, *Pholas*
    - OSTEODESMATA ....: *Pholadomya*, *Osteodesma*, *Periploma*, *Anatina*, *Thracia* — **Pandora*; *Corbula**, *Mya*; *Thracia*, *Corbula*, *Mya*, *Lutraria* — *Anatinella*
    - MACTRACEÆ .. ..: *Lutraria*, *Mactra*, *Mesodesma*, *Crassatella*, *Erycina*, *Amphidesma*
    - TELLINIDES ....: *Tellina*, *Psammobia*, *Donax*
    - CONCHÆ........ . . .: *Astarte*†, *Venus*‡ — Glauc-on-ome
    - CYCLADES ....: *Cyclas*, *Cyrena Cyrenella*‖, *Galathea*
    - CARDIACEÆ ....: *Cypricardia*, *Isocardia*, *Cardium*§ > *Opis*
    - TRIDACNEÆ ....: *Tridacna*, *Hippopus*
  - The lobes of the mantle disunited ....
    - NAYADES.... .. ..: *Cardita*, *Unio*
    - TRIGONEÆ ....: *Trigonia*, *Nucula*
    - ARCACEÆ ....: *Pectunculus*, *Arca*, *Cucullæa*
    - MYTILACEÆ ....: *Mytilus*, *Pinna*, *Avicula*
- MONOMYARIA
  - Having a foot..........
    - MALLEACEÆ ....: *Malleus*, *Vulsella*, *Crenatula*, *Perna* — *Gervillia*, *Inoceramus*, *Catillus*
    - PECTINIDES.... ... .: *Lima*, *Pedum*, *Pecten*, *Hinnites*, *Plicatula*, *Spondylus*
  - Having no foot ....
    - OSTRACEÆ ....: *Ostrea*¶

SOLENACEÆ: *Solenya*, *Solen*, *Panopæa*, *Glycimeris*, *Solenertus*, (from *Clavagella* and *Psammobia*)

PETRICOLÆ: *Galeommea*, *Saxicava*, *Petricola*, *Venerupis*;

LUCINIDÆ: †*Corbis*, ‖*Lucina*, *Ungulina*

CAMACEA: *Myochama*, §*Cleidothærus*, *Chama*, *Diceras**, *Etheria*

RUDISTES: **Spherulites*, *Hippurites*, *Caprina*

PLACUNIDÆ: ¶ *Placuna*, *Placunanomia*, *Anomia*†

† *Terebratula*,

The lobes of the mantle, the thick edges of which form the principal secreting organ, determine apparently the form of the shell. [SHELL, PEARL.] In the *Conchifera* it is bivalve, or composed of two pieces, often covered with an epidermis, joined at their upper edge (corresponding to the dorsal part of the animal) by a hinge.

The hinge is entirely formed by the inner layer of shell, and consists of either a simple cardinal process, or a serrated edge, or of projections, or teeth as they are called, and corresponding cavities into which they are inserted. To this hinge is superadded a ligament, which binds the two parts together, and keeps the parts composing the hinge in their places. The ligament is either internal or external, internal when it is hidden by the outside of the cardinal edge, external when it appears beyond it, and is highly elastic, being composed of a number of fibres parallel to each other, and perpendicular to the valves which they connect. This is a beautiful contrivance for the necessities of the animal. When undisturbed, the elastic ligament keeps the valves open, and the animal functions are carried on without any effort; when danger is apprehended, or circumstances require it, the adductor muscle or muscles contract, overcome the resistance of the hinge, and shut the valves close till they may be opened in safety. One of the earliest signs of the loss of vitality in the Conchifers is the more than ordinary wide gaping of the shell. This arises from the state of the adductor muscle, which being relaxed by death is no longer an antagonist to the elastic ligament.

The common oyster will serve as an example of the Monomyarians, and the cuts will give a general idea of the Dimyarians, their shell, and its muscular impressions.

CONCHODERMA. [CIRRIPEDIA.]

CONCHOLEPAS. [ENTOMOSTOMATA.]

CONCHOLOGY is that branch of science which teaches the structure and forms of the shells which are the hard external covering of the animals belonging to the class *Mollusca*. Although these shells present great variety of forms, and are variously marked, they are only a subsidiary part of the structure of the animals to which they belong. Hence amongst naturalists the shells are only studied in connection with the structure of the animals which inhabit them. An account of these animals, with their shells, will be found in the articles MOLLUSCA, BRACHIOPODA, TUNICATA, CONCHIFERA, GASTEROPODA, PTEROPODA, CEPHALOPODA; also under the heads of the more important of the families and genera of the *Mollusca*.

CONDAMINEA, a genus of Plants belonging to the natural order *Cinchonaceæ*. It has a campanulate calyx, 5-crenate or 5-toothed limb, deciduous; corolla funnel-shaped, with a somewhat curved tube, which is a little longer than the calyx, a dilated throat, and a 5-parted limb; stamens inserted above the middle of the tube or near the throat; anthers oblong, linear, bifid at the base, length of corolla; stigma 2-lobed. Capsule turbinate, truncate, opening in the middle of the cells. Seeds numerous, very small, wedge-shaped. The species are American shrubs, with 2-parted acuminate stipules and terminal many-flowered corymbs.

C. corymbosa is a native of the hills and ravines of the Peruvian Andes. It has ovate-oblong leaves, acuminate, cordate, sessile, plicated, coriaceous; corymbs large, brachiate, trichotomous; corolla purple externally, with the throat and filaments naked; teeth of the calyx broad, short, and blunt. The bark is febrifugal. The bark-gatherers of Peru are said to use this plant for adulterating samples of *Cinchona*. Its bark is only slightly bitter, and may be easily recognised by its being white inside, rather bitter, and viscid.

C. tinctoria is a native of South America, and is used occasionally as a dye.

(Lindley, *Vegetable Kingdom;* Lindley, *Flora Medica.*)

CONDOR, or *Cuntur*, one of the largest Birds belonging to the family *Vulturidæ*. Of the size and habits of this bird many exaggerated accounts were at one time current. It was compared to the Roc of the Arabian romance-writers; nay, by some it was considered identical with that monstrous oriental conception. In the 'Musæum Tradescantianum,' under title 'Clawes,' we find "the claw of the bird Rock, who, as authors report, is able to trusse an elephant." This may have been the claw of a Condor, exaggerated by some of the artists who wrought extraordinary zoological forms for the collectors of the day. Near the passage quoted there is a notice of a toucan's (Aracari's) bill, and other parts of birds from Brazil and 'the West Indies.' In the old French 'Encyclopédie,' after noticing Condamine's statement, the writer adds that it is believed that these birds exist also in the region of Sophala, of the Kaffirs, and of Monomotapa, as far as the kingdom of Angola, and that it is supposed that they do not differ from those which the Arabians call 'rouh.'

Ray, in his 'Synopsis,' confesses that such was the enormous and almost incredible magnitude attributed to it, that he at one time considered the Condor the mere offspring of fiction; that he dared not insert the bird in Willughby's 'Ornithology;' and that it was to Sir Hans Sloane, who possessed a feather plucked from the wing of one shot on the coast of Chili, and presented to him by Captain Strong, who gave him at the same time the measurement of the bird, that he first owed his belief of its existence.

Joseph Acosta, Garcilasso de la Vega, and John de Laet, all speak of this vulture. Acosta says that the birds called Condors are of great magnitude, and of such strength that they are not only able to eviscerate and devour a sheep, but even an entire calf. Garcilasso enumerates among the rapacious birds those called Cuntur, and corruptly by the Spaniards Condor, and states that some of those killed by the Spaniards measured 15 or 16 feet from tip to tip of the extended wings. He further observes that nature, in order to temper their ferocity and strength, has denied them the crooked talons which she has bestowed on the eagle, and given them claws more like those of the Gallinaceous Birds; but that she has however endowed them with a beak sufficiently strong to perforate and tear off a bull's hide, and to rip out its entrails. Two of them, he adds, will dare to attack a cow or a bull, and will devour it; "neither do they abstain from the human race, but will set upon and slay single-handed boys of ten or twelve years, and it is by a providence of nature, for the protection of the flocks and the natives, that many are not hatched; for, if they were numerous, they would cause great slaughter among the herds, and the greatest damage to the inhabitants." The account given by John de Laet, who speaks of the 'vasta moles' of the bird, is much the same with that of Garcilasso.

In relation to the Condor's alleged attack upon children, Condamine notices a story of the Indians setting up a figure of a child made of very viscous clay; on this the Condors were said to pounce, and so entangle their claws that they were held fast.

Abbeville assures his readers that it is twice the size of the most colossal eagle. Desmarchais gives eighteen feet as the extent of the wings, which, he says, are so enormous that the bird can never enter the forest; and he adds that it will attack a man, and carry off a stag. Linnæus seems to have drawn up his account of the habits of the bird from the writers above noticed, some of whom he quotes. "It preys," says Linnæus, "on calves, sheep, nay, on boys of ten years; a pair will tear up and devour a cow;" and he adds, that the rushing of its wings, as it nears the earth, renders men planet-struck, as it were, and almost deafens them—"in terram devolans, susurro attonitos et surdos fere reddit homines:" he makes the alar extent from 13 to 16 feet. These marvellous stories were left to work upon the minds of men always prone to receive the wild and the wonderful; for, till within the last forty or fifty years, one or two specimens, and those not perfect, were the only evidences of the Condor in the cabinets of Europe.

The Great Vulture of the Andes was a striking instance of the way in which things imperfectly known are exaggerated. "It was with the Condor," observes Vieillot, "as it was with the Patagonians,—"both shrank before examination." To the scrutiny of the Baron Von Humboldt and of M. Bonpland we owe the reduction of the bird to its proper dimensions. Nestling in the most solitary places, often upon the ridges of rocks which border the lower limit of perpetual snow, and crowned with its extraordinary comb, the Condor for a long time appeared to the eyes of Humboldt himself as a winged giant, and he avows that it was only the measurement of the dead bird that dissipated this optical illusion. The grand scenery among which it is found had a precisely contrary effect on Lieutenant Maw ('Journal of a Passage from the Pacific to the Atlantic'), who, in describing his descent into the deep and narrow valley of Magdalena, says: "Whilst descending, several condors hovered round us, and about the rocks on which they build their nests; but so vast was the scale of the rocks and mountains, that even these immense birds appeared quite insignificant, and I doubted for a time that they were condors."

Under the name of Zopilote, a word derived from the Mexican word Tzopilotl, which is said to signify 'King of the Vultures,' M. Vieillot places the Condor in the same genus with the bird usually termed 'the King of the Vultures' (*Vultur papa* of Linnæus and others), and the Californian Vulture (*Vultur Californianus*, Latham and others). His Latin name for this genus is *Gypagus*. Mr. Bennett adopts this arrangement, and, as his description of the bird is accurate, and evidently made from personal observation, we give it the preference. "The condor," writes Mr. Bennett, "forms the type of a genus, a second species of which is the *Vultur papa* of Linnæus, the 'King of the Vultures' of British writers. They are both peculiar to the New World, but approach in their most essential characters very closely to the vultures of the Old Continent, differing from the latter principally in the large fleshy or rather cartilaginous caruncle which surmounts their beaks; in the large size of their oval and longitudinal nostrils, placed almost at the very extremity of the cere; and in the comparative length of their quill-feathers, the third being the longest of the series. The most important of these differences—the size and position of their nostrils—appears to be well calculated to add to the already highly powerful sense of smell possessed by the typical vultures, and for which these birds have been almost proverbially celebrated from the earliest ages. There is also a third species, the Californian vulture, two noble specimens of which, the only pair in Europe, are preserved in the Society's museum, rivalling the condor in bulk, and agreeing in every respect with the generic characters of the group, except in the existence of the caruncle, of which they are entirely destitute.

"In size, the condor is little, if at all, superior to the bearded griffin (the Lämmergeyer of the Alps), with which Buffon was disposed conjecturally to confound it, but to which it bears at most but a distant relation. The greatest authentic measurement scarcely carries the extent of its wings byond 14 feet; and it appears rarely to attain so gigantic a size. M. Humboldt met with none that exceeded 9 feet, and was assured by many credible inhabitants of the province of Quito that they had never shot any that measured more than 11 feet. The length of a male specimen somewhat less than 9 feet in expanse, was 3 feet 3 inches from the tip of the beak to the extremity of the tail; and its height, when perching, with the neck partly withdrawn, 2 feet 8 inches. Its beak was 2¾ inches in length, and an inch and a quarter in depth when closed.

"The beak of the condor is straight at the base, but the upper mandible becomes arched towards the point, and terminates in a strong and well-curved hook. The basal half is of an ash brown, and the remaining portion towards the point is nearly white. The head and neck are bare of feathers, and covered with a hard, wrinkled, dusky reddish skin, on which are scattered some short brown or blackish hairs. On the top of the head, which is much flattened above and extending some distance along the beak, is attached an oblong firm caruncle or comb, covered by a continuation of the skin which invests the head. This organ is peculiar to the male. It is connected to the beak only in its anterior part, and is separated from it at the base in such a manner as to allow of a free passage of the air to the large oval nostrils which are situated beneath it at that part. Behind the eyes, which are somewhat elongated and not sunk beneath the general surface of the head, the skin of the neck is, as it were, gathered into a series of descending folds, extending obliquely from the back of the head over the temples to the under side of the neck, and there connected anteriorly with a lax membrane or wattle, capable of being dilated at pleasure, like that of the common turkey. The neck is marked by numerous deep parallel folds, produced by the habit of retracting the head, in which the bird indulges when at rest. In this position scarcely any part of the neck is visible.

"Round the lower part of the neck both sexes, the female as well as the male, are furnished with a broad white ruff of downy feathers, which forms the line of separation between the naked skin above and the true feathers covering the body below it. All the other feathers, with the exception of the wing-coverts and the secondary quill-feathers, are of a bright black, generally mingled with a grayish tinge of greater or less intensity. In the female the wing-coverts are blackish gray; but the males have their points, and frequently as much as half their length, white. The wings of the latter are consequently distinguished from those of the female by their large white patches. The secondary quill-feathers of both sexes are white on the outer side. The tail is short and wedge-shaped. The legs are excessively thick and powerful, and are coloured of a bluish-gray, intermingled with whitish streaks. Their elongated toes are united at the base by a loose but very apparent membrane, and are terminated by long black talons of considerable thickness, but very little curved. The hinder toe is much shorter than the rest, and its talon, although more distinctly curved, is equally wanting in strength; a deficiency which renders the foot much less powerful as an organ of prehension than that of any other of the large birds of the raptorial order."

This bird is found in the Andes, and the greater part of the vast mountain chain which runs up South America to 7° N. lat., but most common in Peru and Chili.

The Condor is found most frequently at an elevation of from 10,000 to 15,000 feet above the level of the sea, and there they are to be seen in groups of three or four, but never in large companies, like the true vultures. Many of the clusters of rocks and of the elevated plateaux are named after them Cuntur Kahua, Cuntur Palti, and Cuntur Huacana, for example—names which, in the language of the Incas, are said to signify the Condor's Look-out, the Condor's Roost, and the Condor's Nest. In this rarefied atmosphere the bird breathes freely, and resorts to the plains only when impelled by hunger. Then two of them will attack the vicuña, the guanaco, the heifer, and even the puma, the lion of South America, persecuting the tormented quadruped till overpowered it falls beneath the wounds inflicted by their claws and beaks, groaning and protruding its tongue. Upon this and the eyes, their favourite morsels, the Condors instantly seize, and the bloody banquet is continued till they are quite gorged. Humboldt saw them after such repasts sitting sullen and sombre on the rocks; and when thus overloaded, they will suffer themselves to be driven before the hunter rather than take wing. But he has also seen them, when on the look-out for prey, and especially on serene days, soaring at a prodigious height, as if for the purpose of commanding the most extensive view. "C'est l'oiseau," says Cuvier, speaking of the Condor, "qui s'élève le plus haut." With regard to the stories of their carrying off children, Humboldt never heard of an instance, although the infants of the Indians who gather snow for sale are frequently left sleeping in the open air in the midst of the haunts of these birds. He often approached within a few feet of three or four of them as they sat on the rocks, but they never manifested any disposition to attack him: and the Indians of Quito assured him that men have nothing to fear from Condors: he admits indeed that two of these vultures would be dangerous antagonists for a single man to cope with; and Sir Francis Head describes a severe struggle between one of them and a Cornish miner, with his usual graphic power. When the bird descends into the plains, it rarely perches on trees, preferring the ground, for standing and walking on which its toes and straight claws are better adapted.

Humboldt was assured that the eggs, which are white, and three or four inches in length, are deposited on the bare rock without any border of straw or other defence. The young ones are said to remain with the female during one year. The nestlings have no feathers; their bodies for some months are covered with a very fine curling whitish down or hair, something like that of young owls; and they are so puffed out by this envelope, that they look almost larger than adults. At the age of two years the Condor is not yet black, but of a yellowish-brown; up to this time the female has no appearance of the white ruff (*golilla* of the Spaniards), and it is owing to want of observation on this change of plumage that many naturalists and travellers—nay, the inhabitants of Peru themselves—talk of two species of Condor, the black and the brown (Condor negro y Condor pardo). Thus Lieutenant Maw, in the sequel to the passage above quoted, says, "There were two kinds of Condors; one dark-brown, the other white on the back, with half the upper side of the wings next the back, and a white ring round the neck."

At Peru, Quito, and in the province of Popayne, Condors are taken alive with the lasso. To this end a cow or a horse is killed. Down come the Condors, and are permitted to gorge themselves. Then the Indians, with their lassoes, appear on the scene, and soon capture them. When one of the birds finds itself hampered, it makes incredible efforts to raise itself in the air, and succeeds, after vomiting freely. The Spaniards call this sport 'correr Buitres,' and it is, next to the bull-feasts, the great amusement of the country people. In other countries it is said that poisonous herbs are placed in the belly of the quadruped that serves as a bait, and then the Condors appear as if intoxicated after their meal.

The tenacity of life exhibited by the Condor almost rivals the endurance of the Grisly Bear. [BEAR.] Humboldt relates that at Riobamba he saw some Indians first strangle one with a lasso and hang it on a tree, pulling it forcibly by the feet for some minutes. The lasso was hardly removed when the Condor arose, and walked about as if nothing extraordinary had happened. At less than four paces, three balls were then discharged from a pistol at it, all of which entered its body, wounding it in the neck, chest, and abdomen: the bird still kept its legs. Another ball broke its thigh, and brought it to the ground; but the wretched creature did not die till after an interval of half an hour. Ulloa asserts that in the colder parts of Peru the skin of the Condor is so closely covered with feathers, that eight or ten balls may be heard to strike it without penetrating its body.

This celebrated vulture, *Vultur Gryphus* of Linnæus, *Gypagus Gryffus* of Vieillot, *Sarcoramphus Gryphus* of Duméril, is said to possess a most exquisite sense of smelling. It may be doubted however whether, as in other vultures, the eye is not at least as great an assistant to the bird in discovering its prey as the nostrils are. [BIRDS.] Lieutenant Maw saw the Condor's quill used as a pen in the Cordillera (Toulca).

The Condor (*Sarcoramphus Gryphus*, male).

The Zoological Society of London have now made this bird, of which such romantic tales were told and credited, familiar to the whole population of the metropolis. It is a striking contrast to rise from the perusal of one of these marvellous stories, and look at the living bird in the Regent's Park.

CONDROLITE. [MACLURITE.]

CONDURRITE, a Mineral found in Cornwall. It is an arsenate of copper of a brownish-black or blue colour. It gives out, like the other arsenates, an alliaceous odour when heated on charcoal before the blow-pipe.

CONDYLU'RA, Illiger, a genus of Insectivorous *Mammalia*, founded on the *Sorex cristatus* of Linnæus. Cuvier observes that Desmarest was the first who made the peculiar dentition of the genus known.

It has the following characters:—Body thick, furry; muzzle much elongated, bordered with membranous crests, disposed star-like round the opening of the nostrils; no external auricles; eyes extremely small; anterior feet short, large, with five toes, furnished with robust claws proper for digging; posterior feet slender, with five toes: length of tail moderate.

$$\text{Incisors, } \frac{2}{4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{8-8}{7-7}=40.$$

Teeth of *Condylura cristata* (F. Cuvier).

Lesson observes that the generic name rests on an error made by La Faille, who had represented the radiated mole with knotty swellings on the tail; but it is generally received by zoologists. The genus is allied to the Moles and to *Scalops*.

The species are entirely confined to North America, as far as is known at present. Speaking of some specimens of *Condylura longicaudata* in the Museum of the Zoological Society, obtained from Moose Factory, Hudson's Bay, Sir John Richardson says, "They were not accompanied by any account of their habits, or notice of the exact locality where they were killed; but, as the most southern fur posts depending upon Moose Factory are situated upon the borders of Lake Superior, it is probable that they came from that quarter. Pennant's specimen was received from New York."

C. macroura (Harlan), the Thick-Tailed Star-Nose. The following is Sir John Richardson's description of a specimen presented to him by the unfortunate Mr. David Douglas, and which the latter had procured on the banks of the Columbia River.

"The head is remarkably large; the body is thick and short, and becomes narrower towards the tail, and the hind legs are consequently nearer to each other than the fore ones. The nose is rather thick, and projects beyond the mouth; it is naked towards its end, is marked with a furrow above, and terminates in a flat surface, which is surrounded by 17 cartilaginous processes, with two more anterior ones situated above the nostrils, and a pair of forked ones immediately below the nostrils. The surfaces of these processes are minutely granulated. Some white whiskers spring from the side of the nose, and reach about half the length of the head. There are others not so long on the upper and under lips. The fur on the body is very soft and fine, and has considerable lustre. It is longer than the fur of the other two known species. Its colour on the dorsal aspect is dark umber-brown, approaching to blackish-brown. On the belly it is pale liver-brown. When the fur is blown aside, it exhibits a shining blackish-gray colour towards its roots. It is longer on the hind-head and neck than on the belly. The tail is narrow at its origin, but it suddenly swells to an inch and a half in circumference; it then tapers gradually until it ends in a fine point, formed by a pencil of hairs, about half an inch long. It is round, or very slightly compressed, and is covered with scales about as large as those on the feet, and with short, tapering, acute hairs, which do not conceal the scales. The hairs covering the upper surface of the tail are nearly black; those beneath are of a browner hue. The extremities are shaped almost precisely like those of the *C. longicaudata*. Only the palms and toes of the fore feet project beyond the body. The palms are nearly circular, and are protected by a granulated skin like shagreen. The sides of the feet are furnished with long white hairs, which curve in over the palms. The five toes are very short, equal to each other in length, and, together with the back of the hands, are covered with hexagonal scales. The fore claws are white, nearly straight, broadly linear, and acute, convex above and flat beneath. The palms turn obliquely outwards, which causes the fourth claw to project rather farthest; but the third one measures as much, the second is shorter, and the first and fifth are equal to each other, and a little shorter than the rest. The hind feet are also turned obliquely outwards, and are scaly, with a few interspersed hairs above, and granulated underneath. The sides are narrow, and present a conspicuous callous tubercle, posterior to the origin of the inner toe. The hind legs are very short, and are clothed with soft brown hair, a tuft of which curves over the heel. There are no hairs on the sides of the hind feet, like those which form a margin to the fore ones. The hind toes are longer than the fore ones, and are armed with more slender claws, which are white, awl-shaped, curved, and acute. They have a narrow groove towards their points underneath. Length of the head and body 4 inches 3 lines; of the head, 1 inch 6 lines; of the tail, 2 inches 6 lines, including the pencil of hairs at its extremity, 3 inches 3 lines; naked part of the nose, exclusive of the awl-shaped processes, $2\frac{1}{4}$ lines," &c. ('Fauna Boreali-Americana.')

Thick-Tailed Star-Nose (*Condylura macroura*).

Dr. Godman observes, that though the external ear in *C. cristata* is destitute of auricle, it is very extensive, and is situated at a short distance from the shoulder, in the broad triangular fold of integument connecting the fore-arm and head.

Two or three other species are known.

CONESSI BARK is the produce of a plant belonging to the natural order *Apocynaceæ*, a native of the western coast of Hindustan. It is the *Wrightia antidysenterica*, and is a valuable astringent.

CONFERVACEÆ, a name sometimes considered synonymous with *Algæ*. It is limited in systematic botany to a section of *Algæ*, consisting of simple tubular jointed species inhabiting fresh water. [ALGÆ.]

CONFERVITES, species of Fossil Plants, probably of the Confervaceous Family, occurring in the chalk of Bornholm and the south of England, in the Greensand of Maidstone, and Chalk-Marl of Hamsey. (Mantell.)

CONGER-EEL. [MURÆNIDÆ.]

CONGLOMERATE. This term is most usually applied by geologists to designate rocks more or less distinctly inclosing displaced fragments of mineral masses which had been consolidated at some previous epoch, and subsequently broken up, removed from their original site, and placed in circumstances such as to permit of their being re-aggregated, and more or less cemented together by intervening smaller particles. Thus the old red conglomerate on the borders of the Grampians is full of fragments of the still more ancient schistose and gneissic strata, worn by attrition in water, and reunited into a solid rock by interposed red sands. In some volcanic regions the materials thrown out by eruptions are re-aggregated into conglomerate, by the operation of water.

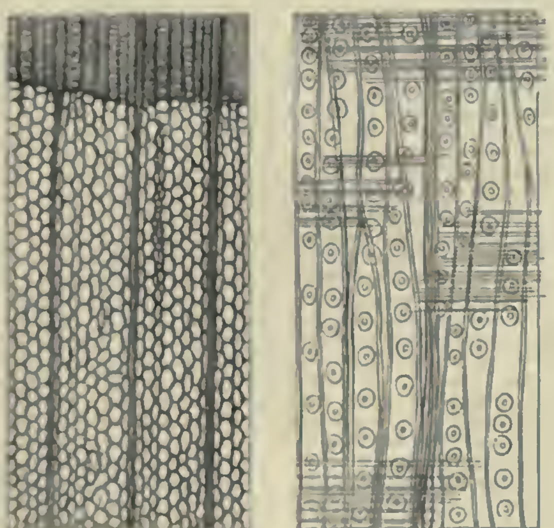
The coarser conglomerates are sometimes called Pudding-Stone. Conglomerates differ in their nature, and vary in the size of their component parts according to the process by which they have been brought into the form of conglomerate. Along the base of the Maritime Alps the rivers, with few exceptions, are now forming conglomerate and sand. (Lyell's 'Geology.') Near Nice the mud, pebbles, and portions of rock brought down by the torrents form beds of shingle; but the greater part are swept into the deep sea, where they form strata of inclined conglomerate, about 1000 feet in thickness and 7 or 8 miles in length. Volcanic eruptions also tend to the formation of conglomerate by uniting masses of rock together. Conglomerates, as already observed, to whatever causes owing, are characterised by being manifestly a congeries of fragments of rock, of various sizes, which have undergone the process of attrition, and consequently have been formed by fragments of various rocks that have been carried considerable distances. [BRECCIA.] Many of these conglomerates are sometimes so well compacted as to form a hard rock, capable of receiving a considerable degree of polish, as we observe in two colossal fragments of heads in the British Museum, the faces of which are tolerably smoothed by Egyptian art, while the broken parts exhibit a conglomerate consisting of irregular-sized rounded grains, and masses of quartz and other rocks. According as they consist of granite, quartz, limestone, &c., they are called granitic, quartzose, calcareous. In building, the conglomerates are generally only employed for the coarser kinds of work, as for foundations and the abutments of bridges.

CONIDÆ, a family of Gasteropodous *Mollusca*, including the genera *Conus* [CONUS] and *Pleurotoma* [PLEUROTOMA]. They are characterised by the shell being inversely conical; the aperture long and narrow; the outer lip notched at or near the suture; operculum minute and lamellar. The animal has an oblong foot truncated in front, with a conspicuous pore in the middle. The head is produced, and the tentacles are far apart. The eyes are attached to the tentacles. The gills are two. The lingual teeth are in pairs, elongate, subulate, or hastate.

Lamarck records nine fossil species of *Conidæ*. Deshayes in his 'Tables' makes the number forty-nine (tertiary), one of which, *C. Mediterraneus*, he gives as both living and fossil (tertiary). Mr. G. B. Sowerby ('Genera') says:—"Fossil cones are not unfrequent; but we believe that they occur only in the newer strata, or those above the chalk, such as the London Clay and Crag in England, the Calcaire Grossier in France, and the contemporaneous beds in other countries. There are a few seen in collections, filled with a coarse dark-green arenaceous substance; these belong to the Terrains Calcareo-Trappéens of Brongniart. Doubtful casts are met with in the inferior Oolite, according to Conybeare and Phillips." The same author gives a figure of *C. dormitor*, a fossil from Barton, approaching very near to a *Pleurotoma*. Many species are found in the blue marls of the south of France (M. Marcel de Serres). M. de Basterot gives many from Bordeaux and Dax, &c.; one of them, *C. deperditus* of Lamarck, as analogous to the existing species at Owhyhee. Among the fossil species from the western borders of the Red Sea, collected by Mr. James Burton, named by Dr. J. E. Gray and Mr. Frembley, and communicated to Sir Charles Lyell by Mr. Greenough, are twelve species all living; but neither *C. Mediterraneus* nor *C. deperditus* appears in the list.

Tennant in his List of British Fossils records three species of *Pleurotoma* in the Crag and nineteen in the London Clay, and nine species of *Conus* in the latter formation.

CONIFERÆ, a natural order of Gymnospermous Exogens (called by Dr. Lindley *Pinaceæ*), consisting of resinous, mostly evergreen, hard-leaved trees or shrubs, inhabiting all those parts of the world in which arborescent plants can exist. Under this name are collected the various races of fir-trees, pines, cedars, junipers, cypresses, and the like, which, however dissimilar they may at first sight appear, correspond not only in their universally terebintaceous sap, but in the following points of organisation:—They all branch from numerous buds, proceeding from the side of a main stem. Their wood consists of tubes of nearly equal diameter, among which there are here and there fistular cavities which receive the resin that exudes from the wood. The sides of the woody tubes are marked by circular discs, which when highly magnified appear as if consisting of a smaller internal and a large external circle: the nature and use of these discs are unknown. The following cut represents highly-magnified sections of a piece of deal. A shows the nearly equal size of the woody tubes when viewed transversely; B is a perpendicular section with the discs seen on the sides of the tubes.



A B

The leaves are articulated with the stem, and very often are linear, veinless, and sharp-pointed; but in some cases, as *Salisburia adiantifolia*, *fig.* 1, and *Podocarpus aspleniifolia*, *fig.* 2, the leaves become broad, and then they are filled with veins, which are all of the same size, and branch by repeatedly forking; a mode of veining known only in these plants and in ferns. The flowers are collected in little scaly cones; males in one cone and females in another. The females have no pericarpial covering, but consist of naked ovules, to which fertilisation is communicated directly from the pollen, without the interposition of a style or stigma. When the fruit is ripe it consists of a certain number of scales collected into a cone, and inclosing the naked seeds in their axils. Sometimes such scales are thin as in the larch, or hard and long as in the pine, or even succulent as in the juniper, whose berries, as they are named, are small cones with succulent consolidated scales.

Fig. 1. Fig. 2.

Salisburia adiantifolia. *Podocarpus aspleniifolia.*

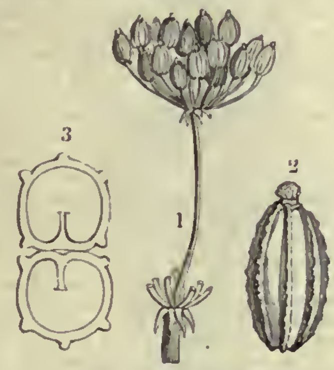
Lindley places this order between the *Cycadaceæ* and *Taxaceæ*. There are 20 genera and above 100 species, which include trees and shrubs of universal importance to mankind. Gigantic in size, rapid in growth, noble in aspect, robust in constitution, these trees form a considerable proportion of woods and plantations in cultivated countries, and of forests where nature remains in temperate countries in a savage state. They are natives of various parts of the world, from the perpetual snows of arctic America to the hottest regions of the Indian Archipelago. The principal part of the order is found in temperate climates. In Europe, Siberia, China, and the temperate parts of North America, the species are exceedingly abundant. The timber of these trees is exceedingly valuable in commerce, and is known under the names of Deal, Fir, Pine, and Cedar. Their resinous secretions are also well known by the names of Oil of Turpentine, Burgundy Pitch, Canadian Balsam, &c. The common Larch yields Venetian Turpentine; Liquid Storax is procured from a species of Pine; the branches of the Hemlock Spruce are used in making spruce beer; and the Savin, which is well known in medicine, is a species of Juniper.

CONIROSTRES, a family of Birds, the third amongst Cuvier's *Passeres*. It comprises those genera which have a strong bill, more or less conical, and without notches. Cuvier says that they live exclusively upon seeds, in proportion as their bill is more or less thick. The *Conirostres* form one of the five tribes of the order *Insessores* of Mr. Vigors. [BIRDS.]

CONIUM, a genus of Plants belonging to the natural order *Apiaceæ*, or *Umbelliferæ*. It has an obsolete calyx; petals obcordate, somewhat emarginate, with a very short inflexed lobe. Fruit compressed at the side; ovate. Half-fruits with five prominent equal undulated ridges, of which the lateral are on the border. Channels with many striæ, but no vittæ. Biennials. Root fusiform; stem taper-branched; leaves decompound; both involucres 3-5-leaved, the partial one-halved. Fowers white, all fertile.

C. maculatum, Hemlock, is found in waste places throughout Europe, the east of Asia, and the cultivated parts of America. It possesses highly narcotic and dangerous qualities, but is used medicinally as a remedy in nervous affections. It has a white fusiform biennial root; an erect branched bright-green spotted stem, from five to ten feet high, on which are planted so many smooth finely cut large fern-like leaves. When very healthy, and growing in a spot where it is neither injured by storms nor disfigured by dust, the Hemlock is one of the most noble of our wild plants. Its little greenish white flowers, arranged in umbels after the manner of its order, have a minute involucre of several leaves at the base; and the partial umbels have three or four short oval leaflets on one side. The fruit is globular, each half having five projecting angles, which are slightly crenelled, without either vittæ or appendages or projections between them. It grows in wild places, sometimes by the sides of ditches in meadows, but more frequently in light upland pastures, flowering in June and July. It is almost the only wild umbelliferous plant whose fruit is destitute of vittæ, and consequently not aromatic.

It is necessary to pay the greatest attention to the botanical characters of *Conium maculatum*, in order that the genuine plant may be collected. Sometimes plants resembling it are collected, which are almost or entirely inert when employed as a medicine; or plants possessed of greater potency are used in its stead, from which fatal results have followed. It is a "well-known circumstance that the greatest discrepancy prevails among medical men as to the activity of hemlock, not merely as a remedy but also as a poison." This discrepancy admits of satisfactory explanation on several grounds. The activity of the plant—even supposing the proper one to be collected—depends greatly upon its place of growth, the kind of season, the time when collected, and the means employed to dry it or form it into an extract; on the temperature and dryness of the place where it is preserved, and on the length of time it has been kept. In the



Fruit of *Conium maculatum.*

1, a partial umbel, loaded with fruit, natural size; 2, the back view of a fruit, much magnified; 3, a transverse section of the same, showing the ridges, the absence of vittæ, and the involute albumen.

south of Europe it is much more energetic than in the north, owing to the greater intensity of light; even in the southern provinces of France it is more powerful than in the northern. The wild plant, growing in well-exposed situations, is always to be preferred to a cultivated one; the kind of season markedly influences its power, which is greatest in a dry sunny season, and least in a wet gloomy one. The leaves during the first year of growth possess little potency; nor do they possess much during the early period of the second, till the flower-stem is developed, and the flowers are about to expand. If this period, which is the fittest time for collecting the leaves, is allowed to pass, it is better to wait two months longer, and collect the fruits instead, as they become the recipient of the active principle. The leaves should be dried quickly, but not by the application of a high temperature; they should never be powdered till the time when it is intended to use them, but preserved meanwhile in a cool dry place. If an extract be formed which requires much care in the preparation, it can rarely be kept beyond twelve months. A fresh supply of leaves, fruits, or extract, should consequently be procured every year, and the former thrown away, as the action of time or heat volatilises the active principle (Conia), and renders the residue nearly inert. When these precautions are attended to, Hemlock is a medicine of great power and unquestionable value.

The fresh leaves are dark green, shining: odour strong, stupifying, unpleasant, resembling that of mice, or the urinous odour of fresh Spanish Flies; when dried the colour is lighter, a grayish green; the taste is disagreeably saline, nauseously bitter, and at last somewhat acrid. The expressed juice is green.

According to Linnæus, sheep eat the leaves, but horses, cows, and goats refuse it. Ray informs us that the thrush will feed upon the seeds even when corn is to be had. The first physician who endeavoured to bring hemlock into repute as a medicine was Baron Stoerck of Vienna, who announced that it exerted extraordinary effects on the most inveterate chronic disorders in 1760. The whole plant is a virulent poison, but varying much in strength according to circumstances. When taken in an over dose it produces vertigo, dimness of sight, nausea, and paralysis of the limbs. In small doses however it is found very useful in scirrhus, scrofulous tumours, dropsy, epilepsy, and as an anodyne. Dr. Pereira and Dr. Christison recommend an alcoholic tincture of the bruised ripe fruit instead of the leaves.

In what way hemlock proves useful as a remedial agent in many diseases is by no means clear, unless it be by allaying irritability in the diseased parts, and giving an opportunity to the vital powers to recover their heathful action. That it lessens irritability in many diseased organs is certain, from the effects of the administration of even a few doses, especially in many cases of scrofulous affections, and above all from allaying the irritation of the lungs during the formation of tubercles, and indeed during all the subsequent stages of consumption. Even when inhaled along with the vapour of warm water the same good effect is said to follow, but this is rather doubtful. Its beneficial influence over external ulcers is however open to observation; and John Hunter remarked, that under the combined action of conium and cinchona-bark, many obstinate buboes, which resisted every other mode of treatment, soon took on a healing process. Many irritable or painful ulcers are soothed and improved by a hemlock poultice. Rheumatic pains, and those attending nodes, are said to be effectually allayed by conium and ipecacuanha. From the very decided sedative action of conia on the spinal cord, Dr. Gordon has suggested that it will prove a useful remedy in tetanus and other spasmodic diseases.

Dr. Christison is of opinion that the *Conium maculatum* of the present day is not the plant which furnished the poison employed to dispatch Phocion and Socrates. Waller considers it to have been *Cicuta virosa.* [CONIA, in ARTS AND SC. DIV.]

For further particulars with regard to the subject of this article we refer to Dr. Christison's 'Memoir on the Poisonous Properties of Hemlock and its Alcaloid, Conia.' ('Transactions of the Royal Society of Edinburgh,' vol. xiii.)

CONNARACEÆ, a natural order of tropical Trees or Shrubs allied to *Anacardiaceæ* and *Leguminosæ*. It contains 5 genera and about 40 species. The leaves are compound, not dotted, alternate, without stipules. The flowers terminal and axillary, in racemes or panicles, with bracts. Calyx 5-parted, regular, persistent; æstivation either imbricated or valvular. Petals 5, inserted on the calyx, imbricated, rarely valvate in æstivation. Stamens twice the number of petals, hypogynous, those opposite the petals shorter than the others; filaments usually monadelphous. Carpels solitary or several, each with a separate style and stigma. Ovules 2, collateral, orthotropal,

Connarus Asiaticus.

1, an expanded flower, much magnified; 2, its stamens and styles; 3, a section across the ovary.

ascending; styles terminal; stigmas usually dilated. Fruit dehiscent, follicular, splitting lengthwise internally. Seeds erect, in pairs or solitary, with or without albumen, often with an aril; radicle superior, at the extremity opposite the hilum; cotyledons thick in the species without albumen, foliaceous in those with albumen. Brown says the genus can be distinguished from Leguminous plants by the relation which parts of its embryo bear to the umbilicus of the seed; that is to say, by the radicle being at the extremity most remote from the hilum. From *Anacardiaceæ* and others they are at once known by their total want of resinous juice and their orthotropal ovules.

The species are all tropical; most common in America. The beautiful zebra-wood now so much used by cabinet-makers is ascertained to be produced by *Omphalobium Lamberti*, a large Guyana tree of this order.

CONNOCHETES. [ANTILOPEÆ.]

CONNOR, a Fish belonging to the family *Labridæ.* [CRENILABRUS.]

CONO'CERAS, a genus of *Cephalopoda*, fossil on Lake Huron. Bronn founds the characters of it on the form of the septa, which are convex towards the base of the cone.

CONOELIX, CONŒLIX, or CONOHELIX, a genus of Turbinated *Mollusca*, established by Mr. Swainson for a group which, in his opinion, "form a beautifully defined link connecting the Cones with the Volutes, strictly so termed." It has the following generic character:—"Shell coniform. Spire very short. Outer lip simple. Columella or pillar plaited. Aperture linear, narrow, longer than the spire. Generic type, *Conolix lineatus*." (Swainson.)

Mr. Swainson ('Zoological Illustrations') figures three species, and mentions that several specimens are in the Banksian collection from the Pelew Islands. To one of these species in that collection, Taheite, usually called Otaheite, is given as a locality. Mr. Cuming brought home another species, *C. Virgo*, which Mr. Swainson considers as representing *Conus Virgo*, from the reefs at the island of Rictea. It was in shallow water.

C. lineatus. "Shell smooth, whitish, with transverse capillary fulvous lines. Spire depressed, the apex prominent. Pillar six-plaited. Inhabits the South Seas (?)." (Swainson.) The figures, which are of the natural size, are copied from the accurate drawing in the 'Zoological Illustrations.' All the other known species are comparatively small.

Conolix lineatus.

De Blainville divides the genus *Mitra* into five sections, and makes his fifth consist of *Imbricaria*, Schum., and *Conolix*, Sow., meaning Sowerby; but the genus is Swainson's, and is generally adopted.

CONOPS, a genus of Insects belonging to the order *Diptera* and the family *Conopidæ*. The family *Conopidæ* is thus characterised:—Proboscis distinct, last joints of antennæ forming a short style. Wings perfect. Cubital vein simple; brachial veins without spurious vein; axillary lobe rounded. Halteres uncovered.

The genus *Conops* has the following characters:—Body of middle size, rather slender, generally adorned with yellow or red bands. Head thick, vesiculose, the crown especially, with a transverse vesicular tubercle; front broad in both sexes. Eyes prominent, oblong; ocelli none. Proboscis long, porrect, stiff, clavate, horizontal, or somewhat raised into a curve, geniculate at the base, arched above, hollow beneath, obliquely notched at the tip, much shorter than the labium. Lingua slender, filiform, transparent. Palpi uniarticulate, short, very small, fringed at the tips with fine bristles. Labium obliquely porrect, cylindrical, twice the length of the lingua, narrower towards the tip, most slender in the male, bilobed, slightly hairy, and with three shallow transverse furrows at the tip. Antennæ about as long as the head, porrect, seated on a tubercle, approximate at the base, diverging thence; first joint short, cylindrical, pubescent, forming an angle with the second; second long, sub-clavate; third conical, shorter than the second; fourth very short; fifth and sixth larger, widened on one side; sixth and seventh like a little spine. Thorax almost quadrate, slightly convex above, with a scapula on each side; scutellum small, semicircular. Wings lanceolate, finely pubescent, incumbent, and parallel in repose, præbrachial vein united with the cubital towards the tip; præbrachial and discal areolets long, the latter closed near the posterior margin by a transverse vein; anal areolet long, distinct, complete. Abdomen arched, rather long, with six segments more or less slender towards the base, obclavate towards the tip, which is incurved. Legs rather stout; tibiæ very slightly curved, compressed and dilated at the tips, in some cases with a transverse suture; tarsi rather broad; ungues and onychia distinct.

Male.—Abdomen with a projecting conical process on the fourth segment beneath.

These flies frequent flowers; their larvæ are parasitic on those of the humble-bee. There are twenty species of this insect in the collection at the British Museum, of these not more than three are found in England, the rest having been caught in the south of France, North America, and Australia.

A single specimen of *C. strigata* was found near Killarney, in Ireland, in the year 1850. (Walker, *Insecta Britannica*.)

CONOVULA. [MELAMPUS.]

CONULA'RIA, a fossil genus of *Mollusca*, generally ranked with *Cephalopoda*. [THECOSOMATA.]

CO'NULUS, a generic name for *Echinida*, to which also the term *Galerites* is applied.

CONUS, a genus of Gasteropodous *Mollusca*, founded by Linnæus. The animal is elongated, very much compressed and involved, with a very distinct head, terminated by a proboscis capable of much extension; mouth with a tongue rather short, but projecting, and armed with two rows of sharp teeth; tentacula cylindrical, carrying the eyes near the summit; foot oval, elongated, wider before than it is behind, with a transverse anterior channel; mantle scanty, narrow, forming an elongated siphon in front.

Shell thick, solid, rolled up as it were in a conical form; epidermis membranous, sometimes very thick; spire of different degrees of elevation, sometimes almost flat; aperture long and very narrow, widening a little anteriorly; lips generally straight and parallel, the outer lip simple and sharp-edged, sometimes a little curved, the inner lip without any plaits on the columella, but with a few elevated striæ on its anterior termination. Operculum horny, very small, subspiral, with a terminal summit, placed obliquely on the back part of the foot, and, when compared with the length of the aperture, appearing like a rudiment.

The species are found in southern and tropical seas. The form becomes gradually less developed as the locality approaches the north. In the Mediterranean there are a few species, but none appear to have been detected in the northern seas. They are carnivorous, and found on sandy mud at depths varying from near the surface of the sea to seventeen fathoms.

The species are very numerous. Lamarck records 181 recent; and several of these include varieties. The following observations of Mr. Broderip in his introduction to the description of some new species in the Cumingian collection may be of use to the student. After pointing out the difficulty of the task arising from the infinite varieties presented by the genus, and the very few points of form and structure in the shell that can be relied on as the foundation of specific character, the author thus continues:—"M. de Blainville, when noticing the numerous species already recorded, gives us a hint that many of them may be what Adanson calls 'espèces de cabinet,' and no one can examine an extensive collection of Cones, particularly if it contain many individuals of each species, for the purpose of comparison, without being struck by the force of the observation. Colour, granulation, or smoothness, length or shortness of the spire, its plainness or coronation, will be found in many species the result of locality, food, or temperature." M. Duclos, in reference to the numbers given by Lamarck, states that he is convinced that there are many of the species which can only be regarded as varieties at most. About 269 recent species and 80 fossil species have been described up to the present time.

Many of these species and varieties are very beautiful, both in shape and colour, and the genus has always been highly valued by collectors. *Conus gloria-maris*, *C. cedo-nulli*, *C. omaicus*, *C. aurisiacus*, *C. ammiralis*, and some others, have brought very large prices, and some of the finest specimens of these shells are now in this country.

Lamarck separates the genus into two divisions: the first comprising those species whose spire is coronated; and the second those whose spire is simple. By far the greater proportion of species belong to the latter division.

De Blainville thus divides the genus:—

a.

Conical species with a projecting spire, which is not crowned with tubercles. (Example, *C. generalis*.)

β.

(Genus *Rhombus*, De Montfort.)

Conical species with a coronated spire, which is either projecting or flattened. (Example, *C. imperialis*).

γ.

(Genus *Cylinder*, De Montfort.)

Species a little elongated, suboval; the spire projecting and pointed, but not coronated. (Example, *C. textile*.)

δ.

(Genus *Rollus*, De Montfort.)

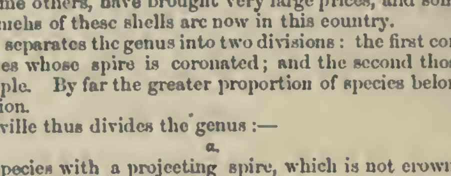
Subcylindrical species, the spire apparent and coronated. (Example, *C. geographus*.)

ε.

(Genus *Hermes*, De Montfort.)

Elongated, cylindrical species with a projecting spire, and the aperture as in the genus *Terebellum*, that is, angular posteriorly. (Examples, *C. Nussatella* and *C. mitratus*.)

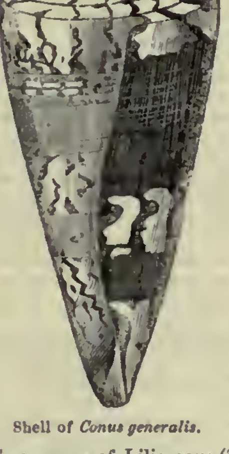
Mr. G. B. Sowerby ('Genera of Recent and Fossil Shells') observes that the Cones are liable to be confounded with the *Pleurotomata*, and the young specimens of some *Strombi*; and those which are rather



Animal of *Conus bandanus*.

a, seen in profile; *b*, view of under side; *c*, operculum.

ventricose with young *Cypræa*; but that they may be distinguished from the *Pleurotomata* by their short spire, their linear aperture, and their straight columella; from the young *Strombi*, by their being entirely destitute of varicose sutures, and by their never having any appearance of a notch near the lower extremity of the outer lip; the young *Strombi* moreover are seldom, if ever, so regularly cónical; and from the young *Cypræœ* by the thickness of their shell, by the coronated or abrupt spire, aud by their not being naturally polished in every part, which the *Cypræœ* always are, in cousequeuce of the want of epidermis which covers the shell of the Cone, while in the *Cypræœ* the large mantle comes in contact with the whole of the shcll.



Shell of *Conus generalis*.

CONVALLARITES, a genus of Liliaceous (?) Plants, fossil in thc Red-Sandstone of Sulzbad. (Brougniart.)

CONVOLVULA'CEÆ, a natural order of Monopetalous Exogcnous Plants, with bell-shaped flowers, opening or contracting beneath the influence of light, a plaited æstivation of the corolla, 5 stamens, and a fruit with 2 or 3 cells, in which 1 or 2 ovules stand erect. The embryo is crumpled up in the midst of very firm alhumen. The common Bind-Weeds of the hedges, the *Ipomœæ* and *Convolvuli* of the gardens, offer illustrations of the ordinary state of this order, the species of which have purgative roots; and in the case of scammony, yielded by *Convolvulus Scammonia*, and of jalap, produced by various species of *Ipomœa* [IPOMŒA], are of great medicinal importance. Occasionally the purgative principle is so much diffused among the fæcula of the root as to be almost inappreciable, as is the case in the *Convolvulus Batatas*, or Sweet Potato of America, which was the forerunner of the common potato, and gave it its name, and which is still cultivated in the south of Spain and France. [BATATAS.]

1, a bracteal leaf of *Neuropeltis racemosa*, with a flower growing from its midrib; 2, one of its flowers magnified; 3, a corolla opened, showing the stamens; 4, a small closter of flowers; 5, one of its ovaries with two styles; 6, a section of the calyx of a *Convolvulus*; 7, half a capsule, with valves separating by their edge from the dissepiments; 8, a transverse section of a seed, showing a part of the embryo lying in the albumen.

In most instances the stems of this natural order are twining, and in such cases it is immediately recognised; but occasionally they are erect and more spiny, and when that happens it is not so easy to know the order. If however attention is paid to the very imbricated state of the calyx, two of the sepals being quite exterior with respect to the other three, no real difficulty in identifying it need be experienced. For illustration we have taken a singular East Indian genus called *Neuropeltis*, in which the flowers grow from the midrib of the bracteal leaves.

The species are abundant in all parts of the tropics, but raro in cold climates where only a few are found. In the coldest climates they are unknown. The roots abound in a milky juice, which is strongly purgative: this property depends on a peculiar resin which is the active principle of jalap, scammony, and others of like nature. There are 43 genera and above 600 species. The order, according to Dr. Lindley, is allied to *Solanaceœ*, *Boraginaceœ*, and *Nolanaceœ*.

CONVOLVULUS, a genus of Plants belonging to the uatural order *Convolvulaceœ*. The species are chiefly herbs or herb-shrubs. The genus is known by the style being divided into 2 linear arms and its ovary having 2 cells in which stand 2 erect ovules. There are above 130 species of this genus. They are commonly kuown by the name of Bind-Weeds.

C. Scammonia, Scammony Bind-Weed, is a native of Syria, Cappadocia, and of the island of Rhodes, in hedges. It has large campanulate cream-coloured or very pale red corollas. The roots, which are very long and thick, when fresh contain a milky juice. This is obtained by removing the earth from the upper part of the roots, and cutting off the tops obliquely. The milky juice which flows out is collected in a vessel in the earth at the lower end of the cut. Each root furnishes a few drachms, and the produce of several roots is added together, and then dried in the sun. This is the true and unadulterated Scammony. It is light, of a dark gray colour, aud becomes of a whitish-yellow when touched with the wet finger. It seldom reaches us in a pure state, but is commonly mixed with the expressed juice of the root, and often with flour, sand, or earth. The best comes from Aleppo, and a second quality from Smyrna. Scammony is an efficaceous and powerful purgative. [SCAMMONY, in ARTS AND SC. DIV.]

C. arvensis has angular striated stems; leaves sagittate, somewhat auricled; peduncles usually 1-flowered; sepals ovate, rouudish; corolla white or rose-colour. It is native throughout Europe in sandy fields and by road-sides; also iu China, Persia, and some parts of India. It is very common in Great Britain. This species is said to possess a purgative quality, as also *C. Soldanella*, *C. maritimus*, and *C. macrocarpus*.

C. panduratus abounds in prussic acid, and is one of the plants from which the liqueur Noyau is prepared.

C. altrœoides is a native of the South of Europe, North of Africa, and Levant, climbing among hushes. It has stems branched from the bottom, climbing or spreading, taper and leafy; the corolla about two inches long, and of a beautiful rose-colour. According to M. Loiseleur Deslongchamps the roots contain a purgative resin, which is given in doses from 15 to 24 grains.

C. Soldanella and *C. sepium* are now referred to the genus *Calystegia* by Robert Brown. [CALYSTEGIA.] Several of the species are natives of Great Britain. Many grow well in our gardens, and form haudsome and showy flowers.

CONY'ZA, a genus of Plants belonging to the natural order *Compositœ*, to the sub-order *Tubulifloræ*, the tribe *Eupatoriaceœ*, the subtribe *Baccharideœ*, the division *Conyzeœ*, and the sub-division *Enconyzeœ*. It has an herbaceous imbricate involucre, the flowers of the ray tubular, 3-toothed, pistiliferous, those of the disc tubular, 5-toothed, hermaphrodite; the anthers caudate, the achenium beakless, the pappus pilose, the receptacle naked. The species are herbs and shrubs, and are found in Europe, Asia, Africa, and America.

C. squamosa, Floabane, Ploughman's Spikenard, has the scales of the involucre all linear, the lcaves ovate-lanceolate, downy, denticulate, the lower leaves narrowed into a footstalk, the florets of the ray subligulate, the fruit terete. This is a common plant on calcareous soils, in Great Britain and throughout Europe. It possesses a volatile oil with a peculiar scent, and is used for the purpose of driving away fleas and gnats. It seems to have had this reputation from an early period, as its names in most languages have reference to this quality. Its Latin name is *Pulicaria*; French, Hèrbes aux Puces; English, Fleabane. This species has been referred by De Candolle, in his 'Prodromus,' who is followed hy Babington, in his 'Manual,' to the genus *Inla*, under the name of *I. Conyza*.

C. anthelmintica has ovate or oval-oblong leaves, acuminate at hoth ends, coarsely serrated, and downy; the heads corymbose, each containing 40-50 florets; the scales of the involucre lanceolate, linear, acute, the outer somewhat spreading, leafly, and obovate-linear. It is a common plant among rubbish and in dry uncultivated ground in the East Indies. It is the *Vernonia anthelmintica* of Willdenow. The fruit is used by the doctors of India as a powerful remedy for worms.

C. genistelloides has very small lcaves reduced to sharpish somewhat ternate scales; 1-2 heads in interrupted spikes, the involucre turbinate, with the scales all acuminate. This plant is a native of Peru and Brazil. It is the *Baccharis genistelloides* of Persoon, the *Molina reticulata* of Lessing. It contains a bitter extractive matter and an aromatic oil, and is not unlike in its medicinal characters the common wormwood. It is employed in the Brazils in intermittent fevers, and may be used in all those cases where the Artemisia is indicated. It is particularly beneficial in the chronic diseases of horses, which are very fond of this plant. It may be employed in the form of an extract or decoction.

C. Marylandica has sessile, broad-lanceolate, acute, serrated leaves; the corymbs terminal and fastigiate. It is a native of North America, and secretes a powerful volatile oil, which gives out the odour of camphor. This property is also possessed by *C. camphorata*.

(Loudon, *Encyclopædia of Plants;* Koch, *Flora Germanica;* Lindley, *Flora Medica.*)

COOKIA, a genus of Plants belonging to the natural order *Aurantiaceæ*. The species are small trees with impari-pinnate leaves; leaflets alternate, unequal at the base, or oblique.

C. punctata is a native of China and the Moluccas; it has ovate lanceolate leaflets, acuminated, hardly unequal at the base. It is a middle-sized tree bearing eatable fruit about the size of a pigeon's egg, yellow on the outside, the pulp white, rather acrid, but sweet. This fruit is esteemed as an article of diet in China and the Indian Archipelago, and is known by the name of Wampee. There are two or three other species, natives of the East, all known as Wampee Trees.

COOT. [RALLIDÆ.]

COPAIFERA, a genus of Plants belonging to the natural order *Fabaceæ* or *Leguminosæ*, sometimes placed in the *Amyridaceæ*. It has a 4-parted calyx, segments diverging, the lowest the narrowest. Corolla wanting; stamens 10, declinate. Ovary roundish, compressed, with 2 ovules. Fruit pedicellate, oblique, obovate, 2-valved, 1-seeded; seed inclosed in a 1-sided aril. The species are trees or shrubs, inhabiting tropical America. Their trunks yield balsam by incision. The leaves are alternate, pinnated equally or unequally; leaflets opposite or alternate, either dotted or not. The flowers are arranged in compound axillary and terminal spikes.

C. Jacquini, the *C. officinalis* of Jacquin, is a native of the West Indies. The leaves are generally equally pinnated; leaflets in 2-5 pairs, incurved, ovate, unequal-sided, obtusely acuminate, with pellucid dots. From this species is obtained the Copaiva Balsam of the West Indies, which is used in medicine. [COPAIVA, in ARTS AND SC. DIV.]

Copaifera Jacquini.

C. multijuga has equally-pinnated leaves; leaflets 6-10 pairs, somewhat incurved, unequal-sided, with a long tapering point and pellucid dots, the lower ovate-oblong, the upper lanceolate. This is said to yield the Copaiva exported from Pará.

C. Langsdorfii grows in the province of S. Paulo in Brazil. It has leaflets in 3-5 pairs, equal-sided, obtuse, with pellucid dots; the lower ovate, the upper elliptical: the petioles and peduncles slightly downy.

The Copaiva Balsam of Brazil is furnished by this and the next species.

C. coriacea is also a native of S. Paulo in Brazil. It has leaflets in 2-3 pairs, elliptical, equal-sided, emarginate, not dotted; petioles and peduncles nearly smooth. The Balsam of Copaiva, an acrid bitter nauseous liquid resin, is apparently furnished by all the species of this genus; the above are given upon the authority of Hayne, who discontinues the name *C. officinalis*, which appears to have been applied indiscriminately to many different species.

The Purple Heart, a Guyana tree yielding timber of great toughness, which is very valuable for resisting the shock of artillery-discharges, and is therefore employed for making mortar-beds, is the *C. pubiflora* and *bracteata*. The balsam is said to gush out of the heart of these trees in large quantities when wounded.

COPAL, a resin possessed of peculiar properties, the produce of the *Rhus copallinum*, a native of Mexico; it is in rounded masses, smooth and brittle, transparent or nearly so, without colour or having a slight tinge of yellow; it has but little taste, and is nearly inodorous; it is insoluble in water, fusible, and inflammable. It differs from most other resins in its very sparing solubility in alcohol; and of the little that dissolves with the assistance of heat the greater part is deposited as the solution cools. It is dissolved by ether and some essential oils.

A substance resembling Copal is also found mineral, which is called *Fossil Copal*. It is however insoluble in alcohol.

CO'PHINUS, a fossil genus whose affinities are uncertain. (Murch. 'Sil. Syst.' pl. 26, f. 12.)

COPPER, one of the metals, occurs native in considerable quantities; also combined with oxygen, sulphur, selenium, and various acids. The ores of copper vary in specific gravity from 3·5 to 8·5, and seldom exceed 4 in hardness. Many of the ores give to borax a green colour in the outer flame, and an opaque dull red in the inner. With carbonate of soda on charcoal, nearly all the ores are reduced, and a globule of copper obtained; borax and tinfoil are required in some cases, where a combination with other metals conceals the copper. When soluble in the acids, a clean plate of iron inserted in the solution becomes covered with copper, and ammonia produces a blue solution.

NATIVE COPPER.—Monometric. In octahedrons; no cleavage apparent. Often in plates or masses, or arborescent and filiform shapes. Colour copper-red. Ductile and malleable. Hardness, 2·5 to 3. Specific gravity, 8·58.

Native copper often contains a little silver disseminated throughout it. Before the blow-pipe it fuses readily, and on cooling it is covered with a black oxide. It dissolves in nitric acid, and produces a blue solution with ammonia.

Native copper accompanies the ores of copper, and usually occurs in the vicinity of dykes of igneous rocks. Siberia, Brazil, and Cornwall, are noted for the copper they have produced. A mass, supposed to be from Bahia, now at Lisbon, weighs 2616 lbs. The vicinity of Lake Superior is one of the most extraordinary regions in the world for its native copper, where it occurs mostly in vertical seams in trap, and also in the inclosing sandstone. A mass weighing 3704 lbs. has been taken from thence to Washington city. One large mass weighing 80 tons was quarried out in the same district. It was 50 feet long, 6 feet deep, and averaged 6 inches in thickness. This copper contains intimately mixed with it about 3-10ths per cent. of silver. Besides this, perfectly pure silver in strings, masses, and grains is often disseminated through the copper; and some masses when polished appear sprinkled with large white spots of silver. Crystals of native copper are also found penetrating masses of prehnite and analcime in the trap rock. This mixture of copper and silver cannot be imitated by art, as the two metals form an alloy when melted together. It is probable that the separation in the rocks is due to the cooling from fusion being so extremely gradual as to allow the two metals to solidify separately at their respective temperatures of solidification; the trap being an igneous rock, and ages often elapsing, as is well known, during the cooling of a bed of lava covered from the air. Small specimens of native copper have been found in various parts of the United States. It occurs also in Australia.

Vitreous Copper Ore.—Trimetric. Cleavage parallel to the faces of a right rhombic prism, but indistinct. Secondary forms, variously modified rhombic prisms. It occurs also in compound crystals like arragonite; often massive. Colour and streak blackish lead-gray, often tarnished, blue or green, streak sometimes shining. Hardness, 2·5 to 3. Specific gravity, 5·5 to 5·8. Composition:—

Sulphur	20·6
Copper	77·2
Iron	1·5

Before the blow-pipe it gives off fumes of sulphur, fuses easily in the external flame, and boils. After the sulphur is driven off a globule of copper remains. Dissolves in heated nitric acid, with a precipitation of the sulphur. The vitreous copper ore resembles vitreous silver ore; but the lustre of a surface of fracture is less brilliant, and they afford different results before the blow-pipe. The solution made by putting a piece of the ore in nitric acid covers an iron-plate or knife-blade with copper, while a similar solution of the silver ore covers a copper-plate with silver.

This ore occurs with other copper ores in beds and veins. In Cornwall splendid crystallisations occur. Siberia, Hesse, Saxony, the Bannat, Chili, and the United States, also afford it.

Copper Pyrites—Sulphuret of Copper and Iron. Dimetric. Crystals tetrahedral or octahedral, sometimes compound. Cleavage indistinct. It occurs also massive and of various shapes. Colour brass-yellow, often tarnished deep yellow, and also iridescent; streak unmetallic, greenish-black, and but little shining. Hardness, 3·5 to 4. Specific gravity, 4·15 to 4·17. Composition:—

Sulphur	36·3
Copper	32·1
Iron	31·5

It fuses before the blow-pipe to a globule, which is magnetic, owing to the iron present. Gives sulphur-fumes on charcoal; with borax affords pure copper. The usual effect with nitric acid.

This ore resembles native gold and also iron pyrites. It is distinguished from gold by crumbling when it is attempted to cut it, instead of separating in slices; and from iron pyrites in its deeper yellow colour, and in yielding easily to the point of a knife, instead of striking fire with a steel.

Copper pyrites occurs in veins in granite and allied rocks; also in grauwacke, &c. It is usually associated with iron pyrites, and often with galena, blende, and carbonates of copper. The copper of Fahlun, Sweden, is obtained mostly from this ore, where it occurs with serpentine in gneiss. Other mines of this ore are in the Harz, near Goslar, in the Bannat, Hungary, Thuringia, &c. The Cornwall ore is mostly of this kind, and 10,000 to 12,000 tons of pure copper are smelted annually. There is much of this ore found in the United States. Besides being mined for copper, this ore is used extensively in the manufacture of blue vitriol (sulphate of copper) in the same manner that sulphate of iron (copperas) is obtained from iron pyrites.

Variegated Copper Pyrites.—Monometric. Cleavage octahedral, in traces. Occurs in cubes and octahedrons; also massive. Colour between copper-red and pinchbeck-brown; tarnishes rapidly on exposure; streak pale grayish-black, and but slightly shining. Brittle. Hardness, 3. Specific Gravity, 5. Composition:—

Sulphur	25·7
Copper	62·8
Iron	11·6

It fuses before the blow-pipe to a globule, attractable by the magnet. On charcoal affords fumes of sulphur. Mostly dissolved in nitric acid. This ore is distinguished from the preceding by its pale reddish-yellow colour. It occurs with other copper ores in granitic and allied rocks, and also in secondary formations. The mines of Cornwall have afforded crystallised specimens, and it is there called from its colour Horseflesh Ore. Other localities of massive varieties are—Ross Island, Killarney, Norway, Hesse, Silesia, Siberia, and the Bannat. Fine crystallisations occur in some of the United States.

Gray Copper Ore.—Monometric. Occurs in modified tetrahedrons, and also in compound crystals. Cleavage octahedral, in traces. Colour between steel-gray and iron-black; streak nearly as the colour. Rather brittle. Hardness, 3 to 4. Specific Gravity, 4·75 to 5.1. Composition:—

Sulphur	26·3
Copper	38·6
Antimony	16·5
Arsenic	7·2

together with some iron, zinc, and silver, amounting to 15 per cent. It sometimes contains 30 per cent. of silver, in place of part of the copper, and is then called *Argentiferous Gray Copper Ore*, or *Silver Fahlerz.* The amount of arsenic varies from 0 to 10 per cent. One variety from Spain included 10 per cent. of platinum, and another from Hohenstein some gold; another from Tuscany 2·7 per cent. of mercury. These varieties give off before the blow-pipe fumes of arsenic and antimony, and after roasting yield a globule of copper. It dissolves, when pulverised, in nitric acid, affording a brownish-green solution. Its copper-reactions before the blow-pipe, and in solution in nitric acid, distinguish it from the gray silver ores. The Cornish mines, Andreasberg in the Harz, Kremnitz in Hungary, Freiberg in Saxony, Kapnik in Transylvania, and Dillenberg in Nassau, afford fine crystallisations of this ore. It is a common ore in the Chilian mines, and is worked there and elsewhere for copper, and often also for silver.

Red Copper Ore.—Monometric. In regular octahedrons, and modified forms of the same. Cleavage octahedral. Also massive, and sometimes earthy. Colour deep red, of various shades; streak brownish-red. Lustre adamantine, or sub-metallic; also earthy, sub-transparent to nearly opaque. Brittle. Hardness, 3·5 to 4. Specific Gravity, 6. Composition:—

Copper	88·88
Oxygen	12

Before the blow-pipe on charcoal it yields a globule of copper. It dissolves in nitric acid. The earthy varieties have been called *Tile Ore*, from the colour. From cinnabar it differs in not being volatile before the blow-pipe, and from red iron ore in yielding a bead of copper on charcoal, and copper-reactions. It occurs with other copper ores in the Bannat, Thuringia, Cornwall, at Chessy, near Lyon; in Siberia, and Brazil; also in the United States. The octahedrons are often green, forming a coating of malachite.

Black Copper. Tenorite.—An oxide of copper occurring as a black powder and in dull black masses and botryoidal concretions, in veins or along with other copper ores. From Cornwall, and also the Vesuvian lavas. It is an abundant ore in some of the copper mines of the Mississippi Valley, and yields 60 to 70 per cent. of copper. The oxides of copper are easily smelted by heating with the aid of charcoal alone. They may be converted directly into sulphate or blue vitriol by means of sulphuric acid, but are more valuable for the copper they afford.

Blue Vitriol. Sulphate of Copper. Copperas.—Triclinate. In oblique rhomboidal prisms; also as an efflorescence or incrustation. Colour deep sky-blue; streak uncoloured. Sub-transparent to translucent. Lustre vitreous. Soluble. Taste nauseous and metallic. Hardness, 2 to 2·5. Specific Gravity, 2·21. Composition:—

Sulphuric Acid	31·7
Oxide of Copper	32·1
Water	36.2

A polished plate of iron in a solution becomes covered with copper. It occurs with the sulphurets of copper as a result of their decomposition, and is often in solution in the waters flowing from copper mines. Occurs in the Harz, at Fahlun in Sweden, and in many other copper regions.

Blue Vitriol is much used in dyeing operations, and in the printing of cotton and linen; also for various other purposes in the arts. It has been employed to prevent dry rot by steeping wood in its solution, and is a powerful preservative of animal substances; when imbued with it and dried they remain unaltered. It is afforded by the decomposition of copper pyrites, in the same manner as green vitriol from iron pyrites. It is manufactured for the arts from old copper sheathing, copper turnings, and copper refinery scales. The scales are readily dissolved in dilute sulphuric acid at the temperature of ebullition; the solution obtained is evaporated to the point where crystallisation will take place on cooling. Metallic copper is exposed in hot rooms to the atmosphere after it has been wetted in weak sulphuric acid. By alternate wetting and exposure it is rapidly corroded, and affords a solution which is evaporated for crystals. 400,000lbs. is the annual consumption of blue vitriol in the United States. In some mines the solution of sulphate of copper is so abundant as to afford considerable copper, which is obtained by immersing clean iron in it. It is called Copper of Cementation. At the copper springs of Wicklow, Ireland, about 500 tons of iron were laid at one time in the pits: in about twelve months the bars were dissolved, and every ton of iron yielded a ton and a half, and sometimes nearly two tons, of a precipitated reddish mud, each ton of which produced 16 cwt. of pure copper. The Rio Tinto mine, in Spain, is another instance of working the sulphate in solution. These waters yield annually 1800 cwt. of copper, and consume 2400 cwt. of iron.

Green Malachite. Green Carbonate of Copper.—Monoclinate. Usual in incrustations, with a smooth tuberose botryoidal or stalactitic surface. Structure finely and firmly fibrous; also earthy. Colour light green; streak paler. Usually nearly opaque. Crystals translucent. Lustre of crystals adamantine, inclining to vitreous; but fibrous incrustations silky, on a cross fracture. Earthy varieties dull. Hardness, 3·5 to 4. Specific Gravity, 4. Composition:—

Carbonic Acid	18
Oxide of Copper	70·5
Water	11·5

Dissolves with effervescence in nitric acid. Decrepitates and blackens before the blow-pipe, and becomes partly a black scoria. With borax it fuses to a deep green globule, and ultimately affords a bead of copper. It is readily distinguished by its copper-green colour and its association with copper ores. It resembles a siliceous ore of copper, *Chrysocolla*, a common ore in the mines of the Mississippi valley; but it is distinguished by its complete solution and effervescence in nitric acid. The colour also is not the bluish-green of chrysocolla. Green malachite usually accompanies other ores of copper, and forms incrustations, which when thick have the colours blended, and extremely delicate in their shades and blending. Perfect crystals are quite rare. The mines of Siberia, at Nischne Tagilsk have afforded great quantities of this ore. A mass partly disclosed measured at top 9 feet by 18 feet; and the portion uncovered contained at least half a million pounds of pure malachite. Other noted localities are Chessy in France, Sandlodge in Shetland, Schwartz in the Tyrol, Cornwall, Australia, and the island of Cuba. This mineral receives a high polish, and is used for inlaid work, and also ear-rings, snuff-boxes, and various ornamental articles. It is not much prized in jewellery. Very large masses are occasionally obtained in Russia, which are worked into slabs for tables, mantel-pieces, and vases, which are of exquisite beauty, owing to the delicate shadings and radiations of colour. In the Great Exhibition of 1851 there were magnificent specimens of this material in the shape of doors and vases sent thither by the Emperor of Russia. At Versailles there is a room furnished entirely with tables, chairs, &c., wrought in malachite, and the same are to be found in other European palaces. At Nischne Tagilsk, a block of malachite was obtained weighing 40 tons. Malachite is sometimes passed off in jewellery as turquoise, though easily distinguished by its shade of colour and much inferior hardness. It is a valuable ore when abundant, but it is seldom smelted alone, because the metal is liable to escape with the liberated volatile ingredient, carbonic acid.

Azurite. Blue Carbonate of Copper.—Monoclinate. In modified oblique rhombic prisms, the crystals rather short and stout; lateral cleavage perfect; also massive; often earthy. Colour deep blue, azure, or Berlin blue; transparent to nearly opaque; streak bluish.

Lustre vitreous, almost adamantine. Brittle. Hardness, 3·5 to 4·5. Specific Gravity, 3·5 to 3·85. Composition :—

Carbonic Acid	25·5
Oxide of Copper	69·1
Water	5·5

Before the blow-pipe and in acids it acts like the preceding. Azurite accompanies other ores of copper. At Chessy in France its crystallisations are very splendid. It is found also in Siberia, in the Bannat, and near Redruth in Cornwall. As incrustations, and rarely as crystals, it occurs near Singsing, New York; also in other parts of the United States.

When abundant it is a valuable ore of copper. It makes a poor pigment, as it is liable to turn green.

Chrysocolla. Silicate of Copper.—Usually as incrustations; botryoidal and massive; also in thin seams and stains; no fibrous structure apparent, nor any appearance of crystallisation. Colour bright green, bluish-green. Lustre of surface of incrustations smoothly shining; also earthy. Translucent to opaque. Hardness, 2 to 3. Specific Gravity, 2 to 2·3. Composition :—

Oxide of Copper	40·0
Silica	36·5
Water	20·2
Carbonic Acid	2·1
Oxide of Iron	1·0

This mineral varies much in the proportion of its constituents, as it is not crystallised. It blackens in the inner flame of the blow-pipe without melting. With borax it is partly reduced. No effervescence nor complete solution in nitric acid, cold or heated.

It is distinguished from green malachite, as stated under that species. It accompanies other copper ores in Cornwall, Hungary, the Tyrol, Siberia, Thuringia, &c. In Chili it is abundant at the various mines. In Wisconsin and Missouri it is so abundant as to be worked for copper. It was formerly taken for green malachite. This ore in the pure state affords 30 per cent. of copper, but as it occurs in the rock will hardly yield one-third of this amount. Still, when abundant, as it appears to be in the Mississippi valley, it is a valuable ore. It is easy of reduction by means of limestone as a flux.

Dioptase is another silicate of copper, occurring in rhombohedral crystals and hexagonal prisms. Colour emerald green. Lustre vitreous; streak greenish. Transparent to nearly opaque. Hardness, 5. Specific Gravity, 3·28. From the Kirghese Steppes of Siberia.

Besides the above salts of copper, the following species, which are of little use in the arts, are given in Dana's 'Manual of Mineralogy':—

Arsenates of Copper.

Euchroite has a bright emerald-green colour, and contains 33 per cent. of arsenic acid and 48 per cent. of oxide of copper. Occurs in modified rhombic prisms. Hardness, 3·75. Specific Gravity, 3·4. From Lebethen in Hungary.

Aphanesite is of a dark verdegris-green inclining to blue, and also dark blue. Hardness, 2·5 to 3. Sp. Gr., 4·19. It contains 30 per cent. of arsenic acid and 54 per cent. of oxide of copper. From Cornwall.

Erinite has an emerald-green colour, and occurs in mammillated coatings. Hardness, 4·5 to 5. Sp. Gr., 4·04. Contains 33·8 per cent. of arsenic acid and 59·4 per cent. of oxide of copper. From Limerick, Ireland.

Lirioconite varies from sky-blue to verdigris-green. It occurs in rhombic prisms sometimes an inch broad. Hardness, 2·5. Sp. Gr., 2·8 to 2·9. Contains 14 per cent. of arsenic acid and 49 per cent. of oxide of copper.

Olivenite presents olive-green to brownish colours, and occurs in prismatic crystals or velvety coatings. Hardness, 3. Sp. Gr., 4·2. Contains 36·7 per cent. of arsenic acid and 56·4 per cent. of oxide of copper.

Copper Mica is remarkable for its thin foliated or mica-like structure. The colour is emerald or grass-green. Hardness, 2. Sp. Gr., 2·55. It contains 21 per cent. of arsenic acid, 58 per cent. of oxide of copper, and 21 per cent. of water. From Cornwall and Hungary.

Copper Froth is another arsenate of a pale apple-green and verdigris-green colour. It has a perfect cleavage. It contains 25 per cent. of arsenic acid, 43·9 of oxide of copper, 17·5 of water, and 13·6 of carbonate of lime. From Hungary, Siberia, the Tyrol, and Derbyshire.

Condurrite has a brownish-black or blue colour. From Cornwall.

These different arsenates of copper give an alliaceous odour when heated on charcoal before the blow-pipe.

Phosphates of Copper.

Pseudo-Malachite occurs in very oblique crystals or massive and incrusting, and has an emerald or blackish-green colour. Hardness, 4·5 to 5. Sp. Gr., 4·2. Contains 68 per cent. of oxide of copper. From near Bonn on the Rhine, and also from Hungary.

Libethenite has a dark or olive-green colour, and occurs in prismatic crystals and massive. Hardness, 4. Sp. Gr., 3·6 to 3·8. Contains 64 per cent. of oxide of copper. From Hungary and Cornwall.

Thrombolite is a green phosphate occurring massive in Hungary. Contains 39 per cent. of oxide of copper.

These phosphates give no fumes before the blow-pipe, and have the reaction of phosphoric acid.

Chlorides of Copper.

Atacamite.—Colour green to blackish-green. Lustre adamantine to vitreous; streak apple-green. Translucent to sub-translucent. Occurs in right rhombic prisms and rectangular octahedrons; also massive. Consists of oxide of copper 76·6, muriatic acid 10·6, water 12·8. Gives off fumes of muriatic acid before the blow-pipe, and leaves a globule of copper. From the Atacama Desert between Chili and Peru, and elsewhere in Chili; also from Vesuvius and Saxony. It is ground up in Chili, and sold as a powder for letters under the name of Arsenillo.

A Sulphate Chloride of Copper has been observed in Cornwall, in blue acicular crystals, apparently hexagonal.

Beaumontite of C. T. Jackson is a hydrous crenato-silicate of copper, containing 15·8 per cent. of crenic acid. It is bluish-green to greenish-white, and pulverulent when dry. From Chessy, France.

Vanadate of Copper.—Massive and foliated or pulverulent; folia citron-yellow, pearly. From the Ural.

Buratite.—A hydrous carbonate of copper, zinc, and lime, occurring in bluish radiating needles. Sp. Gr., 3·2. From Chessy, France; the Altaï Mountains; and Tuscany.

Velvet Copper Ore. — In velvety druses or coatings, consisting of short fine fibrous crystallisations. Colour, fine smalt blue.

Copper has been known since the earliest periods. It is obtained for the arts mostly from pyritous copper—the gray sulphurets and the carbonate; also to some extent from the black oxide and from solutions of the sulphate. The principal copper mines in the world are those of Cornwall and Devon in England; of the island of Cuba; of Copiapo and other places in Chili; Chessy, near Lyon, in France; in the Erzgebirge, in Saxony; at Eisleben and Sangerhausen, in Prussia; at Goslar, in the Lower Harz; at Schemnitz, Kremnitz, Kapnik, and the Bannat, in Hungary; at Fahlun, in Sweden; at Turmsk, Nischne Tagilsk, and other places in the Urals; also in China and Japan. Lately extensive mines have been opened in Southern Australia. Copper, united with zinc in different proportions, forms brass and pinchbeck. Bronze is an alloy of copper with 7 to 10 per cent. of tin. This is the material used for cannon. With 8 per cent. of tin it is the bronze used for medals. With 20 per cent. of tin, the material for cymbals. Bell-metal is composed of copper with a third to a fifth as much tin by weight. Sheet-copper is made by heating the copper in a furnace, and rolling it between iron rollers. Copper is also worked by forging and casting. In casting, it will not bear over a red heat without burning.

(We are indebted for the substance of this article to Dana's excellent 'Manual of Mineralogy.')

COPPER, ORES OF. [COPPER.]

COPPERAS. [COPPER.]

COPROLITES (κόπρος and λίθος), the fossilised excrements of reptiles, fish, and other animals, found in various strata of the earth. Dr. Buckland in his 'Bridgewater Treatise' first drew attention to the probable nature of these substances, some of which had been previously known under the name of Bezoar Stones. These fossils were first detected in the Lias at Lyme Regis and in other localities, and their true nature inferred from the fact of their identity with similar masses found actually within the body of many species of *Ichthyosaurus*. The *Coprolites* are often found to contain scales of fishes, and occasionally teeth, and fragments of bone, belonging to species of fishes and reptiles which have been swallowed by the animal as food, and have passed undigested through its stomach. They often occur in a spirally twisted form, which is a characteristic of the excrements of some of the larger forms of recent fish, and have been accepted by comparative anatomists as indications of the nature of the intestinal tube in the extinct forms of Reptiles and Fishes.

Professor Liebig says in his 'Letters on Chemistry,' "In the autumn of 1842 Dr. Buckland pointed out to me a bed of Coprolites in the neighbourhood of Clifton, from half to one foot thick, inclosed in a limestone formation, extending as a brown stripe in the rocks for miles along the banks of the Severn. The limestone marl of Lyme Regis consists for the most part of one fourth part of fossil excrements and bones. The same are abundant in the Lias of Batheaston, and Broadway Hill, near Evesham. Dr. Buckland mentions beds several miles in extent, the substance of which consists in many places of a fourth part of Coprolites."

Coprolites, when chemically examined, are found to contain a large proportion of phosphate of lime. Liebig states that some he examined from Clifton contained above 18 per cent. of phosphate of lime, whilst other specimens have afforded a much larger per centage. The occurrence of phosphate of lime in these substances has led to their use as manures, and large quantities are annually collected in this country for that purpose. Before being used they are submitted to the action of sulphuric acid, by which the phosphate is converted into a super-phosphate of lime. [MANURE, in ARTS AND SC. DIV.]

Not only have the beds of the Lias afforded deposits of phosphate of lime which have received the name of *Coprolites*, but they have also been found in the Greensand, in the Wealden Formation, and in the Red Crag. In the latter formation it may be altogether doubted as to whether the phosphate of lime there found in the form of dark-brown or blackish smooth nodules, can be appropriately called Coprolites. These nodules occur in beds or seams running through the Red Crag of Suffolk, where, in the neighbourhood of Ipswich and

Woodbridge, and on the sea-coast of Felixstow and Bawdsey, it is worked to a considerable extent. In addition to these nodules, are found the fragments of the bones of various forms of *Cetaceæ*, all of which contain large quantities of phosphate of lime, and are collected under the name of Coprolites. It is still a question of interest as to how the nodules not having an organic basis have been formed. It has been supposed that all deposits of phosphate of lime are derived from the destruction of organised beings, but it is very evident that phosphate of lime must have existed in some form or another before the creation of either vegetable or animal beings. The increase also of the number of individuals of species of plants and animals demand that there should be some constant supply of this substance from the mineral kingdom. Whatever may be the result of further inquiry on this point, there can be little doubt of the impropriety of calling all deposits of phosphate of lime Coprolites. A better general name and which is not exposed to the objection of a false theory would be *Phosphatite*. [PHOSPHATITE.]

COPROPHAGI. [SCARABÆIDES.]

COPTIS (from κόπτω, to cut), a genus of Plants belonging to the natural order *Ranunculaceæ*. It has 5-6 sepals, coloured, petaloid, deciduous; the petals small, cucullate; the stamens 20-25; the capsules 6-10, on long stalks, somewhat stellate, membranous, ovate, oblong, tipped with the style; 4-6 seeded.

C. trifolia, Gold Thread, has ternate leaves, obovate blunt toothed hardly 3-lobed leaflets; the scape 1-flowered. It is a native of Iceland, Norway, Greenland, Siberia, and Kamtchatka, in swampy woods, and also of the cedar-swamps of North America, from Canada to Virginia. It is a small plant with white flowers and a yellow fibrous rhizoma which runs in all directions. The French in Canada call it Tissavoyanne jaune. A decoction of the leaves and stalks is used by the Indians for giving a yellow colour to cloth and skins. The rhizomata are bitter, and when administered as a medicine act in the same manner as quassia, gentian, and other bitters, but are not astringent; it is a popular remedy in the United States for aphthous affections of the mouth in children.

C. asplenifolia has biternate leaves, the leaflets rather pinnatifid, very acutely serrated, the scape 2-flowered. It is a native of Japan and the north-west coast of America.

Both species are pretty plants, and will thrive in a peat soil. A moist situation agrees with them, or they may be planted in pots among alpine plants. They may be propagated by seed, or by dividing the roots.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

CORACES. [CORACIAS.]

CORACIAS, a genus of Birds belonging to the Insessorial or Perching division.

Linnæus arranged the genus *Coracias* between *Corvus* and *Oriolus*. Pennant ('British Zoology') gives it a position between the Nut-Cracker and the Oriole; M. Duméril placed it between the Birds of Paradise and the Crows; and Meyer arranged it in his second order, *Coraces*, among which it stands in Illiger's method. Cuvier placed the Rollers (*Coracias*, Linn.) between the Crows (*Corvus*, Linn.) and the Birds of Paradise (*Paradisea*, Linn.), the position assigned to them by Lacépède; and includes under that title the Rollers properly so called (*Coracias garrula*, Linn. &c.), and the Rolles (*Colaris*).

Mr. Vigors places them in his family *Corvidæ*. [CORVIDÆ.]

M. Lesson's family *Eurystomidæ* (Rolliers of Cuv.) consists of the Rollers (*Galgulus*, Brisson, and *Coracias*, Linn.); the genus Rolle (*Eurystomus*, Vieill. [MEROPIDÆ], *Colaris*, Cuv., *Coracias*, Linn.); the genus *Mainatus* (*Eulabes*, Cuv., *Gracula*, Linn.); and the genus *Mino*, Less. M. Lesson rejects the term *Coracias*, because many authors have so dismembered it, according to their different views, that a confusion calculated to produce error is the result.

In the system of Mr. Swainson, who retains the generic name *Coracias*, the Rollers appear among the *Meropidæ*. [MEROPIDÆ.]

The Prince of Canino arranges the genus *Coracias*, giving as an example the common Roller, (*C. garrula*, Linn.) in the family *Ampelidæ*. ('Birds of Europe and North America.')

In Mr. Gould's great work on the 'Birds of Europe,' the Roller (*C. garrula*) comes down between the Bee-Eater (*Merops apiaster*) and Kingfisher (*Alcedo aspida*).

Mr. Yarrell ('British Birds') arranges the common Roller under the family *Meropidæ*.

C. garrula, the Roller. It is the Pica Marina and Pica Merdaria of the Italians; Rollier of the French; Birk-Heher, Blaue-Racke, and Mandelkrahe, of the Germans; Spransk Kraka, Blakraka, and Allekraka, of the Swedes; Ellekrage of Brunich; and Rholydd of the Welsh. The bill is black towards the point, becoming brown at the base with a few bristles; irides of two circles yellow and brown; head, neck, breast, and belly various shades of verditer-blue changing to pale green; shoulders azure-blue, back reddish-brown, rump purple, wing-primaries dark bluish-black, edge lighter, tail-feathers pale greenish-blue, the outer ones tipped with black, those in the middle also much darker in colour; legs reddish-brown; in old males the outer tail-feathers are somewhat elongated.

Adult females differ but little from the males; young birds do not attain their brilliant colour till the second year. (Gould, 'Birds of Europe.') Length about 13 inches.

This bird appears to have a wide geographical range. In Europe, it is found in Denmark, Sweden (where it arrives with the Cuckoo), and the southern provinces of Russia; is more common in Germany than France, where however it has been found in Provence; and it has been taken at Gibraltar. In Italy, according to Prince Bonaparte, it is rather common, arriving in the spring and departing in September. In Malta and Sicily it is exposed for sale in the shops of poulterers, and is said to have the taste of a turtle-dove. In the Morea it is considered a delicacy in the autumn, when it is fat with its summer food. It has been captured at Aleppo, and at Trebizond and Erzerum. It visits the countries between the Black and the Caspian seas; and Dr. von Siebold and M. Bürger include it among the birds of Japan. In North Africa it is found from Marocco to Egypt. Flocks were seen by Adanson at Senegal, and he concluded that they passed the winter there. Dr. Andrew Smith records it among the birds of South Africa. In Great Britain it has been killed in Cornwall, in Suffolk, and Norfolk, in Cambridgeshire, in Yorkshire, Northumberland, Perthshire, the east of Scotland, and Orkney. It has been only occasionally seen in Ireland.

The Roller (*Coracias garrula*).

Deep forests of oak and birch appear to be the favourite haunts of the Roller. In the 'Annals of Natural History' for 1839, it is stated by a traveller in Asia Minor, that the Roller, which was most common throughout the south and west parts of the country wherever the magpie was not found (for it was not seen in the same district with that bird), was observed to fall through the air like a Tumbler Pigeon. Temminck states that it makes its nest in the holes of trees, where it lays from four to seven eggs of a lustrous white. M. Vieillot states that in Malta, where trees are scarce, the bird builds on the ground. In Barbary it has been observed to form its nest in the banks of the Sheliff, Booberak, and other rivers; and Pennant remarks that where trees are wanting, it makes it in clayey banks. These last modes of nidification bring it very close to the Bee-Eaters and Kingfishers, whose eggs quite resemble those of the Roller in colour and shape, and only vary in size. The male takes his turn to sit. The food is very varied, according to Temminck, who enumerates moles, crickets, cockchafers, grasshoppers, millipedes, and other insects, slugs, and worms. Gould states that it feeds on worms, slugs, and insects generally. Yarrell informs us that the food consists of worms, slugs, insects in their various stages, and berries.

Bechstein observes that till lately he had thought that the Roller was untameable; but Dr. Meyer of Offenbach had convinced him to the contrary, having himself reared them in his room by the following method:—The young ones must be taken from the nest when only half grown, and fed on little bits of cow's-heart or any other meat which is lean and tender, till they can feed alone; small frogs, worms, and insects may then be added. Its mode of killing and swallowing insects is thus described: it commences by seizing and crushing them with its bill, and then throws them into the air several times, in order to receive them in its throat, which is very capacious. When the morsel is too large, or the insect is still alive, the bird strikes it hard against the ground, and begins again to throw it into the air till it falls not across, but so as to thread the throat, when it is easily swallowed. Bechstein says that he had never seen the bird drink. The translator of Bechstein's interesting little book states, that he once saw a Roller drink after having swallowed dry ants'-eggs; it then ate greedily of lettuce and endive. "Another which I kept," adds the translator, "liked the outside of lettuces and spinach after having eaten insects, especially beetles, which are very heating. To judge from what I have observed, the Roller is by nature wild and solitary; it seldom changes its situation except to seek its food or to hide itself from strangers. It is a good thing, whether kept in a cage or let range, always to have a box in its way, in which it may take refuge when frightened; it will not fail to hide itself there, and by this means will not be tempted to beat itself violently, which it does when it cannot fly from the object of its fright. It knows its mistress very well, lets her take it up, comes near her, and sits without any fear on her knees for whole hours without stirring. This is as far as it goes even when tamed. It is neither caressing nor familiar: when frightened it utters harsh cries, softer ones when its food is brought; but 'crag, crag, craag,' at the same time raising its head, is the expression of its joy or triumph."

Gracula religiosa (Linnæus), the Mino-Bird, is the Bëo and Meucho of the Javanese, Tecong of the Sumatrans, and is referred by Mr. Swainson to the *Sturnidæ*. Mr. G. R. Gray arranges it under the family *Corvidæ*, in the sub-family *Graculinæ*. Mr. Swainson states that analysis has convinced him that neither the Rollers nor the bird in question belong to the *Corvidæ*; and he remarks that the little value that can be attached to speculations on the rank of the present genera founded upon mere synthesis, will best appear by looking to those artificial arrangements that place the short-legged Rollers close to the long-legged and powerfully-constructed Grakle (*Gracula religiosa*). M. Lesson places this bird next to the Rollers, and among the *Eurystomidæ*.

Mino-Bird (*Gracula religiosa*). (*Eulabes Javanus*, Vieill.)

It is the type of Cuvier's genus *Eulabes*, which has the following characters:—Bill short, stout, not so long as the head; entirely compressed. Frontal feathers advancing far upon the base, but not dividing the front. Culmen gradually curved from the base to the tip, which is distinctly notched. Commissure but slightly angulated. Under mandible with the base broad and dilated. Nostrils basal, naked, round, sunk in a depression. Frontal feathers short, velvety. Head with naked wattles. Wings as in Pastor. Tail short, even. Feet rather short, very strong. Tarsus and middle toe equal; hinder toe shorter; inner toe almost equal to the outer toe. (Sw.)

Its colour is of a deep velvety black; a white space in the middle of the wing; bill and feet yellow; behind the eye spring fleshy caruncles of a bright orange-colour, and extend beyond the occiput.

It is found in Java, Sumatra, and the great Eastern Islands.

Insects and fruits form the food of the Mino-Bird, which is easily tamed, and learns to whistle and talk with great facility. With the natives it is a great favourite in consequence. Marsden says of it, that it has the faculty of imitating human speech in greater perfection than any other of the feathered tribe. Bontius, who terms it *Pica, seu potius Sturnus Indicus*, heads the chapter where he figures and describes it, with the following lines:—

"Psittacus Eois quamvis tibi missus ab oris
Jussa loquar; vincit me Sturnus garrulus Indus."—

And tells the following story:—There was, when he was in Batavia, an old Javanese woman, the servant of a Chinese gardener, who kept one of these birds, which was very loquacious. Bontius was very anxious to buy it, but this the old woman would not hear of. He then begged that she would at least lend it to him that its picture might be taken, a request which was at last granted with no very good grace, the ancient Mohammedan dame being under great apprehension that Bontius would offer that abomination, pork, to her beloved bird. This he promised not to do, and had the loan of the Mino, which kept continually saying "Orang Nasarani Catjor Macan Babi." This, being interpreted, means "Christian Dog, Eater of Pork;" and Bontius came to the conclusion that the unwillingness of the old woman arose not only from the fear of her bird being desecrated by an offer of swine's flesh, but also from the apprehension that he or his servants, irritated by its contumelies, would wring its neck. M. Lesson also saw one at Java which knew whole phrases of the Malay language.

The general opinion seems to be that there is but one species of Mino-Bird.

Cuvier however states that Linnæus confounded two species under the name of *Gracula religiosa*, namely, *Eulabes Indicus* and *Eulabes Javanus*.

M. Lesson, who states that only one species is known, namely, the Mainate Religieux, *Gracula religiosa*, Linn., Bëo and Meucho of the Javanese, remarks afterwards that there is said to be a smaller variety: this is probably the *Eulabes Indicus* above noticed.

Eulabes Indicus.

The last-mentioned ornithologist applies the old Indian word Mino as a generic term for a very different bird, *Mino Dumontii*, described by him in the 'Zoology of the Coquille,' and there figured at pl. 26. He is also of opinion that *Gracula calva*, Linn., should be added to this genus.

CORA'CINA, a genus of Birds, separated from the Crows (*Corvidæ*) by Vieillot, and divided by him into four sections. The first comprises those species which have the bill furnished at its base with velvety feathers (Les Col-Nus, 'naked necks'); the second those whose nostrils are covered with setaceous feathers, directed forwards, and whose upper mandible is notched towards the end (Les Choucaris, *Graucalus*); the third those whose bill is naked at the base, and notched at the point (*Coracina gymnocephala*, Vieillot; *Corvus calvus*, Latham, for example); and the fourth, that curious species on which Geoffroy-Saint-Hilaire founded his genus *Cephalopterus*.

Cuvier, in the last edition of the 'Règne Animal,' defines *Graucalus* to be the Greek name of an ash-coloured bird (oiseau cendré), and says that three Choucaris out of four are of that colour. M. Vieillot, he adds, confounds these birds with his *Coracinæ*, which comprise the *Gymnoderi* and the *Gymnocephali*.

M. Lesson, who places the group under the *Ampelidæ*, observes that the genus *Coracina* is far from being determined. Thus, he observes, M. Vieillot places under it the *Cephalopterus* of M. Geoffroy-Saint-Hilaire, the Choucaris and the Col-Nu, or *Gymnoderus*. (He might have added the *Gymnocephalus* of Geoffroy and Cuvier.) Temminck adds to it many of the *Cotingas* of Le Vaillant; but for his own (Lesson's) part, he adopts the term *Coracina* for that group of birds which Cuvier has collected together under the name of Piauhaus.

Coracina, Lesson (*Coracina*, Temminck; Les Piauhaus, *Cotinga*, Cuvier; Piauhau, *Querula*, Vieillot).—Bill depressed, smooth, ciliated at the base, thick, narrowed at the point, angular above, a little curved towards the end, slightly toothed at the point; lower mandible a little flattened below; head and neck feathered, but without any ornamental plumes, and without any naked skin.

C. scutata, Temminck and Latham. This species differs but little from *Coracina rubricollis*, *Muscicapa rubricollis*, of Gmelin, in the colour of its plumage, but the wings are shorter. In *C. rubricollis* the plumage is all black, with the exception of the throat and front of the neck, which are of a purpled rose-colour. In *C. scutata*, the red, which covers the throat and breast, goes as low as the upper part of the belly, and the bill is not black as it is in *C. rubricollis*. It is found in Brazil, which is also the habitat of *C. rubricollis*.

Gymnocephalus (*Coracina*, Vieillot).—M. Lesson observes that Messrs. Vieillot and Temminck place the *Gymnocephali* (Bald-Heads) among the *Coracinæ*, and that Cuvier contents himself with observing that *Corvus calvus*, Latham, the type of this new genus, has the bill of the Tyrants, with the ridge (culmen) a little more arched, and a great portion of the face denuded of feathers. Le Vaillant, he states, regarded this denudation of the skin in the front of the head as the

Coracina scutata.

result of a particular habit; and in the 'History of the Birds of Paradise' has printed a note, in which he affirms that he had received from Cayenne a specimen having this part well covered with feathers; but M. Lesson adds that he himself had seen at Rochefort more than twenty skins of *Gymnocephali*, and that all had the face bare of feathers. However it may be, he continues, this genus entirely requires revision.

G. calvus, the Capuchin Baldhead. It is the *Coracina gymnocephala*, Vieillot; *Corvus calvus*, Latham. Size of the crow; and of the colour of Spanish snuff, or, as some authors write it, Capuchin colour, whence the Creoles of Cayenne give it the name of Oiseau mon Père. The quills and the tail-feathers are black. The large beak and ample forehead bare of feathers give a singular air to this bird. Vieillot observes that it has been compared to the rook, on account of the nakedness of the head, a comparison which seems to him just; "for," says Vieillot, "it has not this part naked till it is adult, the young, like the young rook, having the head entirely feathered, and even the

Capuchin Baldhead (*Gymnocephalus calvus*).

nostrils covered with small setaceous feathers, as I can testify, from the inspection of a young individual of which I have made mention in the first edition of the 'Nouveau Dictionnaire d'Histoire Naturelle.'" It is a native of Guyana.

Gymnoderus (*Coracina*, Vieillot, Temminck; *Cotinga*, Le Vaillant).—The principal characters of *Gymnoderus*, Geoffroy-Saint-Hilaire, rest on the possession of a bill like that of the *Coracinæ* and *Cephalopteri*, with a partially naked neck and a head covered with velvety feathers.

G. fœtidus. It is *Coracina gymnodera*, Vieillot; *Corvus nudus*, Latham; *Gracula nudicollis*, Shaw; *Gracula fœtida*, Linnæus; Col-Nu, Buffon. Rather larger than the jackdaw, but the body is thick and fleshy. The sides of the neck are entirely naked, and only present some traces of down. Buffon's figure, on the contrary (Planches Enlum. 609), represents this part as being clothed with a considerably thick down. Upper part of the head, back of the neck and throat, covered with small close-set feathers like black velvet. External edges of the quills of the middle of the wing, the last quills, and all the wing-coverts, bluish-gray. Great quills and tail-feathers black, with bluish reflections. The rest of the plumage, bill, and feet, black. Eyes red brown, with a yellow skin beneath. The female is smaller, and of a brownish black. It is a native of Brazil and Guyana.

Gymnoderus fœtidus, male.

Cephalopterus.—Bill strong, robust; mandibles nearly equal, the upper one convex and scarcely curved at the summit, not notched at the point; lower mandible flattened below. Nostrils longitudinal, open, hollowed into an oval excavation; bristles at the border of the bill, which infringe a little on the frontal feathers. Two rows of feathers, taking their origin on the forehead, and elevating themselves into a plume or crest on the head. The feathers of the neck form a kind of pendent pelerine in front of the neck, which is naked.

C. ornatus. It is the *Coracina cephaloptera* of Vieillot. Colour a

Cephalopterus ornatus.

uniform blue black. Head and base of the bill ornamented with a plume or crest, forming a sort of parasol, composed of straight elevated feathers, with white and stiff shafts, and terminated by an ear (épi) of black beards, which projects forwards (se renverse en devant). The sides of the neck are naked, but long feathers forming a loose pelerine, and hanging down lower than the breast, spring from beneath the throat and from the sides of the neck. Tail long, slightly rounded. General plumage of a deep black. Crest and feathers of the pelerine giving metallic reflections. (Lesson.)

The bird that furnished the description was brought to M. Geoffroy-Saint-Hilaire from Lisbon. M. Lesson states that the belief was that it came from Brazil, but that a well-informed Portuguese had told him that it was from Goa. M. Vieillot says that the colour of the naked skin of the neck is cerulean blue. Mr. Swainson, in his 'Natural History and Classification of Birds,' London, 1836, says:—"The crest of this extraordinary bird is immensely large, advancing so far in front as to touch the end of the bill, and it is compressed in the same manner as that of *Rupicola;* but the ends of the feathers, instead of meeting so as to form a sharp ridge, suddenly recede from each other, curve outwards, and form a most elegant drooping line of plumes, hanging over on the sides so as to shade the face like an umbrella. The figures that have hitherto been given of this rare bird are all taken from the specimen in the Paris Museum, and which has been sadly distorted in the setting up. A minute examination of this specimen has convinced us that the frontal feathers, instead of being raised over the bill, as Temminck represents them, partly repose and overshadow it, at least as much as do those of *Calyptomena* and *Rupicola*" (vol. i. p. 41). The species above noticed is the only one known.

CORACITE (Le Conte), an ore resembling *Pitchblende* [PITCHBLENDE], in which oxide of aluminium supplants a part of the oxide of uranium contained in that mineral. It is found on the north shore of Lake Superior in a vein two inches wide, near the junction of trap and syenite. It occurs massive with a resinous lustre, and has a hardness of 4·5, and a specific gravity of 4·38.

CORAL. [POLYPIFERA.]

CORAL RAG, the most calcareous or at least most coralliferous part of the Oxford Oolite Formation. It is a variable and singular rock, most rich in *Madrephylliæa* and *Echinodermata,* in the vicinity of Calne.

CORALLINA. [CORALLINACEÆ.]

CORALLINACEÆ, a family of Marine Plants belonging to the order *Algæ.* According to Harvey's definition it includes the *Corallineæ* and *Spongiteæ* of Kützing, and the *Corallinidæ* and *Nulliporidæ* of Dr. Johnston.

The forms referred to this family have been alternately regarded as animals and plants. When their structure was imperfectly understood they were regarded with many of the zoophytes (*Polypifera* and *Polyzoa*) and sponges as sea-weeds. When the animal nature of these beings was established it was again an inference that the Corallines belonged to the animal kingdom. Recent researches have however demonstrated the truly vegetable nature of this family both in their general structure and mode of reproduction. The following is Dr. Harvey's diagnosis in his 'Manual of the British Marine Algæ:'—Rigid, articulated, or crustaceous, mostly calcareous seaweeds, purple when recent, fading on exposure to milk-white. Composed of closely-packed elongated cells or filaments, in which carbonate of lime is deposited in an organised form. Tetraspores tufted, contained in ovate or spherical conceptacles. Ceramidia furnished with a terminal pore.

The following general remarks on this family are taken from Dr. Harvey's work:—The root, where this organ is manifested, is an expanded crustaceous disc, often widely spreading. The frond almost always calcareous, effervescing strongly when thrown into acids, rarely destitute of lime, very variable in aspect and habit. The lowest forms of the order are simple incrustations, spreading like the crustaceous lichens over the surface of rocks, or the fronds of the larger *Algæ.* In the smaller of these the crust is a mere film, as thin as paper, generally circular, and extending by means of small additions to the circumference, so that the frond becomes marked as it advances with concentric circles. In the larger the crust is thick and stony, rising here and there into prominences and sinking into depressions. Still farther advance manifests itself by the crust assuming a branched habit: at first papillæ rise from the surface; these thicken, and widen, and lengthen, and at length throw out branches, till a shrubby frond, of stony hardness, but extremely brittle, is formed. All these changes in character take place within the limits of a single genus, *Melobesia.* Nearly related to this (and by many botanists considered identical) is *Mastophora,* a genus in which the frond is expanded into leafy lobes, usually fan-shaped, sessile, or stalked, but not adnate to rocks; of a flexible substance, containing a smaller portion of carbonate of lime than the former group. Some of these have the habit of *Padina,* but differ from that genus in being of a red colour. They are the most perfectly organised of the leafy or frondose Corallines' (*Milleporeæ*). The articulated or true Corallines are filiform, either pinnated or dichotomous, the branches formed of strings of calcareous articulations, truncated at the upper extremity and rounded at the lower, each articulation connected with that above and below it by a flexible joint composed of cellular tissue, destitute of carbonate of lime. This joint in our British species is scarcely evident till after maceration; but in many exotic species (of *Amphiroa*) it is so long as to interrupt the continuity of the articulations, and is either marked or coated with wart-like calcareous tubercles.

The form of the articulations varies extremely, and often in the same species, or even in the same specimen, so that the determination of these plants is sometimes difficult. In many the articulations are cylindrical, in others oval and compressed, in some flat and irregularly shaped; but in the greater number they are heart-shaped or wedge-shaped, with the upper angles frequently prolonged with horns.

The fructification consists of hollow external or immersed conceptacles containing a tuft of oblong spores, divided at maturity by three horizontal fissures into four parts. They are therefore tetraspores, precisely similar to those of *Plocamium, Hypnea,* &c. The nature of the conceptacle varies even in the same species. Thus in *Corallina* it is normally formed by the metamorphosis of the terminal articulation of the branches, which swells at the sides and becomes pierced at the apex; but in *C. squamata* and even in *C. officinalis* other articulations frequently bear numerous small hemispherical conceptacles on their sides; and sometimes the whole surface is warted with such, and these irregular organs are equally furnished with tetraspores as the normal ones. These latter conceptacles, which are irregular in *Corallina,* are the normal fruit of *Amphiroa,* a genus chiefly from the Southern Ocean. In *Jania* the conceptacle is similar to that of *Corallina,* except that it generally bears a pair of ramuli (resembling the antennæ of an insect) from its upper angles.

The Corallines are found in all parts of the ocean, but are much more numerous in warm than in cold countries, and some of the species of the tropical and sub-tropical ocean are among the most beautiful of marine vegetables. Until recently the plants of this order were with other calcareous *Algæ* confounded with *Zoophytes,* or polypiferous corals. They are however undoubtedly of vegetable nature, and when the lime which they contain is removed by acid, the vegetable framework concealed beneath it is found to be of a similar structure to that of other Rhodosperms, to which group of *Algæ* they are further allied by their colour and the nature of their spores. The order consists of two, or if *Lythocystes* be rightly placed in it, of three sub-orders, as follows:—

Synopsis of the British Genera.

Sub-order 1. *Corallineæ.*—Frond filiform, articulated.

1. *Corallina.*—Frond pinnated. Ceramidia terminal, simple.

2. *Jania.*—Frond dichotomous. Ceramidia tipped with two horn-like ramuli.

Sub-order 2. *Nulliporeæ.*—Frond crustaceous or foliaceous, opaque, not articulated.

3. *Melobesia.*—Frond stony, forming either a crustaceous expansion or a foliaceous or shrub-like body.

4. *Hildenbrandtia.*—Frond cartilaginous, not stony, forming a crustaceous expansion.

Sub-order 3. *Lythocysteæ.*—Frond plane, hyaline, composed of cells radiating from a centre. Fructification unknown.

5. *Lythocystis.*—A minute parasite.

Sub-order 1. *Corallineæ.*

1. *Corallina.*—Frond filiform, articulated, branched (mostly pinnate), coated with a calcareous deposit. Fructification turbinate or obovate, mostly terminal ceramidia, pierced at the apex by a minute spore, and containing a tuft of erect pyriform or club-shaped transversely parted tetraspores. Name from *Corallium,* Coral, which these plants resemble in having a stony substance.

C. officinalis is the most common example of this genus on British shores. It is decompound, pinnate, the lower articulations cylindrical, twice as long as broad, upper slightly obconical, round edged, their angles blunt, ultimate ramuli cylindrical obtuse. It is found on rocks between the tide marks, extending from the limits of high to the extremity of low water mark. Perennial. Winter and spring. The root is a widely expanded red crust. The fronds from two to six inches high, tufted, much branched, bipinnated, but varying greatly in luxuriance according to the depth at which it grows.

C. elongata and *C. squamata* are both British species, and are mentioned in Dr. Johnston's work on the Corallines and also by Dr. Harvey.

2. *Jania.*—Frond filiform, articulated, dichotomous, branched, coated with a calcareous deposit. Fructification urn-shaped. Ceramidia formed of the axillary articulation of the uppermost branches (mostly two-horned), pierced at the apex by a minute pore, and containing a tuft of erect pyriform transversely parted tetraspores. Named from *Janira,* one of the *Nereides.*

J. rubens is found on all parts of the British coast on the smaller *Algæ* between tide marks. The articulations of the principal branches and ramuli are cylindrical, about four times as long as broad. The fronds are from half an inch to two inches high, densely tufted, dichotomous, many times forked, fastigiate; branches either erect or spreading gradually, tapering upwards. Articulations cylindrical in all parts of the frond, without prominent angles; those near the base very short, the upper ones gradually longer. Ceramidia subterminal, urn-shaped with long horns, formed of two to four articulations. Colour a pale red with a purplish shade when quite fresh.

J. corniculata is also found on the southern shores of England and Ireland, and in Jersey.

Sub-order 2. *Nulliporeæ.*

3. *Melobesia.*—Frond attached or free, either flattened, orbicular, sinuated or irregularly lobed, or cylindrical and branched (never articulated), coated with a calcareous deposit; fructification conical, sessile. Ceramidia scattered over the surface of the frond, and containing a tuft of transversely-parted oblong tetraspores. The genus is named from one of the sea nymphs of Hesiod.

M. polymorpha is found attached to rocks, thick, stony, incrusting, or rising into short clumsy branches, which are seldom much divided, and often merely rudimentary. Much is yet to be done in working out the species of this genus.

M. pustulata is the largest and most developed of the parasitic section of the genus. It is found on *Phyllophora rubens*, *Chondrus crispus*, &c. It is thick, of a dull purple or green colour, oblong or lobed, incrusting, smooth. Ceramidia numerous, large, rather prominent, and conical. Dr. Johnston refers this species to *Corallina officinalis*. This plant, he says, appears first in the guise of a circular calcareous patch of a purplish colour, and in this state is common on almost every object that grows between tide-marks. When developing on the leaves of *Zostera*, or in other unfavourable sites, these patches are usually pulverulent and ill-coloured, green or white, and never become large; but in suitable situations they continue enlarging in concentric circles, each marked with a pale zone until they ultimately cover a space of several inches in diameter. The resemblance which in this condition the crust has to some crustaceous fungi, more especially to *Polyporus versicolor*, is remarkably exact; and neither is it less variable than the fungus in its growth, the variations depending on the nature of the site from which it grows. If this is smooth and even, the folliaceous coralline is entirely adnate and also even; but if the surface of the site is uneven or knobbed, the coralline assumes the same character. If it grows from the edge of a rock, or the frond of a narrow sea-weed, or from a branch of the perfect coralline, the basal laminæ spread beyond in overlapping imbrications of considerable neatness and beauty; they are semicircular, wavy, either smooth or studded with scattered granules, and these granules (ceramidia) may be either solid or perforated on the top. Such states of the coralline have been described as *Millepora lichenoides*, while its earlier states constitute Lamoroux's various species of *Melobesia*.

4. *Hildenbrandtia.*—The frond cartilagineo-membranaceous (not stony), crustaceous, suborbicular, adhering by its lower surface; composed of very slender closely-packed vertical filaments; conceptacles immersed in the frond, orbicular, depressed, pierced by a hole, and containing tetraspores and paraphyses at the base of the cavity.

H. rubra is found on smooth stones and pebbles between tide-marks and in deep water. It is very common, and forms a thin membranous crust, at first orbicular, and spreading concentrically, at last irregular in form, following the sinuosities of the body to which it may be attached. Viewed under the microscope, a small portion shows minute cells lying in a clear jelly. When in fruit, the surface is pitted with disc-like depressions, pierced by a hole which communicates with a chamber in which the spores lie. The colour is variable; now a bright, now a dull red.

Sub-order 3. (?) *Lithocysteæ.*

Lithocystis.—Plant calcareous; consisting of a single plane of cellules, which are disposed in radiating dichotomous series, forming an appressed flabelliform frond. Named from a stone in the bladder, because the cells have stony coats.

5. *L. Allmanni* is parasitical on *Chrysymenia clavellosa* from an oyster bed at Malahide, Dublin, by Professor Allmann. It forms minute dot-like patches of a whitish colour on the fronds of the *Chrysymenia*. Each dot consists of one or several fan-shaped fronds composed of quadrate cells disposed in dichotomous series. The plant is brittle, colourless, and effervesces in acid.

(Harvey, *British Algæ.*)

CORALLINES. [CORALLINACEÆ.]

CORALLIUM. [POLYPIFERA.]

CORALLORHI'ZA, a genus of Plants belonging to the natural order *Orchideæ*, and to the tribe *Malaxideæ*. It has a converging perianth; the lips with two prominent longitudinal ridges at the base; 3-lobed, the lateral lobes small, the middle lobe large, slightly emarginate; the spur short or obsolete; the stigma triangular; the rostellum obsolete, but with a large globose appendage; the anthers terminal, 2-celled, opening transversely; the column elongated; the germen slightly stalked, straight.

C. innata has the spur obsolete or wanting. It has thick fleshy roots with much branched fibres. The flowers are seated on a spike, and are of a yellowish colour. It is found in Great Britain in mountainous woods, but is a rare plant. There are several American species. They are exceedingly difficult of cultivation.

CORALWORT. [DENTARIA.]

CORBULA, a genus of Marine *Mollusca*, belonging to the *Lamellibranchiata*. The shell is suborbicular or oval, tumid or depressed, very inequivalve, slightly inequilateral, rounded anteriorly, more or less truncated posteriorly; beaks prominent; surface of the valves more or less furrowed or transversely striated, covered with an epidermis. Hinge composed of a recurved primary tooth in one or both valves, with corresponding socket and ligamental pit beside it. Ligament small, interior. Muscular impressions slightly marked, united by a pallial one with a very slight sinus. The animal is short, with very short united siphonal tubes. Orifices fimbriated. Mouth closed, except in front, where there is an opening for a bony narrow thick foot of considerable dimensions. Anal siphon with a conspicuous tubular membrane. Labial tentacles slender.

This genus was once abundant in the European seas, especially during the early part of the Tertiary epoch. Only a few species now exist. It has more species in the tropical seas of the present day.

C. nucleus is one of the most common species in the seas around the British Islands. Whilst very frequently found in the dredges, it is seldom washed on shore or found in shallow waters. It is about half an inch in length and about one-fourth less in breadth.

This genus belongs to De Blainville's family *Pyloridea*, which embraces *Solen*, *Panopea*, *Mya*, and other allied species. [PYLORIDEA.]

CORCHORUS, a genus of Plants belonging to the natural order *Tiliaceæ*. The leaves of *C. olitorius* are used in Egypt as a pot-herb. Fishing-lines and nets, rice bags, and a coarse kind of linen called tat, are made in India of the fibres of *C. capsularis*.

CORDIA, a genus of Plants belonging to the natural order *Cordiaceæ*. It has a tubular calyx, 4-5-toothed. Corolla funnel shaped or campanulate, with a flat 5-7-cleft limb, and a hairy or naked throat. Stamens 5, short, inserted in the throat of the corolla. Style protruding, bifid, with 4 stigmas. Ovary 3-4-celled. Drupe containing 1 stone with 1 or 3 cells, two of which are usually abortive.

C. latifolia is a native of Hindustan. It has numerous spreading and drooping branches; the young shoots angular and smooth. The general height of trees ten or twelve years old about 20 feet. Leaves alternate, petioled, round, cordate, and ovate, often slightly repand; 3-nerved; of a hard texture, smooth above, scabrous and pale underneath; from 3 to 7 or even 8 inches long, and rather less in breadth. Petioles nearly rounded and smooth. Panicles short, terminal, and lateral, roundish; the branches alternate, diverging, and one or more frequently dichotomous. Flowers numerous, small, white. Bracts minute, villous. Calyx villous, campanulate, leathery; mouth unequally toothed. Corolla short, campanulate. Segments 5, linear-oblong; filaments as long as the segments of the corolla, and inserted immediately under their fissures. Anthers incumbent. Ovary ovate, 4-celled, with one ovule in each attached to the upper end of the axis. Style short. Stigma 4-cleft; segments long, rugose, and recurved. Drupe oblate-spheroidal, about an inch or an inch and a quarter in diameter; smooth when ripe, straw-coloured, covered with a whitish bloom. Under the name Sebesten Plums, Sebestans, or Sepistans, two sorts of Indian fruit, have been employed as pectoral medicines, for which their mucilaginous qualities, combined with some astringency, have recommended them. They are believed to have been the *Persea* of Dioscorides. Linnæus has erroneously applied the name of Sebesten to an American species of this genus which is not known in medicine.

C. Myxa is a native of many parts of India, Persia, Arabia, and Egypt. The trunk is generally crooked, from 8 to 12 feet high, and as thick or thicker than a man's body. The bark gray, cracked in various directions. Branches numerous, spreading, and bent in every possible direction, forming a dense shady head. The flowers are numerous, white, small; a very large proportion of them are sterile, and they always want the style. The drupe is globular, smooth, the size of a cherry, sitting in the enlarged calyx; when ripe, yellow; the pulp is almost transparent, very tough, and viscid. The smell of the nut when cut is heavy and disagreeable; the taste of the kernels like that of filberts. It is the true Sebesten of the European Materia Medica. The fruits, according to Roxburgh, are not used in the Circars medicinally, but when ripe are eaten by the natives, and also most greedily by several sorts of birds, being of a sweetish taste. The wood is soft, and of little use except for fuel. It is reckoned one of the best kinds for kindling fire by friction, and is thought to have furnished the wood from which the Egyptians constructed their mummy cases. The wood is said by Dr. Royle to be accounted a mild tonic.

C. Gerasacanthus is a native of the West Indies in woods, and of Mexico, near Acapulco. It has ovate oblong leaves, acute, quite entire, glabrous; racemes terminal, aggregate; flowers verticillate, sessile; calyx 10-furrowed, 10-striped, downy; limb of corolla 5-cleft; throat villous; stamens the length of the corolla. This is esteemed one of the best timber-trees in Jamaica, of which it is a native. The wood is of a dark brown colour, and gently striped; it is tough and elastic, of a fine grain, and easily worked. It is called Spanish Elm or Prince Wood by the English, and Bois de Chypre by the French.

C. Rumphii has brown wood beautifully veined with black, and smelling of musk.

There are above 100 species of this genus.

(Lindley, *Flora Medica.*)

CORDIA'CEÆ, a small natural order of Monopetalous Exogens, with a shrubby or arborescent habit, a gyrate inflorescence, and a drupaceous fruit. The leaves are alternate, usually covered with asperities, and destitute of stipules. The calyx is inferior and 5-toothed; the corolla regular, with 5 stamens proceeding from the tube, and alternate with the segments. There is a pendulous ovule in each cell, and the style is twice-forked. The cotyledons are crumpled or folded in plaits lengthwise. The affinities of the order are almost equal between *Boraginaceæ* and *Convolvulaceæ*, but preponderates in favour of the former. The only economical plants contained in it are the Sebesten Plums, the produce of *Cordia Myxa* and *Sebestena*, the rind of which is succulent and mucilaginous. All the species are tropical.

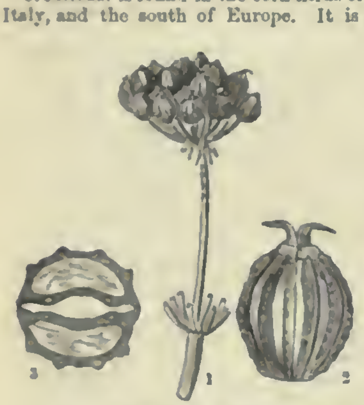
CORDIERITE. [IOLITE.]

COREGONUS. [SALMONIDÆ.]

CORIANDER. [CORIANDRUM.]

CORIANDRUM, a genus of Plants belonging to the natural order *Umbelliferæ*. It has 5 acute calyx teeth, unequal and permanent; petals obovate, emarginate, with an inflexed segment, the exterior radiating and bifid. Fruit globose, with 10 ribs scarcely separating. Half fruits, with 5 primary depressed wavy ridges, and 4 secondary ones (besides the marginals) more prominent and keeled. Channels without vittæ; commissure with 2 vittæ. Seed hollowed out in front with a loose skin. The species are smooth herbs. Leaves multifid; umbels with 3 or 5 rays. Involucre none; involucels about 3-leaved, halved.

C. sativum is found in the corn-fields of Tartary, the Levant, Greece, Italy, and the south of Europe. It is not really wild in England. The root is tapering, the stem erect, 12 or 18 inches high, more or less branched, leafy, round, striated. The lower leaves are pinnate on longish slender stalks, their leaflets wedge-shaped or fan-shaped, and acutely notched; upper leaves multifid in fine lineal segments. The flowers are white, often of a reddish tint. The fruit pale brown, somewhat coriaceous, spherical, 1½ lines in diameter; all the ridges indistinctly shown on account of their slight elevation; the vittæ of the commissure short, lunate, just visible without dissection. The fruit is carminative and aromatic. Cullen considered it more powerfully corrective of the odour and taste of senna than any other aromatic. (Lindley, 'Flora Medica.')



Coriandrum sativum.

1, a portion of an umbel, in fruit; 2, a fruit magnified; 3, a transverse section of the same.

Coriander fruit, or seeds as they are incorrectly called, are used in sweetmeats, in certain stomachic liqueurs, and in some countries in cookery: they are little esteemed in England.

CORIARIA'CEÆ, a very small natural order of Gynobasic Polypetalous Exogenous Plants, with opposite or alternate exstipulate leaves, 10 stamens, with an hypogynous insertion, and 5 distinct ovaries, with distinct spreading stigmas. The two genera, of which alone the order consists, are nearly allied to *Rutaceæ*, but their leaves are not dotted. The only plant that gives the order any interest is *Coriaria myrtifolia*, a shrub inhabiting the south of Europe, and employed by dyers for staining black. Its fruit is succulent, and said to be poisonous.

Coriaria myrtifolia.

1, a flower with its bract, the anthers not yet visible; 2, the same with the anthers projecting; 3, a cross section of the ovary; 4, a seed; 5, a vertical section of the same.

CORIOCELLA. [CHISMOBRANCHIATA.]

CORK, botanically considered, is a soft and elastic layer of bark which becomes remarkably developed in the kind of oak inhabiting Spain and Portugal. [QUERCUS; BARK.] This substance is developed in other plants, but in none in so large quantity as in the *Quercus Suber*. As soon as the bark dies it ceases to grow, and then, not distending as it is pressed upon from within, it falls off in flakes which correspond to the layers that are formed annually. These flakes are the layers of cork which the Spaniards collect under the name of the outer bark, while the inner living bark is or rather should be spared. We are told however by Captain S. Cook that the Spaniards have been in the habit of stripping off the inner bark also, although it is of no value except for tanning, and although its removal destroys the trees. The same intelligent observer states that the cork-tree occurs in Spain throughout the whole extent of the Tierra Caliente, but is most abundant in Catalonia and Valencia, whence the principal exports have been made. Cork appears to be a corruption of the Latin word 'cortex.' For the uses of Cork in the arts see CORK in ARTS AND SC. DIV.

CORK, MOUNTAIN. [ASBESTUS.]

CORK-TREE. [QUERCUS.]

CORK-WING. [CRENILABRUS.]

CORKLING. [CRENILABRUS.]

CORMORANT. [PELECANIDÆ.]

CORN-MARIGOLD. [CHRYSANTHEMUM.]

CORN-SALAD. [VALERIANELLA.]

CORNA'CEÆ, a small natural order of Polypetalous Exogenous Plants. They consist principally of shrubs, very rarely of herbaceous plants. They have opposite strongly-veined leaves without stipules; an inferior ovary, in each of whose cells is one pendulous ovule; 4 valvate petals; 4 stamens alternating with them; and a drupaceous fruit with two cells; the embryo lies in some fleshy albumen.

Cornel-Tree (*Cornus mas*).

1, an expanded flower, with the petals and stamens; 2, an ovary cut through vertically, showing a cup-like disc surrounding the base of the style, and the pendulous ovules; 3, a fruit cut so as to show the stone; 4, a vertical section of the stone, exhibiting the embryo and albumen.

Many of the species are cultivated in European gardens, especially *Cornus mas*, the Cornel-Tree; *C. alba*, *C. sanguinea*, and *C. sericea*, called Dogwood; together with *Benthamia fragifera*. They are valued either for their bright-red shoots, which in the winter are highly ornamental, or for their richly-coloured fruit. *Benthamia fragifera* in particular has its drupes collected in roundish strawberry-like heads, which have a beautiful effect in the south-west of England, where it has been several years introduced from the Himalaya Mountains. The bracts of some species of this order are very large, and resemble petals, and being white they are a gay substitute for the flowers themselves, which are small and inconspicuous. This is particularly the case with *Cornus herbacea*, *C. florida*, and *Benthamia fragifera*. Medicinally, Cornaceous plants are of great importance. The American physicians esteem the bark of *Cornus florida* and *C. sericea* equal to *Cinchona* as a febrifuge.

Formerly the *Cornus mas* used to be cultivated in gardens for the sake of its fruit, which were called Cornelian Cherries. It is a deciduous tree, with clusters of small starry yellow flowers, appearing in the spring before the leaves. The leaves are ovate-lanceolate, acute, wavy, and of a dull grayish-green. The fruit consists of oblong drupes of a red or occasionally a yellow colour; they are excessively austere before ripe, but eventually blet like medlars, and then become eatable.

This order is allied to *Umbelliferæ* and *Hamamelidaceæ*. There are 9 genera and above 40 species.

CORNBRASH, a thin calcareous member of the Oolitic Formations. It constitutes the uppermost band of the Bath Oolitic Formation, and is extremely rich in *Echinodermata* and *Conchifera*, but somewhat remarkably deficient in *Belemnites*.

CORNCRAKE. [RALLIDÆ.]

CORNEA. [EYE.]

CORNEL-TREE. [CORNUS.]

CORNELIAN, or CARNELIAN. [AGATE.]

CORNELIAN CHERRY. [CORNACEÆ.]

CORNISH CHOUGH. [CORVIDÆ.]

CORNISH DAW. [CORVIDÆ.]

CORNSTONE. The peculiar Limestone, often mottled in colour, of the Old Red-Sandstone of Hereford, Salop, and South Wales, receives this title. (Murchison, *Silurian System*.)

CORNU AMMONIS. [AMMONITES.]

CORNULITES, an obscurely characterised genus (of *Polypiaria ?*), which occurs in the Silurian Limestones and Sandstones very frequently, as at Dudley, Usk, Marloes Bay, &c. (Murchison, *Silurian System*, pl. 26, f. 5.)

CORNUS, a genus of Plants, the type of the natural order *Cornaceæ*. It has a calyx with a very small 4-toothed limb; with 4 oblong sessile petals; 6 stamens; 1 style; a baccate drupe marked with traces of a calyx; the stone 2-celled, rarely 3-celled; the seeds solitary, pendulous; the albumen fleshy; the radicle of the embryo shorter than the cotyledons. The species are trees, shrubs, or low herbs, with opposite leaves, and white flowers, sometimes yellowish.

C. sanguinea, Dog-Wood, Wild Cornel-Tree, has arborescent straight branches; ovate cuspidate leaves, green on both sides; the cymes flat, without an involucre. This plant is a shrub, reaching a height of 5 or 6 feet. Its branches are of a reddish colour. It is a native of Great Britain, in hedges and thickets. It also inhabits North America, in Canada and the State of New York; but was probably introduced there. It has a dark purple fruit, which is very bitter. Matthiolus says that it contains an oil, which is sometimes expressed, and is used for lamps. The wood is used for making charcoal, from which gunpowder is made. The fruits are sometimes mistaken for those of buckthorn, but do not possess the active properties of that plant. The wood is also used for making skewers for butchers. It is called in the country Female Cornel, Prick-Wood, Dogberry-Tree, Hound's-Tree, Gaten, and Gaten-Tree.

C. suecica, Dwarf Cornel, has herbaceous stems, the leaves all opposite, sessile, ovate; the nerves separate almost to the base; the flowers umbellate, shorter than the 4-leaved petaloid involucre. It is found in high mountain pastures in England and Scotland. It is not so large a plant as the last, and has purple flowers with yellow stamens. The berries are red and sweetish, and are supposed by the Highlanders to create an appetite, of which their name for them, 'Lus-a-Chrasis,' is expressive.

C. florida has shining branches, ovate acuminated leaves, pale beneath, beset with adpressed hairs; the flowers umbellate; the leaves of involucre large, roundish, retuse, the drupes ovate. It is a native of moist forests in the United States, especially on the borders of swamps. The bark of this tree is a powerful tonic, astringent, and antiseptic, resembling *Cinchona* in its action on the system, and much valued by American physicians. The young branches stripped of their bark, when rubbed against the teeth, render them extremely white. The bark of the roots yields a colouring-matter which dyes cloth scarlet.

C. sericea, Silky Dogwood, has spreading branches; woolly branchlets; ovate acuminate leaves, clothed with rusty pubescence beneath; the corymbs depressed, woolly; the nucleus compressed. It is a native of North America, in moist woods. It has the same properties as the last species, and is used for the cure of intermittent fevers. It is probable that these plants contain an alkaloid identical with quinine, but it has not yet been separated.

C. mas, Male Cornel, Cornelian Cherry, has smoothish branches; leaves oval, acuminate, rather pubescent on both surfaces; flowers rising before the leaves; the umbels about equal in length to the 4-leaved involucre; the fruit elliptic. It is a native throughout the continent of Europe, but is not found in Great Britain. It has yellow flowers, which are succeeded by an elliptical fruit of a bright shining scarlet colour, of the size and form of a small acorn. This plant was formerly cultivated for the sake of its fruit, but it is very inferior to many others that can be more easily produced, so that it is not now often used. The fruit is called Corbet by the Turks, and is used by them in the manufacture of sherbet. The wood is very durable.

The species of Cornus form good plants for shrubberries, and many of them will grow under the drip of trees, and in spots where other plants will not thrive. They may be propagated by cuttings, layers, or suckers.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica;* Babington, *Manual of British Botany*.)

COROLLA, the name given by botanists to the innermost of the envelopes of which the flower is composed. Like the Calyx [CALYX] it is formed of leaves changed from the ordinary state of those parts in consequence of an alteration in the office they have to perform, but liable to resume the state of common leaves if exposed to the effect of any disturbing cause. The corolla is usually thin, delicate, perishable, and both larger and more richly coloured than the calyx; hence the older botanists considered those qualities proper to the corolla, and applied the term to all cases in which they existed. But it is now known that the calyx is frequently in the same state, and hence the only distinction that is now made between calyx and corolla is to consider everything calyx which forms the exterior of two or more rows of floral envelopes, everything corolla that belongs to the inner rows, and when there is only one row, to refer that to the calyx, whatever the colour or texture of it may be.

There is little doubt that when a calyx is green and leafy its business is principally to protect the corolla; and that a corolla when large, thin, and brightly coloured, is intended to exercise some special influence upon the fertilising organs of the flower; for while the respiratory action of the calyx when green is not distinguishable from that of common leaves, the corolla differs most essentially in the want of all power of decomposing carbonic acid; it absorbs oxygen from the air, but does not part with it again in a pure state: on the contrary, it combines it with its carbon, and throws off the carbonic acid thus formed. But although there is this difference between the calyx and corolla in ordinary cases, the functions of the corolla are performed by the calyx when it has the appearance of a corolla, and *vice versâ*. The peculiar functions of these parts are therefore performed indifferently by the one or the other according to their structure.

The leaves of which a corolla is composed are called Petals; and the endless varieties of its form and structure depend principally upon the different manner in which those parts are united, or upon the proportions they bear to each other. A Monopetalous Corolla, for instance, is composed of several petals joined more or less together by their edges; Campanulate Corollas originate from petals without a claw or unguis; Tubular Corollas from unguiculate petals. In a regular monopetalous corolla all the petals are of equal size, and are united in the same degree; in an irregular monopetalous corolla, the petals are unequal in size, and perhaps unequally united.

The corolla is generally the part of the flower in which grotesque forms are most frequently met with; such as horns or spurs projecting from the base; or a cowled figure, or dark hairy appearances resembling the bodies of insects, as in the Bee-Larkspur, various orchidaceous plants, &c. The cause of these singular forms is entirely unknown; they appear to be specific cases of which no explanation can be given. [FLOWER.]

COROLLIFLORÆ, a subdivision of the class of Exogenous or Dicotyledonous Plants. It embraces those orders in which the petals are united and the stamens are attached to those organs.

CORONARII. [AMMONITES.]

CORONILLA, a genus of Plants belonging to the natural order *Leguminosæ*. It has a campanulate calyx, short, 5-toothed, the superior teeth approximated and nearly united. Claws of the petals distinctly longer than the calyx; keel acute. Stamens diadelphous. Legume tapering, slender, finally separating into oblong 1-seeded joints. Seeds ovate or cylindrical. The species are shrubs or herbaceous plants. Leaves unequally pennated. Peduncles axillary, bearing an umbel of stalked flowers.

C. Emerus is common all over the South of Europe. It is known by the name of Scorpion Senna, and its leaves are cathartic like those of true Senna, but less so. It is a small bush. Branches deep green, strongly furrowed, quite smooth. Leaflets 2-3 pairs, obovate, retuse or obtuse, when young very downy; stipules ovate, acute, very much shorter than the first joint of the petiole. Peduncles axillary, 2-3-flowered, slender, erect, as long as the leaves. Calyx slightly downy, only half the length of the claws of the petals. Corolla deep bright yellow. Legume a long while before its joints drop in pieces.

C. varia is an herbaceous plant, with distinct lanceolate petals; the leaflets 9-13, oblong, elliptic, mucronate, the lower ones approaching the stem; the umbels 16-20-flowered; the legumes angular, very long, straight. It inhabits meadows and waste places in the south of Europe and in the Crimea. The leaves have a diuretic action on the system, and also purge. The juice is said to be poisonous when taken in large quantities; although this is the action on the human system, cattle feed on this plant with avidity, and it has been proposed to cultivate it in this country as fodder. It probably does not develop its active secretions in climates north of its native districts. In a good soil the stems grow to the height of five feet, so as amply to repay its cultivation, especially in a dry season. When once planted it is difficult to eradicate. *C. globosa* and *C. iberica* have the same tendency.

The species of *Coronilla* are numerous, and are all shrubs or herbs, adapted for ornamental cultivation. Of the hardy shrubby species, ripened cuttings root freely, and may be planted in open ground in the autumn. The frame and greenhouse species are of easy culture. They grow best in a mixture of loam and peat; cuttings strike readily in sand under a hand-glass, and may be turned out into the open border in spring, where they will flower all summer. Many of them are well adapted for rock-work, but are apt to be killed during a severe winter.

(Don, *Dichlamydeous Plants*; Loudon, *Encyclopædia of Plants*; Lindley, *Flora Medica*.)

CORONULA. [CIRRIPEDIA.]

COROPHIUM, a genus of Animals belonging to the class *Crustacea* and the family *Gammarinæ*. With the whole of the family, it is remarkable for the length of its antennæ. It has no claws. One of the species, *Cancer grossipes* of Linnæus, *Gammarus longicornis* of Fabricius, *Oniscus volutator* of Pallas, is well known on the coast of La Rochelle for its habit of burrowing in the sand. They live principally upon the annelides which inhabit the sand, and are remarkable for assembling in great numbers around their prey, and destroying it although it may be twenty times as large as themselves. They also attack fishes, *mollusca*, and the dead bodies of other animals.

CORREA, a genus of Plants belonging to the natural order *Rutaceæ*, of which one of the species, *C. alba*, is used by the settlers in Australia as a substitute for tea. (Lindley, *Vegetable Kingdom*.)

CORRIGI'OLA (diminutive of *corrigia*, a shoe-string), a genus of Plants belonging to the natural order *Paronychieæ*. It has 5 sepals slightly cohering at the base; 5 petals equalling the sepals; 5 stamens; 3 sessile stigmas; a 1-seeded indehiscent fruit; the seed suspended by its cord, which arises from the base of the capsule; the petal, as the sepal, inserted upon an obscurely perigynous ring at the bottom of the calyx. The species are procumbent glaucous herbs, with alternate stipulate leaves.

C. littoralis, Strap-Wort, has the stem leafy on the part only which bears the flowers. It is the only British species of the genus. It is found on sandy shores in England, but it is not an abundant plant. There are three or four other species described, natives of America and Africa.

(Babington, *Manual of British Botany*.)

CORSICAN MOSS. [PLOCARIA.]

CORUNDUM. Several substances differing considerably in colour, and sometimes in form, but nearly agreeing in composition, are classed together under the name of *Corundum*, which is that given to the common variety by the natives of India.

Sapphire, of which there are several varieties, the names of which are dependent chiefly upon their colour: the *White Sapphire*, which is transparent or translucent; the *Oriental Sapphire*, which is blue; *Oriental Amethyst*, which is purple; the *Oriental Topaz*, yellow; the *Oriental Emerald*, green; and some other varieties occur, as the *Chatoyant* and the *Opalescent Sapphire*. The Sapphire occurs in rolled masses and crystallised, and the primary form of this and every variety of crystallised Corundum is a slightly acute rhomboid, presenting a great variety of secondary forms; it usually occurs in the form of 6-sided prisms variously terminated. Its specific gravity is 3·975 to 4·161; it possesses double refraction, and is inferior in hardness only to the diamond. Alone before the blow-pipe it suffers no change; with borax it fuses slowly but perfectly into a colourless glass. In one direction only the crystals cleave readily parallel with the faces of the primary rhomboid, and present a very brilliant surface; the cross fracture is conchoidal. The finest are found in Ceylon. According to the analysis of Chenevix, the Sapphire consists of—

Alumina	92
Silica	5·25
Oxide of Iron	1
	——98·25

According however to Dr. Thomas Muir, this substance is pure alumina, containing no silica but what is abraded from the mortar; and this is the view adopted by modern mineralogists.

Ruby. Colour blood-red or rose-red, sometimes a tinge of violet; primary form as above, and generally occurs in 6-sided prisms. It is not so hard as the Sapphire, and is more readily cleaved. Like the Sapphire, it consists of pure alumina. "The largest oriental ruby known was brought from China to Prince Gargarin, governor of Siberia; it afterwards came into the possession of Prince Menzilkoff, and constitutes now a jewel in the Imperial Crown of Russia." (Dana.)

Common Corundum, the variety usually called *Adamantine Spar*, occurs, like the Sapphire and Ruby, commonly in the secondary form of 6-sided prisms, but usually much larger. It is sometimes nearly colourless, and rather translucent; it presents great variety of colour, but is most commonly greenish or grayish; occasionally brown or red, rarely blue. Although its most common form is the 6-sided prism, it occurs, though rarely, also in acute and obtuse double 6-sided pyramids. On account of its extreme hardness it received the name of Adamantine Spar. It occurs in China, Bengal, Malabar, Tibet, the Carnatic, &c. It is used in the East Indies for cutting and polishing precious stones, and also granite and other hard rocks that are employed in the temples and other public monuments. According to Chenevix, the Carnatic Corundum contains silica, but this does not appear to be constant.

Emery. This substance which, when reduced to powder, is much used for polishing hard bodies, though very different in appearance from the preceding, is, on account of its hardness and analysis, regarded as Amorphous Corundum. Its colour is usually gray; its lustre is somewhat glistening. Its specific gravity is about 3·66 to 4; it occurs massive, and is granular. It is principally imported from the island of Naxos in the Grecian Archipelago, and was found by Mr. Smithson Tennant to consist of—

Alumina	86
Silica	3
Oxide of Iron	4
	—93

It occurs also in Italy, Spain, and Saxony; and it is said, in small quantities, also in Wicklow, Ireland.

CO'RVIDÆ, Crows, a family of Birds belonging to the division *Conirostres*. The bill is strong, slightly cultrirostral, or more or less compressed; the gape or commissure straight. The nostrils are covered with stiff bristle-like feathers directed forwards.

"The *Nucifraga*, Briss., our British Nutcracker," says Mr. Vigors, in his paper 'On the Natural Affinities that connect the Orders and Families of Birds,' in 'Linn. Trans.,' "closely resembling the preceding groups (Fam. *Sturnidæ*) in the form of its bill, in conjunction with *Barita*, Cuv., introduces us into the family of *Corvidæ*. From that genus we may trace a line of affinities, through some intervening forms, to the Jays and Rollers, *Garrulus*, Briss., and *Coracias*, Linn., until we arrive at the *Corvus* of Linnæus, which again branches out into several groups closely allied to each other, but differing considerably in the structure of the bill. Hence we proceed by means of *Glaucopis*, Forst., to some genera, among which we may particularise *Ptilonorhynchus*, Kuhl., *Crypsirina*, Vieill., *Eulabes*, Cuv., and *Fregilus*, Cuv., which, in the metallic lustre of their plumage and the velvet-like process that in some species ornaments the face, indicate our approach to the Birds of Paradise. The last-mentioned genus, *Fregilus*, in particular, by its curved and slender bill, brings us immediately into this group, the *Paradisea*, Linn., which, in conjunction with the *Epimachus* of M. Cuvier, terminates the family of *Corvidæ*. Here we shall probably find the passage from the present to the succeeding family. The *Epimachus*, more united in its front toes than the *Corvidæ* in general, holds a middle station in respect to that character between the two groups; while in the length and curvature of its bill it approaches, in conjunction with many of the *Paradiseæ*, to some of the extreme species of the *Buceridæ*, among which the *Buceros nasutus* of Latham may be instanced." Mr. Vigors, in a note, says that he speaks with considerable hesitation as to the situation of *Epimachus*, which bears too strong a resemblance to the *Promerops* of M. Brisson, a group feeding on vegetable juices, with an extensile tongue, to permit him to separate it without some expression of doubt.

Mr. Swainson, in 'Fauna Boreali-Americana,' vol. ii., thus writes on the *Corvidæ*:—"There are some singular and highly interesting peculiarities exclusively belonging to groups pre-eminently typical, which demand the deepest attention of the philosophic naturalist. One of the most striking of these is the great difference between those forms which belong to perfect and natural genera, strictly so termed. We might cite the restricted genera, *Tanagra*, *Cashmorhynchus* (*Casmarhynchos*), and *Coccothraustes*, as remarkable examples of this fact, and as groups which would repay the most minute analysis. This peculiarity sometimes extends to higher groups; and in the present family, the most pre-eminently typical in the whole circle of ornithology, it is more striking than in any other. It is perhaps to this circumstance that we must attribute the very imperfect manner in which the internal relations of the *Corvidæ* have been illustrated, and the artificial distribution that has been made of the groups it contains. Our space indeed will not permit us at present to throw much light upon the subject, further than what may be gained by studying the following table of sub-families:—

Analogies.		Sub-families.
	1. Typical Group.	
CONIROSTRES.	Wings lengthened, obliquely pointed; lateral toes equal.	*Corvidæ*.
	2. Sub-Typical Group.	
DENTIROSTRES.	Wings shorter, rounded, convex; lateral toes unequal.	*Garrulinæ*.
	3. Aberrant Group.	
SCANSORES.	Bill short, entire, light; feet short.	*Crypsirinæ*.
TENUIROSTRES.	* * * * * * *	?
FISSIROSTRES.	Bill slender, lengthened; feet short.	*Fregilinæ*.

"A glance at the modern arrangements will show how essentially we differ from all ornithologists who like us have attempted to elucidate this very intricate family. The tests however by which every series of animals thought to be natural must be tried, will bring to light many remarkable peculiarities which belong only to the foregoing arrangement. Yet however confident we feel on the general accuracy of this sketch, we are unprepared either to show in what manner the sub-families are connected, or to refer many of the modern genera to their natural divisions. The Jays (*Garrulinæ*) unquestionably represent the Bush-Shrikes (*Thamnophilinæ*); while the genus *Crypsirinæ* and the short-legged *Glaucopinæ* of M. Temminck form part of a group typifying the Drongo-Shrikes. The slender bill of the *Fregelinæ*, at the opposite side of the circle, indicates the position of the fissirostral group, corresponding to the *Buceridæ*. But we have many doubts on the true nature of the tenuirostral type, since it must not only represent the Hang-Nest Starlings (*Icterinæ*), but also the Caterpillar-Catchers (*Ceblepyrinæ*), and the typical *Ampelidæ*, or Chatterers. Now it will strike every ornithologist who has the means of examining the *Gracula calva* of authors, that notwithstanding its general resemblance to the Chauve of Le Vaillant ('Oiseaux de l'Amérique,' pl. 49), it is decidedly a Crow; while the latter is considered by Le Vaillant as unquestionably belonging to the *Ampelidæ*. We have therefore good reason to suspect the *Gracula calva* to be one of the tenuirostral types of the *Corvidæ*. In all probability it will prove to be the sub-family type representing that tribe, although at present we choose to omit its designation in the foregoing table."

In the following article we shall describe the genera *Corvidæ*, and give examples of the species which illustrate them.

Corvus.—Bill straight, large, compressed, and a little swollen on the sides; convex and curved towards the point, its edges cutting. Nostrils open. Fourth quill the longest. Tail even, rounded, or rectilinear.

"The species *Corvus*," says M. Lesson, "is very numerous in its species. Birds which differ in their characters and habits from the crows, properly so called—which are the largest of the *Passeres*, whose way of life is carnivorous, and their food composed of all sorts of substances, especially carrion—have been joined to the genus. The crows possess much intelligence, are easily tamed, and become very familiar. They are very voracious, and live in numerous bands, and their harsh cry has been called croaking. They often commit such havoc that a price is set on their head in some countries. They have at all times been objects of superstition to the people. Some of the crows are sedentary; others again are travellers, and migrate annually. They moult but once a year."

The species of this genus are found in all the four quarters of the globe.

C. Corax, the Raven. This well-known bird is the Κόραξ of the Greeks; *Corvus* of the Latins; Corvo, Corho, and Corvo Grosso of the modern Italians; El Cuervo of the Spaniards; Corbeau of the French; Der Rabe and Der Kolkrabe of the Germans; Korp of the Swedes; Raun of the Danes; Corbie of the Scotch; Cigfran of the Welsh; Kaw-kaw-gew of the Cree Indians; and Toolloo-ak of the Esquimaux. Sir John Richardson says that it abounds in the Fur Countries, and visits the remotest islands of the Polar Seas. "It frequents the Barren Grounds even in the most intense winter colds, its movements being directed in a great measure by those of the herds of rein-deer, musk-oxen, and bison, which it follows, ready to assist in devouring such as are killed by beasts of prey or by accident. No sooner has a hunter slaughtered an animal than these birds are seen coming from various quarters to feast on the offal; and considerable numbers constantly attend the fishing stations, where they show equal boldness and rapacity. The experienced native, when he sees from afar a flock of ravens wheeling in small circles, knows that a party of his countrymen well provided with venison are encamped on the spot, or that a band of wolves are preying upon the carcass of some of the larger quadrupeds, and pushes on briskly in the certain prospect of having his wants supplied. The thievish habits of a tame raven are well known; but it is remarkable that, inhabiting in a wild state the most secluded and worst peopled districts of America, it should exhibit the same disposition to carry off shining metallic bodies and other articles totally unfit either for food or to be used in the construction of its nest. Mr. Kendall, in crossing the height of land which divides the waters that flow towards Hudson's Bay from those which fall into the Arctic Sea, saw a raven flying off with something in his claws pursued by a number of his clamourous companions. The bird being fired at dropped the object of contention, which proved to be the lock of a chest."

The aptitude of the raven for articulating clearly is generally admitted. Mr. Swainson says, "One belonging to Mr. Henslow, of St. Albans, speaks so distinctly that when first we heard it we were actually deceived in thinking it was a human voice: and there is another at Chatham which has made equal proficiency; for living in the vicinity of a guard-house it has more than once turned out the guard, who thought they were called by the sentinel on duty."

Sir John Richardson ('Fauna Boreali-Americana') states that a pied individual was killed on the south branch of the Mackenzie from a flock of the common sort. Its neck, fore part of the back, and part of the wings were gray; the rest of its plumage black.

"This," writes Dr. Latham, "is a universal species, found both in the old and new continents; from Greenland to the Cape of Good Hope in the one, and from Hudson's Bay to Mexico in the other. It was also met with by our circumnavigators in the Sandwich Isles, and at Owhyhee was held in great estimation." Its appearance is recorded in the first and second voyage of Parry as occurring within the Arctic Circle, and in Franklin's Journal. Several pairs were seen at Melville Island, and Sir John Richardson gives a description of one killed at Fort Franklin in March, 1826.

Sir James Ross ('Appendix to Sir John Ross's Second Voyage,' p. 28), speaking of the Raven, says, "This is one of the few birds that are capable of braving the severity of an arctic winter, and of enduring the scorching rays of a tropical sun without any change being produced in its plumage by the extremes of climate. Cuvier and other authors mention that in the north it is frequently found more or less white: we never saw anything corroborative of such an observation. It preserves its plumage and peculiar characteristics unchanged in every quarter of the globe."

In his 'History of British Birds,' Mr. Yarrell has gone into a minute investigation of the structure of the larynx in the Raven, in which he shows that its power of voice depends on the complicated nature of the muscular apparatus with which this organ is supplied.

C. frugilegus (Linn.), the Rook. This well-known gregarious and familiar bird (for it seems to affect the neighbourhood of man, and even not to be scared by the smoky atmosphere of great towns) is the Cornacchia Nera and Cornacchione of the Italians; Graye, Grolle, Freux, and Frayonne of the French; Corneille Moissoneuse of Brisson; Schwartze Krähe of the Germans; Roka of the Swedes; and Ydfran of the Welsh.

Head and Foot of Rook (*Corvus frugilegus*).

Belon and Caius, the latter of whom names the Rook *Spermologus, seu Frugilega*, appear to be of opinion that it is the Σπερμολόγος of Aristotle ('Hist. Anim.' viii. 3). It is doubtless, as Pennant observes, the *Corvus* of Virgil, who has happily described a flock of them—

"E pastu decedens agmine magno." ('Georg.' lib. i. v. 381.)

The Rook is spread over the greater part of Europe; but nowhere does it seem to be more abundant than in Great Britain and Ireland. Wooded and cultivated districts are its favourite haunts. The farther north the observer goes in Scotland the fewer rooks does he see. In Orkney and Shetland there are none, nor are there any in Guernsey and Jersey. They do not appear to be numerous in Denmark, nor in the southern districts of Sweden, nor in Russia and northern Asia, though they may be seen there. In Italy the Rook is common and permanent; but it appears to be migratory over a part of the continent of Europe. In France it is also common, and the following quatrain appears under the cut of it in the 'Portraits d'Oyseaux:'—

"Jamais le Freux ne hante le rivage,
Et ne se paist que de grains et de vers,
Il est oyseau commun, gros et pervers,
Qui vole en trouppe, et crie à l'avantage."

It occurs between the Black Sea and Caspian Sea; and Dr. Von Siebold and M. Bürger note it among the European birds seen by them in Japan.

Grain, and insects especially, form the food of the Rook, and there can be no doubt that it amply repays the farmer for the seed which it takes by its assiduity in clearing his land of wire-worms and the larvæ of the Cockchafer (*Melolontha vulgaris*). These last are called

Rook-Worms in many places, and the birds may be seen following the plough-tail to gather them up as the share exposes them. In the end of May and beginning of June, when the young are able to fly and go abroad with their parents, they may often be seen among the bright green leaves of the horse-chestnut and other trees, bending the branches with their weight as they assemble to pick off the cockchafers in their winged state. Where these birds have been inconsiderately destroyed on account of the supposed damage which they had done, a total failure of the crops has made the farmer glad to try to get them back again. The stick-built nest contains four or five pale greenish eggs, blotched with dark greenish-brown; these are sometimes palmed upon the undiscerning for plovers' eggs, but are easily distinguished from them. Not that a rook's egg is by any means bad, though far inferior in every respect to the other. The male is most attentive to the female whilst she is sitting, and feeds her assiduously; both are very industrious in supplying their young, and the skin under the tongue may at this season be often seen dilated into a kind of pouch by the collected food. During the building season they have great squabbles among themselves about their nests. An account of one of their battles with the herons for the possession of a disputed territory is alluded to in the article ARDEA. They frequently visit their nest-trees in the autumn on their way to roost in some distant wood, and come to them for the purpose of repairing their nest, and setting about the business of incubation early in March.

The Rook is not without the power of mimicry granted so largely to the greater part of the true crows, is docile, capable of learning amusing tricks, and becomes much attached to the kind hand that feeds it. It has been heard to imitate the note of a jackdaw (Hewitson) and the barking of dogs so perfectly that if the mimic had been out of sight no ear could have discovered the deception. (Macgillivray.)

Varieties.—White, pied, and cream-coloured. "A gentleman," says the charming author of the 'History of Selborne,' "had two milk-white rooks in one nest. A booby of a carter finding them before they were able to fly, threw them down and destroyed them, to the regret of the owner, who would have been glad to have preserved such a curiosity in the rookery. I saw the birds myself nailed against the end of a barn, and was surprised to find that their bills, legs, feet, and claws were milk-white." These perhaps were perfect albinos, and might so have continued; but instances are not wanting where the original light colour deepens into the usual sable with age. Mr. Yarrell quotes Mr. Hunt, of Norwich, who states that a gentleman of his acquaintance had in 1816 a young rook of a light ash colour most beautifully mottled all over with black, and the quill and tail-feathers elegantly barred; but when the bird moulted it became a jet-black rook, and in this state was suffered to join its sable brethren in the fields. Mr. Yarrell remarks that this agrees with his own observations, and he adds that accidental varieties will generally be found to be comparatively small and weak birds. As these young birds increase in age and gain constitutional power, the secretions, he observes, become perfect, and the plumage assumes its natural colours, whilst the assumption of white feathers by old birds is probably the effect of the converse operation of the physiological law. ('British Birds.')

It has been, and indeed still is with some, a question whether the loss of the feathers at the base of the beak in the young rook upon the first moult, is or is not a specific distinction, or merely the result of denudation from plunging the bill into the ground in search of prey. It must be borne in mind that some foreign birds resemble the rook in this particular. Mr. John Blackwall's observations ('Researches in Zoology') touching this matter are full of interest. He refers to a rook preserved in the Manchester Museum, which has its mandibles crossed near their extremities, but so slightly that the malformation could not have interfered materially with the mode of procuring food usually resorted to by rooks, as is clearly shown by the denuded state of the nostrils and anterior part of the head, both of which are entirely destitute of feathers. But he notices another specimen, in the possession of Mr. R. Wood of Manchester, which has the mandibles greatly elongated and much curved. "Now," says Mr. Blackwall, "it is evident that the bird possessing a bill thus formed could not thrust it into the ground in search of worms and larvæ of insects, as the rook is known to do habitually; and accordingly the plumage at the base of the bill of this individual, and the bristly feathers which cover its nostrils, are very conspicuous, not having sustained the slightest injury. The opinion entertained by many persons that the naked condition of the nostrils and anterior part of the head is an original peculiarity in the rook is thus satisfactorily proved to be incorrect; indeed the fact that young rooks exhibit no deficiency in these particulars is sufficiently conclusive on this point; but the possibility of an entire species being endowed with an instinct destructive of a usual portion of its organisation was probably never contemplated by these observers; it is not surprising therefore that the inference deduced from a partial view of the subject should be erroneous."

C. Corone, the Carrion-Crow, Gor Crow, Black Crow, Corby Crow, Hoody, Bran.; the Corneille Noire of the French. It has the feathers of the throat short, ovate-lanceolate, compact. Tail straight, slightly rounded. Plumage black, highly glossed, with purple reflections above and green beneath. Young similar, but less glossy.

It is found throughout England, and also in the north of Ireland and Scotland. It also inhabits Germany, France, Spain, Provence, and Italy. Temminck says it is a native of Japan.

Like the raven, the crows keep in pairs all the year, and seldom more than two are found together, unless at a feast of carrion. Its partiality to animal food has given it its various appellations, as well as that of Flesh-Crow. They are dangerous enemies where sheep are. They attack lambs and small quadrupeds, as well as the young of birds. They also eat shell-fish on the sea-shore. In default of meat they eat grain, potatoes, and have been known to feed on green-walnuts. The Carrion-Crow is an early breeder, and commences building its nest in February. The female lays four or five eggs of a pale bluish-green, spotted and speckled with two shades of ash colour and clove-brown.

C. cornix, the Hooded or Royston Crow, Gray-Backed Crow, Gray Crow, Dun Crow, Bunting Crow, Heedy Crow; Corneille Mantelée of the French. The feathers of the throat are short, lanceolate, compact; tail straight, slightly rounded; head, fore-neck, wings, and tail, black; the other parts ash-gray. Young with the plumage all dull black, except a broad band of dusky round the fore part of the body.

This bird resembles the last in its form, and in its habits is said to be even more mischievous. In the southern parts of England it is only a winter visitant, arriving from the north early in October, and departing again in April. In the western and northern parts of Scotland it remains all the year. It frequents marshes near the sea, the banks and shores of tidal rivers, as for instance the Thames. It is called Royston from its frequency in the neighbourhood of that town from October to April. Like the last species, they feed on lambs, poultry, and other animals, and when on the sea-shore partaking of *crustacea*, *mollusca*, and fish. Mr. Selby says, "I have repeatedly observed one of these birds to soar up to a considerable height in the air, with a cockle or mussel in its bill, and then drop it upon the rock in order to obtain the included fish." The Hooded Crow often pairs with the Carrion-Crow, and, what is singular, the produce are not apparent hybrids, but assume either the plumage of the Hooded Crow, or Carrion-Crow.

Pica.—Bill entire, with cutting edges, straight or curved, furnished at the base with setaceous feathers, lying forwards. Tail very long, graduated. (Vieillot.)

The *Picæ*, Magpies, feed much in the same manner as the true crows, build their nests in trees, advance on the ground by hopping, are clamorous, learn to articulate words easily, and the European species is renowned for hiding anything shining and portable that pleases its eye. This bird also has been always an object of superstition with the vulgar.

P. caudata of Ray, *Corvus Pica* of Linnæus, our common Magpie, or Pianet, is, there is hardly any doubt, the Κίττα of the Greeks. It is the *Pica* of the Romans; Gazza, Regazza, Putta, Picha, Gazzuola, Gazzara, Ghiandara, Gaggia, and Gaggia Domenicana, of the Italians; Pie, Jaguette, Dame, and Agasse, of the French; Die Elster, Die Aelster or Aglaster, of the Germans; Skade and Huus Skade of the Danes; Skior and Tnufugl of the Norwegians; Piogen of the Welsh; and Ootawa-kee-askee of the Cree Indians.

The Magpie hardly needs description, its plumage of black and white being so characteristic and well known. It is omnivorous, and lays six or seven oblong eggs of a yellowish-white, spotted with brown, and cinereous: its nest, well fortified with blackthorn twigs, is a curiosity. The female is rather less than the male, and her tail is shorter.

"This bird," says Sir John Richardson ('Fauna Boreali-Americana'), "so common in Europe, is equally plentiful in the interior prairie lands of America; but it is singular that though it abounds on the shores of Sweden and other maritime parts of the Old World, it is very rare on the Atlantic coasts of America, or near Hudson's Bay: only stray individuals passing to the eastward of the Mississippi or of Lake Winipeg. Mr. Say informs us that it winters on the Missouri, and takes its departure northwards on the 23rd of March. It does not entirely quit the banks of the Saskatchewan even in winter, but is much more frequent in summer. On comparing its eggs with those of the European bird, they are found to be longer and narrower; and though the colours are the same, the blotches are larger and more diffused. The manners of the American bird are precisely the same that we are accustomed to observe in the English one." Mr. Swainson adds, that he has been able to compare English and Arctic specimens with one from the interior of China, communicated to him by Mr. Gray, and that he cannot perceive the slightest difference whereon to build even the character of a variety, much less of a species. The tails of the Arctic specimens, he observes, are very beautiful. A white variety of this bird is occasionally seen.

The habits of the Magpie are very suspicious. Although seeking the habitations of man, it is always prompted by self-interest. "It is," says Montagu, "a great enemy to the husbandman and the preserver of game; but has cunning enough to evade their wrath. No animal food comes amiss to their carnivorous appetite; young poultry, eggs, young lambs, and even weakly sheep it will attempt to destroy by first plucking out their eyes; the young of hares, rabbits, and feathered game, share the same fate; fish, carrion, insects, and fruit, lastly grain, when nothing else can be got. It is an artful noisy bird, proclaiming aloud any apparent danger, and thereby gives notice to its associates. Neither the fox nor other wild animal can appear without being observed and haunted; even the fowler is frequently spoiled of his sport, for all other birds seem to know the alarming chatter of the magpie."

Everywhere this bird is marked for destruction, and were it not for its sagacity it would certainly long since have become extinct.

This bird is common in Scotland. Although not known in Ireland a century and half since, they are now common. This bird is very common in Norway, where the inhabitants avoid destroying it. It lives in Lapland, and is common in the Morea. It is also a native of China and Japan.

There are several foreign species of *Pica*. They occur both in the Old and New World.

Dendrocitta—a genus founded by Mr. Gould, and comprehending *Pica vagabunda* of Wagler, *P. Sinensis* of Hardwicke and Gray, and a third species, which Mr. Gould believes to have been hitherto unnoticed.

It has the bill shorter than the head, cultrated, broad at the base; culmen arched, sides subtumid; nostrils basal, partly covered with setaceous feathers. Wings moderate: fifth and sixth quills longest. Tail elongated, cuneated, the tail-feathers spatulate. Feet (tarsi) short and weak: toes moderate; hallux strong, with a strong incurvated claw.

D. leucogastra. Black; occupit, neck, transverse stripe at the base of the quills, and abdomen, white; scapulars, interscapular region (interscapulio), and lower tail-coverts, tinged with chestnut (dilutè castaneis); two internal tail-feathers ash-coloured, except at their tips.

"The shortness and comparative feebleness of the tarsi in *Dendrocitta*, and its more elongated tail, the feathers of which are equally graduated, except the two middle ones, which are much longer than the others, distinguish it from the typical *Picæ*, the common magpie, for example. These characters are in accordance with its habit of wandering from tree to tree in search of its food. It is farther distinguished by the form of its bill.

"All the species yet known are natives of Eastern Asia." (Gould, 'Zool. Proc.,' May 14th, 1833.)

D. vagabunda, Pica vagabunda, Wagler. Head, neck, and crest, of a smoke colour, or blackish gray; the back light cinnamon; the centre of the wings gray; the quills black; the tail gray, each feather being tipped largely with black; under surface pale tawny; beak and tarsi black. Length 16¼ inches; beak 1¼ inch; tarsi 1¼ inch; tail 10 inches. The species is more widely diffused than any of its congeners, being found in considerable abundance all over India. (Gould, 'Century of Birds from the Himalaya Mountains.')

Garrulus.—Bill moderate, straight, with cutting edges, inclined, and with obscure notches near the point. Tail even, sometimes rounded. (Vieillot.)

The Jays are inhabitants of the wooded districts, and live chiefly upon fruits, principally acorns and such vegetable productions. They rarely come into the open country, but make great havoc in gardens and cultivated grounds in the neighbourhood of woodlands. Their food is much less varied than that of the true crows; but they may still be styled omnivorous. Their plumage is generally gay, and even brilliant: the beautiful speculum on the wing is a leading character. The manners of the foreign species are analogous to those of the foreign magpies. Those of the Common Jay and its aptness at imitation are well known.

G. glandarius, the Common Jay, is supposed by Belon to be the Μαλακοκρανεὺς of Aristotle; and we may observe, in confirmation of this opinion, that the editor of the last edition of Pennant says, that the bird is very common in Greece, where it still retains its ancient name, Μαλακοκρανεὺς. Belon states it to be the Gaza Ghiaudaia, or Ghiandara, the Gaza Verla, and the Berla, of the Italians; and the Prince of Canino gives *Ghiandaja, Pica, Pica ghiandaja*, and *Pica palombina* as its Italian appellations. It is the Jay and Geai of the French, the Eichen-Häher (Oak-Jay), Holtzschryer (Wood-Cryer), or Holz-Häher, of the Germans; and Screch y Coed of the Welsh.

The Jay, like the Magpie, is too well known to require description. Its beautiful colours make it one of the handsomest of our native birds. It builds its basket-like nest in trees or high coppice-wood and hedges, and lays five or six eggs of a dull whitish olive, mottled very obscurely with pale brown; towards the large end there are usually two or three black lines. It is a sad enemy to gardeners. Fruits, especially cherries, and peas are its great favourites, and it is frequently taken by springes set upon the rows of peas when in bearing. Dr. Kramer says that it will kill small birds. With regard to their imitative powers, Bewick says, "We have heard one imitate the sound made by the action of a saw so exactly, that though it was on a Sunday, we could hardly be persuaded that the person who kept it had not a carpenter at work in the house. Another, at the approach of cattle, had learned to hound a cur dog upon them, by whistling and calling upon him by his name. At last, during a severe frost, the dog was, by that means, excited to attack a cow big with calf, when the poor animal fell on the ice, and was much hurt; the jay was complained of as a nuisance, and its owner was obliged to destroy it."

Dr. Latham says he has seen two varieties; the one pure white, the other as in the Common Jay, but having the whole of the quills white.

The author last quoted states that this species, though not nearly so far spread as the magpie, exists in various parts of the continent of Europe, and that he has observed it among drawings done in China.

There are several foreign species, both of the New and Old World. Mr. Gould, who figures three species in his 'Century of Birds,' well observes that, "The close affinity which the *Garrulus lanceolatus* bears to some species inhabiting the United States and Mexico is worthy of remark, as a corroboration of the fact so often insisted on, that similar forms of ornithology are found in countries widely separated from each other, whose temperatures are alike." Indeed, the last-mentioned bird immediately reminds the observer of the Blue Jay (*Garrulus cristatus*) of America, while *Garrulus bispecularis* recalls the common jay to his recollection.

Picathartes—a genus founded by M. Lesson, who takes for the type the Pie Chauve (*Corvus gymnocephalus* of Temminck).

It has the bill convex, not very robust, the upper mandible higher than the lower; the latter a little swollen towards its extremity; the base entirely without hairs, and furnished with a cere. Nostrils placed on the middle of the bill, oval, open, hollowed into an oblong excavation. Head entirely naked. Feet (tarsi) long, but little scutellated in front, naked behind; claws feeble; wings rounded, short. Tail long, graduated. (Lesson.)

"The form of this singular bird," says M. Temminck, "the cut of its wings, and its long conical and very graduated tail, serve me as indicia to judge by analogy of what country it may be a native, its locality being unknown. In fact, on comparing our new species with the Piapic of Le Vaillant (*Corvus Senegalensis*), one is inclined, from the marked analogy, to conclude Africa to be its country. Some data, which it is nevertheless not prudent to trust, lead me to believe that the only individual known, which is in the collection of Mr. Leadbeater of London, was brought from the English possessions on the coast of Guinea."

"Proportions (taille) a little stronger, tarsi much longer, and a tail less in proportion distinguish our bird from the Piapic. The head in certain points offers some resemblance to that of the *Gracula calva* of the Philippines, and this approximation is so strong that it would produce doubts as to its African origin, if it did not bear a greater resemblance in its general contour to the Piapic of Africa. In fine, if this bird is not African, it can only be a native of the Philippino Islands."

Picathartes gymnocephalus.

Upon this passage M. Lesson remarks, that he does not find the least analogy between the figure of the Enlum., 538, which is the *Corvus Senegalensis*, and the Pie Chauve, which more resembles a

Cathartes. The conclusion stated in M. Temminck's last sentence M. Lesson is far from admitting.

The following is Temminck's description of the species: "The naked parts of the head offer a particular character. The whole of the auditory meatus is completely destitute of feathers and even of hairs. A small border, or rudiment of membrane, forms, below the orifice of the ear, a sort of external concha, but little apparent, it is true, in the stuffed specimen, but the extent of which must be remarkable in the living bird. All this part of the organ of hearing, as well as a part of each side of the occiput, are covered by a black skin with a slightly-projecting orbicular border, and forming a rounded plaque. The cere which envelops the base of the bill is also black. All the rest of the naked parts of the head, the mesial line of the occiput which separates the black plaques of the temples, and the upper part of the top of the neck, appear to me to have been red or rosy in the living subject; a slight tint of rosy-yellow covers these parts in that before us. The whole of the nape is covered, clearly, by a whitish and very short down. The front of the neck and all the other parts are white. The back, well covered with thick-set feathers, is of an ashy-black; all the rest of the plumage is bistre brown. The feet are yellow, and the bill is black. Length 15 inches." (Temm.)

Podoces.—This genus was founded by M. Fischer, for a bird discovered by Dr. Pander, in the country of the Kirgise beyond Oremburg, whose habits of life are analogous to those of the crows, among which M. Lesson thinks it ought to be placed.

The bill is moderate, of the length of the head, bending downwards at its point, without a notch, and slightly angular, the upper mandible shorter than the lower, receiving and covering the edges of it. Nostrils basal, rounded, large, covered with setaceous overhanging feathers (plumes setacées retombantes). Feet robust and long; claws triangular, very much pointed, and but little curved; a warty membrane bordering the thickness of the phalanges. First quill short, second long, the three next equal. Tail rectilinear. (Fischer.)

P. Panderi. Greenish glaucous above; eyebrows white; bill and claws blackish; feet greenish. The bird flies badly but walks very well. It lives in flocks.

Podoces Panderi.

Myophonus.—Bill very large, strong and hard, furnished at its opening with some stiff bristles and small feathers turned forwards. Nasal fossæ sub-oval, closed by a large membrane. Wings rounded, moderate. Quills nearly equal, the third longest. Feet very long, demiscutellated. Tail rounded.

There are several species, all oriental. Mr. Gould, who has published two, namely, *M. Horsfieldii* and *M. Temminckii*, in his 'Century,' states that, as regards the habits of these birds, little can be said with certainty, but that from their lengthened tarsi and general structure they may be considered as depending in a great measure for their subsistence upon worms, insects, and larvæ. The manners of *M. Temminckii*, when on the ground, are said much to resemble those of the English blackbird. It may be questionable whether this group is properly placed among the *Corvidæ*.

M. flavirostris (*M. metallicus*, Temm.) Entirely of a deep blue-black with metallic tints. Bill of a beautiful yellow. Feet black. It inhabits Java.

Myophonus flavirostris.

Ptilonorhynchus.—Bill strong, robust, widened, rather long, upper basal termination convex, but little marked; point recurved; upper mandible presenting two small notches at its extremity; edges a little swollen; lower mandible slightly convex; commissure of the mouth straight, simple. Nostrils basal, lateral, furnished with short bristles. Wings short, rounded. Tail moderate, graduated. Feet slender. (Lesson.)

The genus, as modified by Lesson, contains but two species. He thinks that it would be better placed among the *Dentirostres* at the side of the Choucaris (*Graucalus*, Cuvier); but he allows that it has all the forms of the Rollers (*Coracias*) and of the Crows. Locality, the warmest islands of the West Indian Archipelago.

P. Sinensis, Coracias Sinensis, Latham. Body above pale aquamarine green clouded with yellowish-green. Forehead furnished with silky round feathers turned in different directions; feathers of the nape long, unravelled as it were, capable of being erected into a tuft—both of a yellowish-green. A black band taking its rise from the angle of the bill surrounds the eye and nape. Throat and cheeks of a yellowish-green. Lesser wing-coverts brown. Quills brown, inclining to olive externally and chestnut internally; the last three progressively terminated with greenish white. Bill red, surrounded by a few black bristles; feet reddish. Size 11 inches. Locality, the Philippine Islands.

The other species, according to Lesson, is *Kitta thalassina*, Temminck.

Kitta.—Bill short, convex, compressed on the sides; upper mandible with the basal termination recurved, and depressed sides; the point sharp and furnished on each side with a small projecting tooth, borders of the mandibles thick, recurved, and covered at the commissure. Nostrils basal, transversal, hidden by the silky feathers of the forehead, and by a row of small bristles. Wings pointed. Tail equal, rounded. Feet robust; toes equal; hallux strong. (Lesson.)

Lesson, who places in this genus *Kitta holosericea*, *Ptilonorhynchus Smithii*, and *Kitta virescens*, says that what was observed as to the last-mentioned genus is applicable to this, which has the general characters of the Rollers and Rolles (*Colaris*).

The birds composing the genus are exclusively peculiar to Australia and the temperate zone. (Lesson.)

K. holosericea, Temminck; *Ptilonorhynchus holosericeus*, Kuhl; Satin Grakle, Latham; *Ptilonorhynchus Mac-Leayii*, Latham MSS., Vigors and Horsfield.

Ptilonorhynchus Sinensis.

Male, very brilliant blackish-blue. Quills and tail-feathers dead black. Bill and feet yellow. A double row of silky and velvety bluish-black feathers at the base of the bill. Length 13 inches. The female has the upper parts of an olive-green. The quills and tail-

Satin-Bird (*Kitta holosericea*).

feathers of a red-brown; wing-coverts varied with brown and a colour inclining to olive; lower parts greenish, barred with black. There are whitish horizontal spots, lanceolated, and bordered with black, on the front of the neck.

Mr. Caley says (Vigors and Horsfield, 'Linn. Trans.,' vol. xv. p. 264) that "the male of this species is reckoned a very scarce bird, and is highly valued. The natives call it Cowry, the colonists Satin-Bird. I have now and then met with a solitary bird of this species; but I once saw large flocks of them on some newly-sown wheat, from whence they fled on being scared into a neighbouring brush. When all was again quiet they soon returned to the wheat. They did not leave the brush above a few yards. There were no black ones among them, nor can I affirm that they were feeding on the wheat."

Nucifraga.—Bill long, thick, with cutting edges terminating in a blunt point, furnished with setaceous feathers at the base, the upper mandible longer than the lower. Nostrils round, open. Wings pointed; fourth quill longest.

Till the publication of Mr. Gould's *Nucifraga hemispila* (see 'Century of Birds') but one species was known, namely, that which we select as the example:—

N. Caryocatactes, Brisson, the Nutcracker; *Caryocatactes nucifraga*, Nils.; *Corvus Caryocatactes*, Linnæus, the Casse-Noix of the French; the Tannen-Häher of the Germans; the Noddekrige of the Danes; the Not-Kraake of the Norwegians; and the Aderyn y Cnau of the Welsh.

This bird is somewhat less than the Jackdaw. The bill is straight, strong, and black. Head, neck, breast, and body, rusty brown. Crown of the head and rump plain, the other parts marked with triangular white spots. Wings black. Coverts spotted like the body. Tail rounded at the end, black, tipped with white. Legs dusky. Locality, most parts of Europe; but the Prince of Canino does not notice it in his 'Specchio Comparativo.'

Pyrrhocorax.—Bill moderate, compressed, subulate, rather slender, furnished at the base with feathers directed forwards, and at the extremity of the upper mandible with two small teeth which are often wanting. Nostrils basal, ovoid, open, hidden by bristles. Feet robust; claws strong and recurved. Fourth and fifth quills longest.

These birds, the Choquards of the French, live in troops like the Jackdaws, which they resemble in their manners. They inhabit the high mountains of Europe, and especially the snowy regions of the Alps. They are omnivorous, feeding on insects, worms, soft fruits, and seeds. They moult once a year, and the sexes are alike externally.

P. Pyrrhocorax. Brilliant black, but the colour is dull in youth, and the bill and feet are black. In the adult bird the black presents iridescent and changeable tints varying to greenish; the bill is yellowish, and the feet bright red. The female lays four white eggs, spotted with dirty yellow; the nest is in holes of the rocks. Locality, Alps of Switzerland. The Prince of Canino ('Specchio Comparativo') notes it as rare, and only occurring in the Apennines.

Fregilus.—Bill longer than the head, slender, entire, arched, pointed. Nostrils covered with feathers directed forwards.

Lesson is of opinion that this genus ought to be united with the last, from which it only differs in having the bill longer and more curved, which made Cuvier place it in the tribe of *Tenuirostres*, near the Hoopoes (*Upupa*). The species have the manners, habits, and general organisation of the crows; and the European species (selected here as an example) perfectly resembles *Pyrrhocorax*. (Lesson.)

F. graculus, Temm.; *Corvus graculus*, Linn. The Cornish Chough, or Red-Legged Crow, is considered by Belon, on no bad grounds, to be the Κορακίας, the Κυρώνη φοινικόρυγκος (Red-Billed Crow) of the Greeks and the *Pyrrhocorax* of the Romans; Spelvier, Taccola, Pason, Zorl, of the Italians (Belon); Choucas aux Pieds et Bec Rouge, Choquar, Choüette Rouge, of the French (Belon); Stein-Tahen and Stein-Frae of the Germans; and Brân Big Gôch of the Welsh.

Back beautifully glossed with blue and purple. Legs and bill bright orange, inclining to red. Tongue almost as long as the bill, and a little cloven. Claws large, hooked, and black. The Chough builds its nests in high cliffs or ruined towers, and lays four or five eggs, white, spotted with dirty yellow or light brown and ash colour.

It is a native of England in Devonshire, Cornwall, and Wales. Pennant says that it is found in different parts of Scotland as far as Straithnavern, and in some of the Hebrides. He also states that it is found in small numbers on Dover cliff, where they came by accident; a gentleman in that neighbourhood had a pair sent as a present from Cornwall which escaped and stocked these rocks. They sometimes desert the place for a week or ten days at a time, and repeat it several times in the year. Montagu, speaking of this locality, says, "We believe the breed in those parts is again lost." Latham states that it is also said to frequent the South Downs about Beachy Head and Eastbourn, where it is called the Red-Billed Jackdaw. With regard to its general geographical distribution, Pennant observes that we do not find it in other parts of Europe except England and the Alps. In Asia the island of Candia produces it; in Africa, Egypt, which last place it visits towards the end of the inundations of the Nile. He quotes Pliny, Brisson, Belon, and Hasselquist, for these statements. The editor of the last edition of Pennant says that the Chough inhabits the lofty cliffs about the mid region of the highest mountains of Greece, but never the maritime parts, as with us. Scopoli speaks of it in Carniola, and says that the feet of some during autumn turn black. These were probably young birds.

The Cornish Chough is easily tamed, and may be taught to speak. One in Colonel Montagu's possession would stand quietly for hours to be soothed and caressed, but would resent an affront both with bill and claws. "It is," says Pennant, "active, restless, and thieving; much taken with glitter, and so meddling as not to be trusted where things of consequence lie. It is very apt to catch up bits of lighted sticks, so that there are instances of houses being set on fire by its means, which is the reason that Camden calls it 'Incendiaria avis.'" Several of the Welsh and Cornish families bear this bird in their coat-of-arms.

There are foreign species—*Fregilus leucopterus*, Vigors and Horsfield (*Pyrrhocorax leucopterus*, Temminck), from Australia, where it is called by the natives Waybung, according to Mr. Caley, and *Fregilus Enca*, of Horsfield, from Java, for instance.

Paradisea.—[BIRDS OF PARADISE.]

Astrapia.—Bill smooth at the base, compressed laterally, straight above, pointed, notched, and bent towards the extremity. Tail very long and very graduated.

Pie de Paradis.

This genus was founded by Vieillot for a bird of the most brilliant plumage, which with other characters places it near the Birds of Paradise, while it has several points which would lead to arranging it among the Thrushes. Thus Gmelin gave it the name of *Paradisea nigra*, and Latham that of *Paradisea gularis*, while Cuvler considered it to come under the genus *Turdus* (Merle de la Nouvelle Guinée). This beautiful bird is the Pie de Paradis or Incomparable of the French. Lesson says:—"I brought from New Guinea two individuals of this magnificent bird, the value of which is sufficiently considerable in France, and which seems to be very rare even in its native country; for, during our sojourn at the Moluccas and the land of the Papous, I only saw there two birds, and one of these now embellishes the galleries of the museum where I deposited it."

No description can convey any idea of the brilliancy of this bird. The metallic tints of almost every hue, varying with the play of the light on the plumage, almost surpass belief. It is well figured in Le Vaillant's 'Oiseaux de Paradis,' plate 20 and 21; but no colouring can give the slightest notion of its splendid intensity and variety. The form may be imagined from the preceding cut taken from the plates above mentioned.

Fossil Corvidæ.

Dr. Buckland mentions the remains of the Raven as occurring in the cave at Kirkdale, and figures the right ulna of one of those birds in 'Reliquiæ Diluvianæ,' plate xi.

CORVUS. [CORVIDÆ.]

CORYDA'LIS, a genus of Plants belonging to the natural order *Fumariaceæ*. It has a calyx composed of two sepals, or absent; 4 petals, the upper one spurred at the base; the stamens diadelphous; the pod 2-valved, many seeded, compressed. The species are mostly small glaucous herbs, with ternate or pinnated leaves, and fusiform tuberous or fibrous roots. Upwards of 40 species of this genus have been described. They are natives of the temperate parts of the earth in the four quarters of the globe.

C. claviculata, White Climbing Fumitory, has a fibrous root; pinnate leaves, with acuminate bracts, the pinnæ ternate; footstalk ending in tendrils. It has small pale-yellow or nearly white flowers. It has a slender climbing stem, 1 to 4 feet long. It is found in bushy places in hilly districts of Great Britain and throughout Europe.

C. lutea, Yellow Fumitory, has a fibrous root, triternate leaves; minute oblong cuspidate bracts; shining seeds, granulate-rugose, with a patent denticulated crest. This plant is a native of the south of Europe, in the fissures of rocks and old walls. It is now naturalised in Great Britain, and forms a picturesque object on the old walls of ruins, as at Castleton in Derbyshire, and Fountains Abbey, Yorkshire. It is a very common plant in gardens.

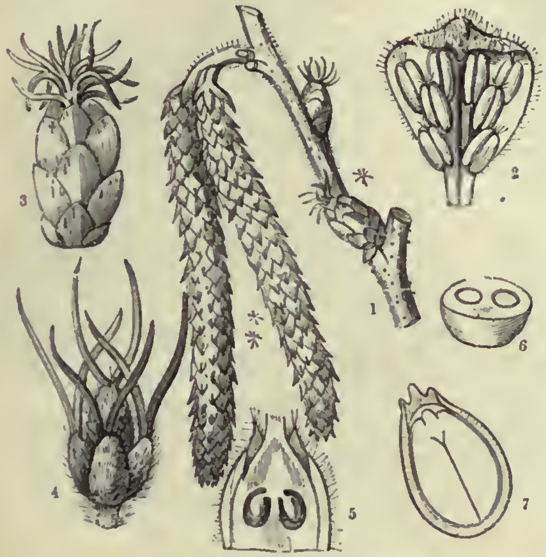
C. solida has a tuberous solid root, with biternate cut leaves, the lowest petiole a leafless scale, the bracts palmate. It is found in Great Britain, but has been undoubtedly introduced.

C. Fabacea has a nearly simple erect stem, scaly under the lower leaf; the leaves stalked, biternate; the bracts ovate, acute, longer than the pedicles. It is a native of shady mountainous places in Sweden, Denmark, and many other parts of the continent of Europe. This species, as well as *C. tuberosa*, a native of the South of Europe, has a tuberous root. The root of both the species is very bitter and rather acrid. That of *C. tuberosa* is hollow, and is found to contain a peculiar alkali called Corydalin. On the continent these roots are used under the name of *Radix Aristolochiæ*, and are employed as external applications to indolent tumours. *C. bulbosa* has a tuber which is somewhat aromatic, extremely bitter, slightly astringent, and acrid, and was formerly used as a substitute for Birth-Worts in expelling intestinal worms, and as an emmenagogue.

Many of the species are cultivated in Great Britain, and, having escaped from gardens, are occasionally found wild, but only *C. claviculata* is a native; *C. lutea* is naturalised. In cultivation they require a light rich soil. They are well adapted for flower-borders and rock-work. The perennial species may be propagated by dividing the roots, the annual by seeds, which should be sown where they are intended to remain. They will grow well under trees if the soil be not very dry.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*; Loudon, *Encyclopædia of Plants*; Babington, *Manual of British Botany*.)

CORYLA'CEÆ, *Mastworts*, the Oak-Tribe, a highly important natural order of Apetalous or Incomplete Exogenous Plants, consisting of trees or shrubs, chiefly natives of the colder parts of the world, and valuable either for the nuts they bear or the timber they produce. The Oak, the Beech, the Hazel, the Hornbeam, and the Sweet Chestnut, all belong to this order, the general character of which is briefly this:—Leaves alternate, usually serrated, often with veins running straight from the midrib to the margin, beyond which they slightly project; at the base of each leaf a pair of membranous stipules. Flowers monœcious; the males in catkins; the females in bud-like clusters. Stamens from 5 to 20, arising from the scales of the catkin. Ovary inferior, crowned by a toothed obsolete calyx, seated in a membranous cup or involucre, with more cells than one, and as many styles as cells; ovules solitary or in pairs, pendulous; all the ovules except one and all the cells disappear after the flowering is over, and when the fruit is ripe there is but one cell and one seed, whatever their number may originally have been. Fruit, a nut (called also acorn, mast, &c.), inclosed within a peculiar kind of involucre or cupule composed of bracts more or less united together, and forming a cup in the oak, a husk in the filbert, and a spiny case in the chestnut and beech. The seed consists of a roundish embryo, with thick fleshy cotyledons, and no albumen. The most southern of the species of this order is the Beech, of which many varieties occur in the lower parts of South America, Australia, and New Zealand. The order is allied to *Juglandaceæ*. For particulars respecting the genera of this most important family of plants see CARPINUS; OSTRYA; CORYLUS; FAGUS; CASTANEA; QUERCUS; LITHOCARPUS.



Flowers of the Hazel-Nut (*Corylus Avellana*).

1, a branch, with the male flowers ** in drooping catkins; the females * in bud-like clusters; 2, one of the scales of the male catkin, with the stamens attached to it; 3, a female bud, with the styles projecting beyond the bracts; 4, the young ovaries with the bracts removed; 5, a section of the ovary, exhibiting the ovules, the toothed calyx, and the base of the style; 6, a cross section of the ovary; 7, a longitudinal section of a nut.

CORYLUS, a genus of Plants after which the natural order *Corylaceæ* receives its name. It consists of the different species of hazel-nut, and is distinguished from the genera associated with it by its cupule being a two-leaved lacerated husk, and its ovary having but two cells, in each of which is one ovule.

C. Avellana, the Common Hazel-Nut. This plant, which is a native of all the cooler parts of Europe, Northern Asia, and North America, is the parent of the many varieties of nuts and filberts now cultivated for their fruit. [HAZEL-NUT, FILBERT, in ARTS AND SC. DIV.] It is specifically known by its husks being hispid with glands, leafy, broad, much lacerated, and rather spreading at the point; never contracted into a long tube, nor divided into narrow rigid segments; by its rounded, heart-shaped, very rugose, angular, toothed, cuspidate leaves, glandular-hispid branches, and shrubby habit. It varies very much in the form of its husks, in the degree of their hispidity, some being nearly smooth, in the shape of their nuts, and in the height to which it grows. In the Hazel-Nut the husk is open at the point, shorter or at least but little longer than the nut, and nearly smooth; while in the Filbert (*Corylus tubulosa* of some writers) it is lengthened considerably beyond the nut, and covered more or less with glandular hairs; all degrees of intermediate structure may be found in the cultivated varieties. This plant is found as a large shrub having numerous stems rising from the root, or as a small bushy tree with a great number of branches, which are covered with hairs when it is young. It is found all over Great Britain, from Cornwall to Sutherlandshire. It grows at the height of 1600 feet above the level of the sea, in the north of England and Scotland. It is cultivated very generally on account of its nuts, especially in the county of Kent, where it attains its greatest perfection. It is also cultivated on the continent of Europe; and every year large quantities of the nuts are brought into England from various parts of France, Portugal, and Spain. The hazel is valued in planting principally as an undergrowth. Its branches and stems are used for various kinds of wicker-work. The wood is said to make the best charcoal for gunpowder, and is also used for making crayons for drawing purposes.

C. Americana is not distinguishable as a variety from the last species. The Beaked American or Cuckold-Hazel is a pretty purple-leaved kind in shrubberies.

C. rostrata, the Horned Hazel-Nut. In this the branches are quite free from glandular hispidity, the leaves are oblong, not cordate, doubly toothed, and acuminate, and the husks globular over the nuts, where they are extremely hispid, without ever being glandular; beyond the nuts the husks are contracted into a tube an inch or more long, and irregularly lacerated at the point. It is a very distinct species inhabiting the mountains of the Carolinas, where it rarely exceeds three or four feet in height. In gardens it is scarcely larger.

C. Colurna, the Constantinople Nut, a white-barked tree 20 feet and more high, with an erect trunk and a dense spreading head. The leaves are shining, much less rugose than in the hazel-nut, cordate, angular, serrated, acute or acuminate, slightly hairy on the under surface. The branches and all the other parts are destitute of glands; the husks are campanulate, deeply cut into narrow hairy rather falcate segments. The nuts are roundish and very hard. It is a native of Asia Minor, and known from all the other garden species by its becoming a tree. It seldom produces its nuts in this climate.

Besides these there are the *C. lacera* and *C. ferox*, two species found in the Himalaya Mountains. Of these, the former, gathered in Kumaon, is hardly different from *C. Colurna*; the other, from Mount Sheopore, has narrow taper-pointed leaves, and excessively hard nuts inclosed in a husk, with divaricating narrow spiny divisions.

CORYMB, a form of inflorescence approaching very nearly to the raceme. The raceme consists of an axis, upon which all the flowers are disposed upon footstalks of the same length; and hence its figure is more or less cylindrical. A corymb consists of an axis, the lowermost flowers on which have very long stalks, and the uppermost very short ones, so that the mass of inflorescence is an inverted cone, as in candytuft and many other cruciferous plants. The corymb is, in fact, an umbel with a lengthened axis.

From this word is derived the term Corymbose, which is applied not only to flowers, but to any kind of branching in which the lowermost parts are very long and the uppermost very short, as is the case in most species of *Aster*. [INFLORESCENCE.]

CORYMBIFERÆ, one of the primary subdivisions in the system of Jussieu, of the natural order *Compositæ*. It comprehends most of the *Tubuliflorœ* of De Candolle. It is characterised by the absence of albumen, an erect seed, a hemispherical involucre, and the florets of the ray, if present, ligulate. This division comprises by far the largest number of the genera of the large order *Compositæ*. The species of *Corymbiferæ* produce more active secretions, and have been used more extensively by man than those of the other subdivisions of the order. They generally represent the *Cichoraceæ* [CICHORACEÆ] in hot climates, and this will perhaps account for their more active properties. In Great Britain the *Corymbiferæ* are more numerous than either the *Cynaraceæ* or *Cichoraceæ*. The number of species in the second edition of Babington's 'Manual of British Botany' is—

Corymbiferæ	62
Cichoraceæ	51
Cynaraceæ	26
Compositæ	139

De Candolle estimates that the species of the *Compositæ* form a tenth part of the flowering plants in the world, and this is about the proportion in which they occur in Great Britain.

The following is a synopsis of the British genera of *Corymbiferæ*:—

Tribe I. EUPATORIACEÆ.
Section I. *Eupatoreæ*.
Eupatorium cannabinum
Section II. *Tussilagineæ*.
Petasites vulgaris
Tussilago Farfara

Tribe II. ASTEROIDEÆ.
Section I. *Astereæ*.
Aster Tripolium
Erigeron . . . 3 species
Bellis perennis
Solidago Virgaurea
Chrysocoma Linosyris
Section II. *Inuleæ*.
Inula . . . . 3 species
Pulicaria . . 2 species

Tribe III. SENECIONIDEÆ.
Section I. *Heliantheæ*.
Bidens . . . 2 species
Section II. *Anthemideæ*.
Anthemis. . . 5 species
Achillea . . . 4 species
Diotis maritima
Chrysanthemum 2 species
Pyrethrum . . 3 species
Matricaria Chamomilla
Artemisia . . 5 species
Tanacetum vulgare
Section III. *Gnaphalieæ*.
Filago . . . 3 species
Gnaphalium . 5 species
Antennaria . . 2 species
Section IV. *Senecioneæ*.
Doronicum . . 2 species
Cineraria . . 2 species
Senecio . . . 9 species

The properties of this division of *Compositæ* are characteristic. Bitterness, with an aromatic odour, is common to all the species. Whether the bitterness depends on an alkaloid or not, chemists have not determined. Many of the species possess properties very similar to those possessed by quinine, and are administered in the same diseases as cinchona; among these are species of the genera *Inula*, *Piqueria*, *Mikania*, and *Emilia*. This bitter principle seldom however gives the character to the plant alone, but is combined with some aromatic oil, which gives the plant the properties of both a tonic and a stimulant. Such a combination is found in many of the species of the genera *Anthemis*, *Artemisia*, *Diotis*, *Santolina*, *Chrysanthemum*, *Eupatorium*, *Liatis*, &c. Sometimes the volatile oil is more prominent than the bitter principle; and this is obvious in the species of *Pyrethrum*, *Tanacetum*, *Stenactis*, *Erigeron*, &c. In some of these the volatile oil assumes the characters of turpentine and the oil of juniper, and acts as a diuretic; hence a certain number of these plants have the reputation of stimulating the action of the kidneys. In some the volatile oil assumes an acrid character, as in *Bidens*, and acts as a sialogogue, as in *Pyrethrum* and *Spilanthes*; in *Maruta* it is sufficiently active to produce vomiting. In some a secretion is produced, similar to that which gives the character to *Cichoraceæ*. Thus *Buphthalmum salicifolium* is said to possess narcotic powers, and the *Arnica montana* is stated by Burnett to have yielded a principle identical with Cytisine, the active principle of the laburnum. Some of the species yield a fixed oil. In addition to the acrid oil in *Pyrethrum officinale*, there is a butyraceous matter, consisting principally of stearine. The seeds of the species of *Helianthus* yield a fixed oil on expression, and this is probably not confined to the seeds of this genus. These seeds also contain nutritive matter (protein?), and are the support of birds and sometimes of man, in America. Another group yield colouring-matters: *Anthemis tinctoria*, and the species of *Calendula* and *Bidens*, are used for dyeing yellow; the *Tanacetum vulgare* for dyeing green. The roots of many species contain starch, and in quantities large enough to afford food for man, as in the tubers of *Helianthus tuberosus*. Many of the species also yield the peculiar kind of starch known by the name of Inulin, so named after the Inulas in which it was first found. Some of them appropriate potash in the spots where they grow, and a species of *Erigeron* is remarkable for the large quantities of this alkali which it contains. Gum is a secretion found in considerable quantities in some species, as of *Gnaphalium*, *Conyza*, and *Tussilago*, and on this account they have been used in medicine as demulcents. Tannin is not found in any quantity in this tribe of plants, so that they seldom exert an astringent action upon the system; the *Achillea millefolium* seems however to possess this property. Many of the ornaments of the garden belong to the *Corymbiferæ*. The *Dahlia*, *Chrysanthemum*, *Xeranthenum*, *Aster*, *Erigeron*, *Solidago*, *Coreopsis*, and *Tagetes*, are amongst the genera that afford the most showy and highly valued flowers in the autumn of the year. Although the properties and uses of these plants in relation to man are important, yet in proportion to the position they occupy in the vegetable kingdom, they are few. Many orders which yield a much smaller number of species afford much more abundant materials for the use of man.

(Lindley, *Flora Medica*; Lindley, *Vegetable Kingdom*; Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

CORYNE. [POLYPIFERA.]

CORYNEPHORUS, a genus of British Grasses, belonging to the tribe *Avenineæ*, with the following characters:—Awn club-shaped, straight, jointed in the middle, the upper portion clavate, a tuft of hairs at the joint, panicle lax, glumes 2-flowered. There is but one species, *C. canescens*, which has a rather dense elongated panicle, the glumes acuminate, longer than the flower, the awn coming from near the base of the palea, the leaves setaceous. It is a native of the sandy coasts of Norfolk and Suffolk and Jersey. (Babington, *Manual*.)

CORYPHA, a genus of Plants belonging to the natural order *Palmaceæ*. It has gigantic fan-shaped leaves, flowers with a 3-toothed calyx, 3 petals, 6 stamens, and a 3-celled ovary. The fruit is composed of round 1-seeded berries.

C. Talliera, the Tara, or Talliera, is an elegant stately species inhabiting Bengal. Its trunk is about 30 feet high, and as nearly as possible of equal thickness throughout. The leaves are in about 80 divisions, each 6 feet long by 4 inches broad, radiating from the point of a leaf-stalk from 5 to 10 feet long, and covered with strong spines at its edge. Roxburgh describes the spadix as decompound, issuing in the month of February from the apex of the tree and centre of the leaves, forming an immense diffuse ovate panicle of about 20 or more feet in height. The fruit is the size of a crab-apple, wrinkled, dark-olive, or greenish-yellow. The leaves are used by the natives of India to write upon with their steel styles, and for other purposes.

C. umbraculifera, the Tala, or Talipat Palm, is a native of Ceylon, and similar in appearance; but its leaves are not so round as those of the Talliera, the divisions in the centre being shorter than those at the sides. The trunk grows 60 or 70 feet high; the leaves are 14 feet broad and 18 feet long, exclusive of this stalk, and they form a head about 40 feet in diameter. Fans of enormous size are manufactured from this plant in Ceylon; the pith of its trunk furnishes a sort of flour from which bread is made; the leaves make excellent thatch, and are also used for writing on, like those of the Talliera.

C. Gebanga is one of the most useful of all the Indian Palms. Its pith furnishes a sort of sago; its leaves are used for thatch and broad-brimmed hats; fishing-nets and linen shirts are woven from its fibres, and ropes from its twisted leaf-stalks; the root is both emollient and slightly astringent; sliced, it is used in slight diarrhœas, and Waitz says that it is a most valuable remedy for the periodical diarrhœas which in the East Indies attack Europeans.

CORYPHÆNA (Linnæus), a genus of Fishes belonging to the section *Acanthopterygii* and family *Scomberidæ*.

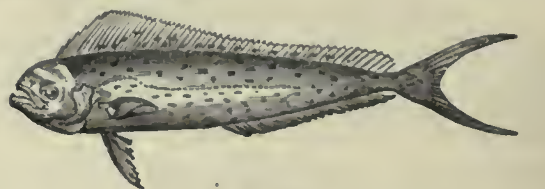
The group of fishes formerly included under the head *Coryphæna* is now subdivided, and the subdivisions may be either termed subgenera of the genus *Coryphæna*, or the group may be looked upon as a sub-family, and the subdivisions as genera. The principal characters of this group are as follows:—Body elongated, compressed, covered with small scales; dorsal fin extending the whole length of the back (or nearly so); branchiostegous rays generally seven in number. These fishes have commonly a long anal fin, in some extending from the tail almost to the ventral. The tail is more or less forked, and the pectoral fin is usually arched above and pointed.

Considering *Coryphæna* as a genus, the following are the sub-genera: —*Coryphæna* (proper), *Caranxomorus*, *Centrolophus*, *Astrodermus*, and *Pteraclis*.

Coryphæna.—The species have the head much elevated, and the palate and jaws both furnished with teeth.

These fishes are very rapid in their motions, usually of large size and they prey upon the flying-fish.

C. hippurus (Linn.), a species not uncommon in the Mediterranean, is about 2 feet in length, of a bluish-lead colour above and pale-yellow beneath. There are dark-blue spots on the back and dorsal fin, and the under parts of the body are furnished with spots of a paler colour. The ventral fins are yellowish beneath and black above, and the anal fin is yellowish. The greatest depth of the body is about one-sixth of the whole length.



Coryphæna hippurus.

There are several other species of this genus, some of which are found in the Mediterranean, and very closely resemble the one just described.

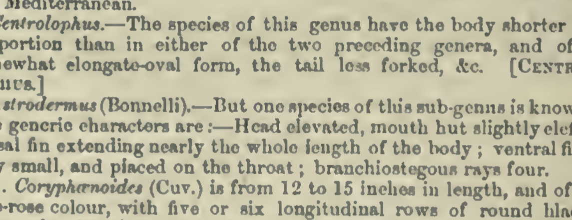
Caranxomorus (Lacépède) is closely allied to *Coryphæna* (proper); the species however may be distinguished by their having the head less elevated and the eye in a medial position; the dorsal-fin is shallow and of equal height throughout: the tail is much forked.

C. pelagicus is about 9 or 10 inches in length, of a bluish colour above and yellowish beneath; the dorsal and anal fins are of the same colour as the back of the fish, and have a whitish margin. It inhabits the Mediterranean.

Centrolophus.—The species of this genus have the body shorter in proportion than in either of the two preceding genera, and of a somewhat elongate-oval form, the tail less forked, &c. [CENTROLOPHUS.]

Astrodermus (Bonnelli).—But one species of this sub-genus is known. The generic characters are:—Head elevated, mouth but slightly cleft; dorsal fin extending nearly the whole length of the body; ventral fins very small, and placed on the throat; branchiostegous rays four.

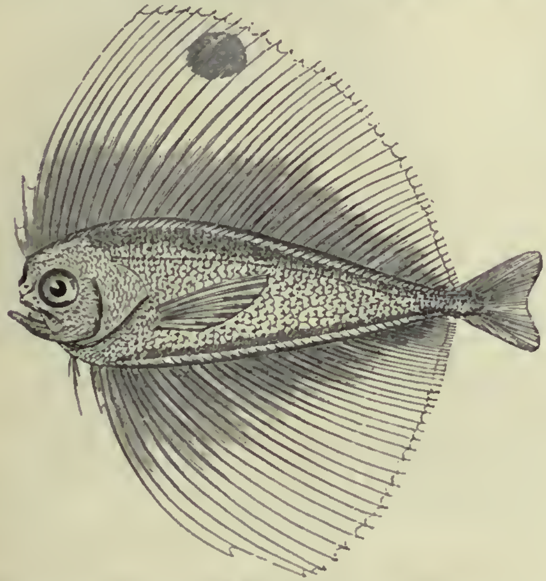
A. Coryphænoides (Cuv.) is from 12 to 15 inches in length, and of a pale-rose colour, with five or six longitudinal rows of round black spots; the dorsal and anal fins are blackish, and the pectoral and caudal fins are of a red hue. The most remarkable character of this fish however consists in the scales, which, instead of folding over each other in the usual way, are scattered over the body and head; they are very minute and serrated, and under a lens resemble small stars. It inhabits the Mediterranean.



Astrodermus Coryphænoides.

Pteraclis (Cuv.) The species of this group are remarkable for the immense size of the dorsal and anal fins, each of which springs from between two tiers of scales, which form a protection, and probably give strength to the basal portion of the fin-rays. These fins extend the whole length of the body; the head and teeth are nearly the same as in the true *Coryphænæ;* the scales are large.

P. ocellatus (Cuv.) is about 4 inches in length, and of a silvery hue; the pectoral and caudal fins are yellowish; the others are bluish-gray, and the dorsal fin has a large blue spot near its highest part.

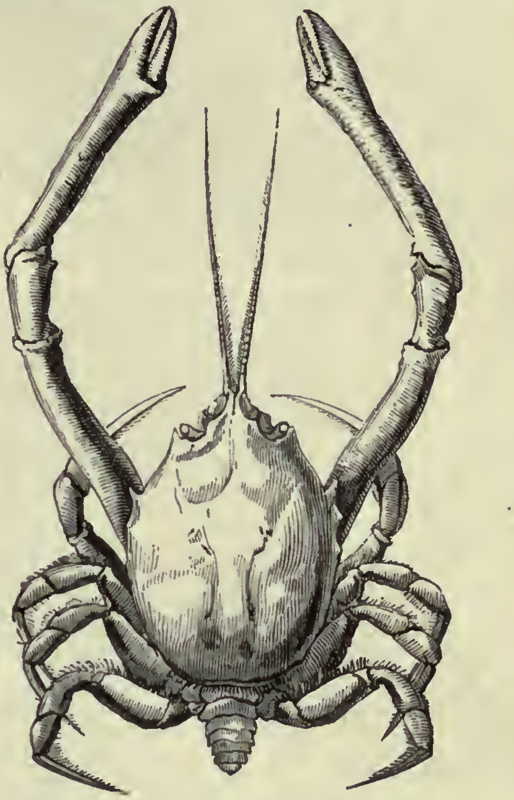


Pteraclis ocellatus.

CORYPHODON, a genus of Fossil Animals belonging to the family of Tapira. The remains of this genus have been found in this country; and although closely allied to the genus *Lophiodon* of Cuvier, Professor Owen regards its differences as of sufficient importance to constitute a new type. The specimen on which this genus was established is unique, and was dredged up from the bottom of the sea between St. Osyth and Harwich on the Essex coast, and now forms part of the collection of John Brown, Esq., of Hanway Green, near Colchester. This specimen is petrified, containing metallic salts, and having the appearance of fossils from the London Clay. There can be little doubt that it was originally imbedded in the Eocene Tertiary Formation of the Harwich coast. It consists of the right branch of the lower jaw, containing the last and part of the penultimate molar teeth of the lower jaw. Although this fragment resembles the same bone in the genus *Lophiodon*, yet a close examination of the crown of the last molar tooth exhibits a smaller antero-posterior diameter in proportion to its transverse diameter, as compared with the corresponding tooth in that genus. It also differs from the teeth of *Anthracotherium*, to which it has some resemblance. Professor Owen infers from this and other characters of these teeth that "the whole dental series of the extinct Eocene Pachyderms offered modifications of the Lophiodont type of dentition, which led towards that of the *Anthracotherium*, more especially of the smaller species from Garonne and Valery. From the closer resemblance which the fossil presents to the true Lophiodons, it must be regarded as a member of the same family of Tapiroid Pachyderms; indicating therein a distinct sub-genus, characterised by the want of parallelism of the two principal transverse ridges, and by the rudimental state of the posterior talon in the last molar tooth of the lower jaw. The name *Coryphodon*, which I have proposed for this sub-genus, is derived from χορυφή, a point, and ὀδοὺς, a tooth; and is significative of the development of the ridges into points. The broad ridged and pointed grinding surface of the tooth indicates its adaptation to comminute the coarser kinds of vegetable substances; and it is very probable that the habits and food of the Tapir, which is the nearest existing analogue of the *Coryphodon*, are not very dissimilar from those which characterised of old the present extinct species and the true Lophiodons."

Professor Owen gives the species the name of *Coryphodon Eocœnus.* He also describes a tooth found in digging for a well at Camberwell, at a depth of 160 feet in the Plastic Clay. After describing this tooth, Mr. Owen says, "From its close resemblance in the essential characters of its form to the canines of the great extinct Tapiroid Pachyderms, and the apparent specific distinctions from any of the known species of *Lophiodon*, I strongly suspect it to have belonged to a *Coryphodon.*" (Owen, *British Fossil Mammals and Birds.*)

CORYSTES, a genus of Brachyurous or Short-Tailed *Crustacea.* The species have the following characters:—Exterior antennæ longer than the body, setaceous, with two rows of cilia. Jaw-feet (pieds-machoires) having their third joint longer than the second, straight, terminated by an obtuse point, with a notch upon its internal border. Eyes rather distant, borne upon large peduncles, which are nearly cylindrical, and somewhat short. Anterior feet (chelæ) large, equal, twice as long as the body, and nearly cylindrical in the males; in the females, of about the length of the body, and compressed, especially towards the hand (manus). The other feet terminated by an elongated nail or claw, which is straight, pointed, and channeled longitudinally. Carapace oblong-oval, terminated by a rostrum anteriorly truncated and bordered posteriorly. The regions but slightly indicated, with the exception of the cordial region, the branchial or lateral regions being very much elongated.



Long-Clawed Crab (*Corystes Cassivelaunus*), male.

Corystes Cassivelaunus, female.

C. Cassivelaunus (Leach), the Long-Clawed Crab; *C. dentata, C. dentatus, C. longimanus*, of Latreille; *Cancer Cassivelaunus, Cancer personatus*, of Herbst; *Albunea dentata* of Fabricius.

This crab has the surface of the carapace somewhat granulous, with two denticles between the eyes, and three sharp points directed forwards on each side. The male has but five abdominal pieces; but, as M. Latreille observes, the vestiges of the separation of the two others may be clearly remarked upon the intermediate or third piece, which is the largest of all.

It is found on the coasts of England and France. The specimens figured by Pennant were dredged up from deep water near Holyhead and Red Wharf, Anglesey.

M. Desmarest is of opinion that the natural relations of his crustacean approximate it to *Atelecyclus*, *Thia*, and *Leucosia*, of which M. Latreille forms his Orbicular Tribe (Les Orbiculaires). Dr. Leach, he adds, in his method, placed them near the first two of the above-mentioned genera, solely because they have the same number of abdominal articulations. The *Leucosiæ*, in which the number of those articulations is less considerable, are removed to a distance.

COSCINO'PORA, a genus of Fossil Corals proposed by Goldfuss. *C. infundibuliformis* occurs in the Chalk of Ireland.

CO'SSONUS (Clairville), a genus of Coleopterous Insects belonging to the family *Curculionidæ*. It has the following characters:—Antennæ short, rather thick; funiculus 7-jointed, the basal joints longer than the following; club large and of an oval form; rostrum rather long, thickened at the apex; thorax truncated before and behind, and somewhat depressed above; elytra elongate, moderately convex above, and covering the abdomen; tibiæ dilated towards the apex, where there is a large hook; tarsi rather slender, the penultimate joint bilobed.

About seventeen species of this genus are known, of which Schönherr selects *C. linearis* as the type. This species is not uncommon in England, and has been found in *Boleti* and in old trees. It is about a quarter of an inch in length, and of a narrow elongated form, and black or brown colour; the elytra are punctate-striated. *C. tardus* is another British species which closely resembles the last, but is of a larger size, being nearly half an inch in length.

COSSUS (Fabricius), a genus of Insects belonging to the section *Lepidoptera nocturna*, Moths, and the family *Hepialidæ* (Stephens). The species have the following characters:—Antennæ long, rather slender, furnished on the inner edge with a series of transverse elevated ridges (which when viewed from the side resemble the teeth of a saw); two distinct palpi, thickly clothed with scales, and each 3-jointed; head very small; upper wings longer and larger than the lower; body large. Larva lignivorous. Pupa inclosed in a cocoon.

C. ligniperda (Fab.), the Goat-Moth, is one of the largest of the British moths, measuring from tip to tip of the wings when expanded from 3 to 3¾ inches. It is of a gray colour; the upper wings are mottled with white, and adorned with numerous irregular black lines; the under wings are almost of a uniform brownish-ash colour; the anterior part of the thorax is of a buff colour, and there is a transverse dark mark towards the posterior part; the body is of a dark brownish-gray colour, with rings of a silver-like hue.

The larva, or caterpillar, is about three inches in length when full-grown, and of a yellowish colour; the upper part of the body is pink, the head is black, and the first segment of the body (or that joining the head) has two irregular black patches above.

This caterpillar emits a very strong and disagreeable odour, and if touched with the hands the scent cannot be discharged from them for some considerable time, although they may be frequently washed. It resides in and feeds upon the wood of the poplar, oak, and aspen; but old pollard willows appear to be its most favourite haunts. These we frequently see perforated with numerous oval holes large enough to admit the finger, and when the caterpillars are abundant the trees attacked eventually fall a sacrifice to their ravages. It is three years before attaining maturity, at which time it incloses itself in a tough cocoon, formed of pieces of wood joined together by a glutinous web.

The moth is common in various parts of the south of England, and the name Goat-Moth has probably been applied to it from the property of emitting a disagreeable odour having been transferred from the caterpillar to the moth.

A detailed history of the *C. ligniperda* will be found in the 'Mémoires pour servir à l'Histoire des Insectes,' by De Geer; and for its anatomy we refer our readers to the 'Recherches sur l'Anatomie et les Métamorphoses de différentes Espèces d'Insectes,' by L. L. Lyonet. This latter author has also published a substantial quarto work, with numerous beautiful plates engraved and drawn by himself, which is entirely devoted to the anatomy of the caterpillar above mentioned. This work, which was the labour of years, must ever stand as a monument of the great skill and perseverance of its author, who boasts of having destroyed but one caterpillar for its completion. It is entitled 'Traité Anatomique de la Chenille qui ronge le Bois de Saule,' &c.

CO'SSYPHUS (Olivier), a genus of Coleopterous Insects of the section *Heteromera* and sub-section *Taxicornes*. The principal character of this genus consists in the dilated and flattened sides to the thorax and elytra—a structure also found in many of the *Nitidulæ* and in the *Cassidæ*. These insects, if it were not for the dilated portions of the thorax and elytra, would be of a long narrow form, but with these parts they present an oval outline. The thorax is nearly semicircular, and its dilated margins as well as those of the elytra are semitransparent. The antennæ are 11-jointed; the last four joints are considerably thicker than the preceding, and rather flattened; the terminal joint of the maxillary palpus is dilated, and of a somewhat triangular form; the head is completely hidden by the anterior part of the thorax.

These insects inhabit the south of Europe and the northern parts of Africa and India. About ten species are known.

C. Hoffmansegii is nearly half an inch in length, and of a dark brown colour; the parts of the thorax and elytra which extend beyond the insect itself are of a paler hue. It is difficult to give an accurate idea of this curious insect, which appears as if it were an ordinary shaped beetle pressed against the under side of a little oval scale of wax, so that its impression is distinctly visible above, being convex, whereas the scale itself is concave.

The present genus, with two others (*Helæus* and *Nilio*), form, according to Latreille, the second tribe of the family *Taxicornes*, and are included under the head *Cosyphenes*.

COTINGA. [CORACINA.]

COTONEASTER, a genus of Plants belonging to the natural order *Rosaceæ*, and to the tribe *Pomeæ*. The segments of the calyx 5; the petals 5; the styles 2-5; the fruit turbinate, its nuts adhering to the sides of the calyx, but not cohering at the centre; the stamens erect, as long as the teeth of the calyx. The species are shrubs, with simple entire leaves, woolly beneath. This genus was separated from *Mespilus* by Lindley.

C. vulgaris, the Common Cotoneaster. It has roundish ovate leaves, rounded at the base, flower-stalks and margins of the calyx downy; the petals are rose-coloured. It is a native of Europe, and is found in North Wales upon the cliffs at the Great Ormeshead. Previous to its having been discovered to be a British plant it had been cultivated in this country. Several varieties are met with both in a wild state and in gardens.

C. tomentosa has its peduncles and calyxes woolly. It is a shrub like the preceding, and is found wild on the rocks of the Jura and other parts of the Alps of Switzerland.

C. laxiflora has its flowers in panicled cymes, and its calyxes quite smooth. It has the same general appearance as *C. vulgaris*, and is probably a variety.

C. frigida is an East Indian species. It is a native of the higher mountains in the northern region of Nepaul.

C. affinis was brought from Chittong, a town of Lower Nepaul, and is similar in general appearance to the last species. *C. acuminata* and *C. nummularia* are likewise species from Nepaul.

C. rotundifolia and *C. microphylla* are probably varieties of the same species. They are both from the north of Hindustan.

All the species are adapted for shrubberies, and many of them are very commonly cultivated in Europe. They are easily propagated by laying down the branches, or by cuttings, which should be placed in a sheltered situation under a hand-glass. They may be also increased by dividing their roots, and by seeds.

(Lindley, *Linnean Transactions*; Loudon, *Arboretum et Fruticetum Britannicum*.)

COTTON, a word derived from *Kutn*, or *Kutun*, one of the names given by the Arabs to this substance, is a filamentous matter produced by the surface of the seeds of various species of *Gossypium*. [GOSSYPIUM.] It consists of vegetable hairs, of considerable length, springing from the surface of the seed-coat, and filling up the cavity of the seed-vessel in which the seeds lie. Hairs are extremely common on the surface of plants; frequently however they are unobserved, in consequence of their small number and minuteness; while on the other hand in some cases they give plants, such as the Mullein for instance, a remarkable hoary appearance. On the surface of seeds they are uncommon; and yet in the *Malvaceæ* and their allies, to which the cotton plants belong, they not only exist abundantly on the seeds of that genus, but in several other species. Vegetable hairs are one of the many forms in which the cellular substance of vegetation is developed, and they consequently partake of two of the great characteristics of that form of tissue, namely, thinness and transparency. In the cotton they are long weak tubes, which, when immersed in water and examined under the microscope by transmitted light, look like flat narrow transparent ribands, all entirely distinct from each other, and with a perfectly even surface and uniform breadth. At certain distances along the hair, an interruption occurs, which looks as if it proceeded from the turning round or twisting of the hair during its growth. On each side opposite these interruptions a slight indentation is observed. Sometimes a slight trace of fine grains is discernible in the interior, but more frequently the hairs seem empty. If strained singly they have little strength and readily break, and it is only when many are entangled together that they acquire any appreciable degree of strength. In all these points cotton differs from the vegetable matter that constitutes linen; the latter consists of woody tissue, in the state of long tubes, but is at once distinguished by the tubes adhering in bundles, which it is difficult under a microscope to break up into their component parts; the tubes are thick-sided, and will not acquire a riband-like appearance when viewed in water, but rather resemble extremely minute thermometer tubes. When they are jointed together the articulation is oblique, the ends of the tubes being pointed and overlying each other; and finally, in each particular tube of the woody tissue, delicate as it may be, there is a sufficiently appreciable degree of toughness when an attempt is made to break it. In short, cotton is a development of cellular tissue. Linen is a form of vascular tissue. Hence it is easy to distinguish with certainty linen from cotton manufactured articles, in cases of doubt; and hence also the well-known superiority of linen to cotton in strength: the latter is manufactured from the most delicate part of plants, the former from the toughest. [TISSUES, VEGETABLE.]

Cotton is produced by many different species and varieties of the genus *Gossypium*, which consists of herbaceous or nearly herbaceous plants, varying in height from 3 or 4 to 15 or 20 feet, according to the sort. Sometimes the branches become woody, but they always partake very much of the herbaceous character. The leaves are downy and more or less lobed, being sometimes however near the top of the stem undivided; at their base is seated a pair of awl-shaped stipules. The flowers are either yellow or dull purple, and have the ordinary structure of the Malvaceous Family; each is surrounded by three heart-shaped bracts, which are more or less lacerated. The calyx is a bluntly 5-toothed cup. The seed-vessel is a capsule opening into from 3 to 5 lobes, and then exposing many seeds enveloped in cotton, which sometimes adheres to them so firmly that it is separated with difficulty; sometimes it parts freely from them; in some sorts it is long and in others comparatively short, giving rise to the commercial names of Long Staple and Short Staple.

The qualities of these hairs most valued by the manufacturer are length of staple, strength, and silkiness. In these respects cotton differs very much, and it is when these three properties are combined in the highest degree that the cotton obtains the highest prices in the markets.

Cotton-plants are found wild in both the Old and New World. Herodotus and Arrian speak of the cotton-plant as indigenous in India, and the cloth found in Peruvian tombs sufficiently attests its having existed in that country long before it could possibly have been carried to America by eastern intercourse. In fact the wild American cotton-plants are specifically different from those of the Old World; but at the present day the cotton of the West is cultivated in Asia and Africa, while that of the East has long since been introduced to the American plantations.

The situations in which cotton-plants have been advantageously cultivated are included between Egypt and the Cape of Good Hope in the eastern, and between the southern banks of the Chesapeake Bay and the south of Brazil, in the western hemisphere. It has not been found to succeed beyond the parallels that limit those countries. In the equinoctial parts of America Humboldt found it at 9000 feet elevation above the sea; in Mexico as high as 5500 feet; and Professor Royle saw it at the elevation of 4000 feet on the Himalayas. It seems generally to prefer the vicinity of the sea in dry countries, and the interior districts of naturally damp climates. Thus, while the best cotton is procured in India from the coast of Coromandel, or other maritime districts, and in the southern states of the American Union from certain coast-islands, the coast cotton of Pernambuco is inferior to what is produced in the interior of that country. These facts lead to the inference that it is not merely temperature by which the quality of cotton is affected, but a peculiar combination of heat, light, and moisture; the most favourable instance of which may be assumed to be the coast of Georgia and the Carolinas, and the worst to be Java and the coast of Brazil.

That this should be so would, in the absence of positive evidence, be probable, considering the nature of cotton. We have seen that it is a hairy development of the surface of the seed; and nothing in the organisation of plants is more affected by the situation they live in than their hairs: thus many water-plants which have scarcely any hairs, when transferred to a dry exposed station are closely covered with such organs, and *vice versâ*. The quantity of hair is also affected in an extraordinary degree by local circumstances. The Venetian sumach-plant, when in flower, has its flower-stalks nearly naked; a large proportion of the flower-stalks has no fruit, and becomes covered with very copious long hairs, whence the French call this plant Arbre à Perruque; but those flower-stalks which do bear fruit remain hairless. In this case the local cause is probably the abundant food thrown by the system of the sumach-plant into the flower-stalks for the nourishment of the fruit; and the fruit not forming, the food intended for it is expended in the formation of hairs upon the surface of the flower-stalk. This is only an accident, but local circumstances conducive to the formation of cotton in excess may be permanent, and derived from the situations in which the plants grow. In a damp cloudy climate the food procured from the soil may not be concentrated upon the surface of the seed, but may be expended in the production of excessive quantities of leaves, and of proportionally few flowers; or it may pass off into the atmosphere in the form of a mere exhalation, a small proportion only being consolidated; or in a dry climate the soil may not be able to furnish food enough to the plant out of which to form more cotton than it is absolutely its specific property to produce under any circumstances. Or, lastly, there may be a mean where the powers of vegetation are called into their utmost activity by warmth and abundant food, and where, nevertheless, the dryness of the atmosphere and the brightness of the sun, constantly acting upon the surface of the cotton pods (seed-vessels), may drive back the juices from the surface of the latter to that of the seeds, and thus augment the quantity and improve the quality of the cotton itself: this may explain the action of climate upon this substance.

The question is however rather more complicated; the different specific qualities of different varieties of the cotton-plant must be also taken into account. A considerable number of varieties of cotton is certainly cultivated, although little is correctly known about them. In some of them the cotton is long, in others it is short; this has it white, that nankeen-coloured: one may be cultivated advantageously where the mean winter temperature does not exceed 46° or 48°, and another may require the climate of the tropics. This is just what happens with all cultivated plants. Some vines will produce only sweet wine, others only hard dry wine, and some are suited only to the table; some potatoes are destroyed by a temperature of 32°, while others will bear an average English winter; only one kind of wheat produces the straw from which the fine Leghorn plait for bonnets is prepared. But to multiply such instances is unnecessary. There can then be no doubt that the quantity and quality of cotton will depend partly upon climate and partly upon the specific properties of particular varieties.

The Cotton-Plant, or *Gossypium*, must not be confounded with the Cotton-Tree, *Bombax*, or *Eriodendron*. The latter has also cottony seeds, but they cannot be manufactured.

For further information see COTTON MANUFACTURE, in ARTS AND SC. DIV.

(Royle, *Illustrations of the Botany and other Branches of the Natural History of the Himalayan Mountains, and of the Flora of Cachmere*, article 'Malvaceæ.')

COTTUS (Linnæus), a genus of Fishes belonging to the section *Acanthopterygii* and family *Loricati* (Jenyns). The species have the following characters:—Head large, depressed, furnished more or less with spines or tubercles; teeth in front of the vomer and in both jaws, none on the palatines; two dorsal fins; ventral fin small; body without scales; branchiostegous rays six.

C. gobio, (Linn.), the River Bull-Head, Miller's Thumb, or Tommy-Logge, affords an example of this genus. This little fish, which is found in almost all the fresh-water streams throughout Europe, is from 3 to 4 inches in length, and of a browish colour above, more or less mottled and spotted, and whitish beneath. The head is very large in proportion to the body, and without spines; the pre-operculum has a single curved spine on the posterior part: the eyes are small, and directed upwards. The number of fin-rays are—anterior dorsal 6 to 9, posterior 17 or 18; pectoral 15; ventral 3; anal 13; caudal 11. The name Bull-Head is given these fishes on account of the large size of their heads. These fish more particularly frequent those streams in which pebbles abound. They feed upon aquatic insects, &c. It is found in the brooks and streams of Great Britain.

The remaining British species of this genus inhabit the salt water, and together with others of the same habits, are distinguished from the fresh-water species by having the head armed with numerous spines.

C. scorpius (Bloch), the Sea-Scorpion, or Short-Spined Cottus, is very common on our coasts, and is found very frequently under stones or sea-weeds, in the little pools left by the retiring tide. It is thus described by Mr. Yarrell. "The head large, more elevated than that of the River Bull-Head; upper jaw rather the longer; teeth small and sharp; eyes large, situated about half-way between the point of the nose and the occiput; irides yellow, pupils bluish-black; one pair of spines above the nostrils, with an elevated ridge between them; the inner edges of the orbits elevated, with a hollow depression above, but no occipital spines; pre-operculum with three spines; the upper one the longest; operculum with two spines, the upper one also the longest, the lower one pointing downwards; there is besides a scapular and a clavicular spine on each side; gill-openings large; the body tapers off rapidly, and is mottled over with dark purple-brown, occasionally varied with a rich red-brown; the belly white; the first dorsal fin slightly connected with the second by an extension of the membrane; lateral line smooth; the ventral fins attached posteriorly by a membrane to the belly." Length rarely exceeding 8 or 9 inches.

This fish feeds upon small *crustacea* and the fry of other fishes.

C. bubalis (Euphrasen), the Father-Lasher, or Long-Spined Cottus, is about the same size, and resembles the last both in appearance and habits; the two species however are seldom found in the same immediate neighbourhood. This species is distinguished from the last by its more perfectly armed head, the spines of which are longer in proportion, the space between the eyes is less, the crest above the eyes is more elevated, and the ventral fins are destitute of the connecting membrane observed in the Short-Spined Cottus. Both these and the last species are remarkable for the length of time they will live out of the water. Hence Mr. Yarrell concludes that it is not a large gill-aperture, as has been supposed, which hastens the death of certain kinds of fish, as these have very large heads and gill-apertures.

C. quadricornis (Linn.), the Four-Horned Father-Lasher, or Cottus, another species also found off the British coast, though less abundantly than either of the foregoing maritime species, may be distinguished, as its name implies, by the four tubercles which are situated on the top of the head, two on the nape, and two near the eyes; the pre-operculum is furnished with three spines, and the operculum with one; length from 10 to 12 inches.

Aspidophorus, Lacépède, is considered by Cuvier as a sub-genus of *Cottus*. This genus, or sub-genus, is thus characterised:—Head large and depressed, more or less armed with spines and tubercles; both jaws furnished with teeth, none on the vomer; body attenuated posteriorly, covered with angular plates; ventrals small; branchiostegous rays six.

A. Europæus (Cuvier), the Armed Bull-Head, Pogge, Lyric, Sea-Poacher, Pluck, or Noble. This little fish, generally about 4 or 5 inches in length, is frequently caught in the shrimping nets, and is called by the fishermen, in some districts, in addition to its other names, the Hook-Nose. Its general covering is brown above and white beneath: there are however most commonly indications, more or less distinct, of several broad dark marks across the back; the nose is furnished with four recurved spines; the upper jaw extends beyond the lower; the infra-orbitals have three blunt tubercles on their lower margin, and a sharp spine directed backwards; the pre-operculum is also armed with a spine; the branchiostegous membrane and chin are each furnished with numerous fleshy filaments; the body is divided longitudinally by eight scaly ridges, those on the upper part being most produced. The number of fin-rays are—dorsal 5 to 7; pectoral 15; ventral 3; anal 7; caudal 11.

The habits of this fish appear in many respects to be the same as those of the *C. scorpius*, &c. It is very frequent on the southern shores of Great Britain.

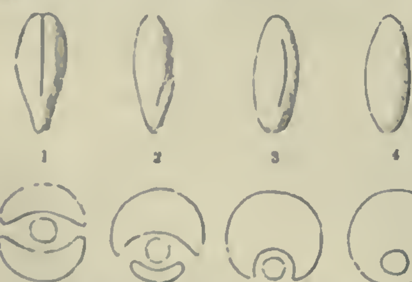
COTUNNITE, a Mineral. It is a native Chloride of Lead, occurring on Vesuvius in white acicular crystals.

COTURNIX. [Tetraonidæ.]

COTYLEDON is the leaf of a seed; it is the part prepared by nature to enable the young plant when it first springs into existence, and before it has been able to form organs of digestion and respiration, to perform both those functions. Sometimes the cotyledon performs these functions under ground during the whole period of its activity; but in many cases its subterranean life extends only to a few days or hours, after which it is elevated above the soil, and takes on the ordinary property of the leaves. [Germination.]

The situation of the cotyledon is on one side of the axis, of which the plumule is the apex, and the radicle the base. In the largest number of known seeds there are two cotyledons on opposite sides on the same plane; in a few there are several opposite to each other in a whorl; in a considerable number there is only one; and among the lower plants there appears to be an absence of any distinct organ of this kind. These differences have given rise to the terms Dicotyledons, Polycotyledons, Monocotyledons, and Acotyledons.

The first two and the last of these forms will be readily understood; but the structure of a Monocotyledon is far more puzzling to the student, in consequence of the axis not being found on one side of the cotyledon, as would have been expected. A common monocotyledonous embryo is a nearly cylindrical body, obtuse at each end, as at *fig.* 4, and its axis of growth is in the interior of the cotyledon, so that it can only be found by cutting the organ open. The following diagram will explain this anomaly. Let the upper line represent four kinds of embryoes seen from the side, and the lower line the plan upon which those embryoes are constructed, the inner circle being always the axis of growth, and the crescent or crescents the cotyledons. *Fig.* 1 is a common dicotyledonous embryo, with its cotyledons equal; *fig.* 2 is a rare kind of embryo of the same kind, with one of the cotyledons exceedingly small. If the smaller cotyledon were absolutely deficient, it may easily be conceived that such an embryo as that at *fig.* 3 would be the result, the angles of the crescent being drawn together round the axis, just as the edges of leaves are drawn together when they roll up in the leaf-bud. If we now suppose that the angles are not only drawn together, but actually united as at *fig.* 4, the presence of the axis within the cotyledon will no longer appear inexplicable.



COTYLEDON, a genus of Plants belonging to the natural order *Crassulaceæ*. It has 5 sepals shorter than the tube of the corolla; the petals cohering in a tubular 5-cleft corolla; the stamens 10, inserted on the corolla; 5 hypogynous scales; 5 carpels. The species are succulent shrubs, mostly natives of the Cape of Good Hope.

C. umbilicus, Navel-Wort, has the lower leaves peltate, concave, orbicular; the bracts entire; flowers pendulous. The flowers are of a greenish-yellow colour, and the stem is from 6 to 12 inches high. It is found very commonly on rocks or walls in the west of England. It is also a native of Portugal. Although this plant belongs to an order with comparatively inert properties, it has obtained a reputation in the treatment of nervous diseases, especially epilepsy.

C. lutea has the lower leaves somewhat peltate, upper leaves crenate or toothed, the bracts toothed, flowers erect. The flowers are of a bright yellow. It has been found wild in England, but is probably not a native.

Many of the species of this genus have been separated under the genus *Umbilicus*, the type of which is the first species named—which is called *U. erectus*. The species of *Umbilicus* closely resemble those of *Cotyledon*. In the cultivation of the species of both genera, they should be placed in pots well drained, with a soil of sandy loam or brick rubbish. They may be propagated by cuttings, which should be laid to dry for a few days after they have been cut off, before they are planted, as they are apt to rot at the wound if otherwise treated. The best situation for these plants is the shelves of a greenhouse.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

COUA. [Cuculidæ.]

COUAGGA. [Equidæ.]

COUCH-GRASS. [Triticum.]

COUMAROUNA, a genus of Plants belonging to the natural order *Leguminosæ*. It has 8 stamens, and the lower segment of the calyx undivided. This genus is also referred to *Dipterix*.

C. odorata is the plant which yields the sweet-scented Tonga Bean of the perfumers. It is a native of French Guyana, where it forms a large forest-tree, called by the natives Coumarou. The trunk is said to be 60 or 80 feet high, with a diameter of 3½ feet, and to bear a large head of tortuous stout limbs and branches. The leaves are pinnated, of two or three pairs of leaflets, without an odd one at the extremity. The flowers appear in axillary branches, and consist of a calyx with two spreading sepals, and five purple petals washed with violet, of which the three upper are the largest and most veiny. The stamens are eight, and monadelphous. The fruit is an oblong hard dry fibrous drupe, containing a single seed; the odour of its kernel is extremely agreeable. The natives string the seeds into necklaces; and the Creoles place them among their linen, both for the sake of their scent and to keep away insects.

Sweet-Scented Tonga (*Coumarouna odorata*).

1, a ripe drupe; 2, the same cut open; 3, a complete flower; 4, the calyx with a young drupe projecting from it.

COURSER. [Cursorius.]

COUZERANITE, a Mineral from the Pyrenees. It has a composition near to that of *Labradorite*. [Labradorite.]

COW. [Bovidæ.]

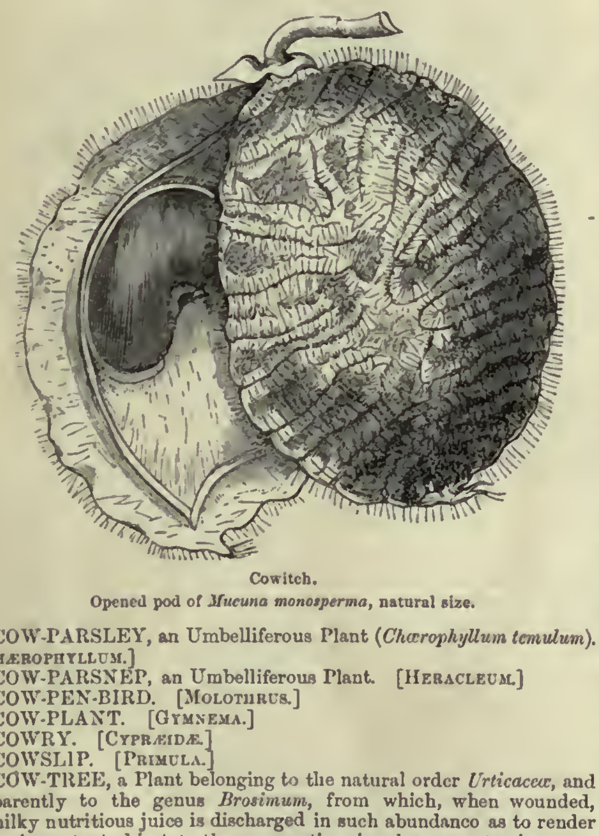
COWBANE, one of the common names for the Water-Hemlock. [Cicuta.]

COW-BERRY, a common name for the Red Whortleberry. [VACCINIUM.]

COW-BUNTING. [MOLOTHRUS.]

COWITCH, or COWAGE, a word of unknown derivation, unless it be a corruption of Al Kooshee, the Bengâli name of one of the plants that produces it, consists of the hairs found upon the pods of different species of *Mucuna*. They are exceedingly slender, brittle, and easily detached, and the fragments readily stick into the skin and produce an intolerable itching; hence they are frequently employed for mischievous purposes. Cowitch is also used medicinally as a vermifuge, by being mixed with syrup till of the consistence of honey, and given in doses of two or three tea-spoonfuls.

The plants that bear these pods are large twining annuals or perennials, with leaves like those of kidney-beans, being dark purple papilionaceous flowers, with a short standard lying close upon the wings and keel, and diadelphous stamens, half of which have round and half arrow-headed anthers. The pods contain from one to six seeds, and are covered by a very wrinkled shriveled skin, which even stands up in little plates. Before they are ripe and their hairs hardened, the pods are employed as a vegetable, like kidney-beans, and are described as being delicious. The species are found in hedges, thickets, on the banks of rivers, and about watercourses in both the East and West Indies, and America within the tropics. *Mucuna urens* and *M. pruriens* usually furnish the substance; but that from *M. monosperma*, called by the Telingas Enooga dola Gunda, or Elephant's Scratch-Wort, is said to exceed the others in the irritating burning property of its hairs. Dr. Roxburgh states that *M. pruriens* was one of the plants formerly used in India to poison wells; "it has turned out, however, not to be the poison it was taken for, and it is more than likely that the other plants employed for the same base ends are fortunately much less dangerous than those who employ them imagine." [MUCUNA.]



Cowitch.
Opened pod of *Mucuna monosperma*, natural size.

COW-PARSLEY, an Umbelliferous Plant (*Chærophyllum temulum*). [CHÆROPHYLLUM.]

COW-PARSNEP, an Umbelliferous Plant. [HERACLEUM.]

COW-PEN-BIRD. [MOLOTHRUS.]

COW-PLANT. [GYMNEMA.]

COWRY. [CYPRÆIDÆ.]

COWSLIP. [PRIMULA.]

COW-TREE, a Plant belonging to the natural order *Urticaceæ*, and apparently to the genus *Brosimum*, from which, when wounded, a milky nutritious juice is discharged in such abundance as to render it an important object to the poor natives in whose country it grows. It is described by Humboldt as being peculiar to the Cordilleras of the coast of Caracas, particularly from Barbula to the lake of Maracaybo, near the village of San Mateo, and in the valley of Caucagua, three days' journey east of Caracas. In these places it bears the name of Palo de Vaca, or Arbol de Leche, and forms a fine tree resembling the Star-Apple of the West Indies. "Its oblong pointed leaves, rough and alternate, are marked by lateral ribs, prominent at the lower surface, and parallel; they are, some of them, ten inches long." Its flowers and fruit have not been seen by any botanist. From incisions in its trunk flows a glutinous milk, similar in consistence to the first milk yielded by a cow after calving. It has an agreeable balsamic smell, is eaten by the negroes, who fatten upon it, and has been found by Europeans perfectly innocuous. In chemical characters it is remarkably similar to the milk of animals, throwing down a cheesy matter, and undergoing the same phenomena of putrefaction as gelatine.

Humboldt supposed the Cow-Tree to belong to the Sapotaceous Order; but, though little has been added to our knowledge of it since his visit to the Caracas, it is at least certain that it is either a species of *Brosimum* or very nearly related to it, and consequently a member of the Urticaceous Order.

The latter circumstance renders the Cow-Tree still more interesting; for the milky juice of Urticaceous plants is in other cases highly poisonous. But botanists are now acquainted with many instances of innocuous plants in poisonous orders; thus the Hya-Hya Treo of Demerara, for instance, belonging to the deadly Apocynaceous Family, yields a thick rich milky fluid destitute of acrimony; and the Kiriaghuna plant of Ceylon is a sort of East Indian Cow-Plant, notwithstanding it belongs to the Asclepiadaceous Order, which is acrid and dangerous. In the absence of precise information as to the circumstances under which the Cow-Trees are milked, it is impossible to say what is the cause of their harmlessness; but every physiologist will see that it is capable of being explained without difficulty in more ways than one.

COYPU. [MYOPOTAMUS.]

CRAB. [CANCER; CRUSTACEA.]

CRAB-APPLE, or WILD APPLE. [PYRUS.]

CRABRO'NIDÆ (Leach), *Crabronites* (Latreille), a family of Hymenopterous Insects of the section *Aculeata* and sub-section *Fossores*. The species have the following characters:—Head large, and appearing almost square when viewed from above; body oval or elliptical, narrowed more or less at the base, and joined to the thorax by a peduncle; antennæ short, and generally thickened towards the apex.

According to Latreille, the following genera are included in this family:—*Tripoxylon, Gorytes, Crabro, Stigmus, Pemphredon, Mellinus, Alyson, Psen, Philanthus*, and *Cerceris*.

The species of *Tripoxylon* provision their nests with small spiders. The species of *Gorytes* are parasitic.

The species of the genus *Crabro* are chiefly distinguished by their having but one perfect cubital cell to the anterior wing; the mandibles terminating in a bifid point, and the antennæ being distinctly geniculated, they are sometimes filiform, and sometimes slightly serrated. The palpi are short, and almost equal. The clypeus is frequently clothed with a fine down of a glossy silver-like hue.

These insects are extremely active in their movements, and may be frequently seen settling on the flowers of umbelliferous plants, on palings, or on the leaves of plants when the sun is shining upon them, lying wait in such situations for the approach of other insects, which they seize and carry to their nests for the purpose of feeding their larvæ. The larger species of this country are mostly of yellow and black colours, the body being adorned with rings of the former colour, the smaller species are for the most part black.

Crabro cephalotes is upwards of half an inch in length; black; the body is adorned with five yellow rings; the basal joint of the antennæ and the tibiæ and tarsi are also yellow.

Crabro patellatus (Panzer), and several other species of this genus, are remarkable in having a large appendage attached to the external part of the anterior tibiæ; this is a thin plate of a somewhat rounded form, convex above and concave beneath, and is undoubtedly used in removing the soil whilst these insects are forming their burrows in the ground. Each burrow is stored with flies or other insects (depending upon the species of *Crabro* to which it belongs); the eggs are then deposited with these flies, which constitute the food of the larvæ when hatched. Many species of *Crabro* form their cells in rotten trees or posts. Much that relates to the habits of these insects however remains to be discovered.

CRA'CIDÆ (Vigors), a family of Rasorial or Gallinaceous Birds (*Rasores*). Mr. Vigors regarded this family as connected with the Struthious Birds, *Struthionidæ* (Ostrich Family), by means of the Dodo [DODO], generally supposed to be now extinct, the foot of which, he observes, has a strong hind toe, and which, with the exception of its being more robust, in which character it still adheres to the *Struthionidæ*, corresponds exactly with the Linnæan genus *Crax*. "The bird," says Mr. Vigors, "thus becomes osculant, and forms a strong point of junction between these two conterminous groups, which, though evidently approaching each other in general points of similitude, would not exhibit that intimate bond of connection which we have seen to prevail almost uniformly throughout the neighbouring subdivisions of nature, were it not for the intervention of this important genus."

"The family of *Cracidæ*," says Mr. Vigors, "thus connected with the *Struthionidæ*, are separated from the typical groups of the order by the length and robustness of the hinder toe, and by its being situated more nearly on a level with those in front. These birds, placed in this manner at the extreme of the present order, assume more of the habits and appearance of the preceding order of Perchers than the other *Rasores*, with the exception of the family of *Columbidæ*. They are found most frequently to make their abode in trees, and to resort to the neighbourhood of forests: in the lesser number of their tail-feathers they evince an equal deviation from their more typical congeners, and they never possess a spur. This family contains the

Ourax of M. Cuvier, and the true *Crax*, Linn., together with the *Penelope* and *Ortalida* of M. Merrem. The two latter genera have their hind toe articulated on a level with the front toes, and thus reconduct us to the *Columbidæ*. Their bills also, more lengthened than those of *Crax*, approach most nearly to those of the Pigeons, which, on the other hand, seem to meet them by the stronger form and curvature of the bill of *Vinago*, which deviates in these particulars from the general structure of its own family. The genus *Ortalida*, in particular, the feathered cheeks of which are distinguished from the naked face of *Penelope*, brings us in immediate contact with that family. Here it is, in this extreme of the order, that I would assign a place to the beautiful New Holland genus *Menura*, Lath., a group that has hitherto afforded more difficulty to the systematic writer than any other in the class. By modern authors it is generally placed among the Perchers on account of the length and low position of the hind toe. But its habits and manners are gallinaceous, as far as we can ascertain, and its general appearance decidedly evinces an affinity to the *Rasores*. The deviation in the structure of the foot from that of the typical Rasorial groups only indicates its being placed at a distance from them, and in that extreme of the order which connects itself with the conterminous order of Perchers. The same deviation, it has been seen, is found in other groups of its own family, and in the adjoining family of *Columbidæ*. A group newly discovered in some islands of the Eastern Archipelago, the *Megapodius* of M. Temminck, serves strongly to illustrate these principles, and to corroborate my opinion as to the situation of the singular New Holland genus before us. The *Megapodius*, brought home to France by one of her late expeditions, is confessedly gallinaceous in its habits, and as such has been placed, without hesitation, among the true *Rasores*, and yet its foot is precisely of the same construction as that of *Menura*. The bill also shows no very material difference from those of the extreme groups of the *Cracidæ*. To return however to the general affinities of the family, it may again be repeated that all the latter genera thus united among themselves, evince an evident approach to the *Columbidæ*, from which, it may be remembered, we commenced our observations on the order. The whole of the groups of the *Rasores*, thus following each other in continued affinity, preserve their circular succession without interruption." [MENURA.]

The following are the characters of the Family:—Three toes before, one behind, the latter touching the ground throughout. Head feathered, generally crested: there is often a cere or naked skin at the base of the bill.

Mr. Swainson, 'Natural History and Classification of Birds,' vol. i., p. 153, states, that "In the family of the *Cracidæ*, which connects the *Insessores* with the *Rasores*, the hinder toe is nearly as long as in the cuckoos, and is considerably more developed than in any other group of rasorial birds. We will say nothing of the genera *Megapodius*, *Palamedea*, and *Menura*, whose feet are well known to be enormous; or of *Opisthocomus*, because specimens of these large and rare birds are not upon our table. Confining ourselves to the genus *Penelope*, we may remark that the toes, considered by themselves, might be taken for those of a cuckoo, if the outer one was only versatile; it is evident also, from the structure of the claws, that these birds are much more arboreal than their congeners, for their claws are more curved; and from their lateral and not horizontal compression, as well from their acuteness, we conclude that they are very little, if at all, employed in scratching the ground, their structure being similar to those of Perchers, and adapted only for clinging. The foot, in fact, of the *Penelope*, is not a rasorial but an insessorial foot, for it does not possess any one of the rasorial characters. Even the hind toe, which in all other rasorial birds is raised above the heel, is here placed upon the same level as the anterior toes. That no ambiguity should rest on this fact, we beg to call the ornithologist's attention to the particular species now before us, the *P. Aracuan* of Spix, one of the most common of the same genus. How this remarkable formation in the foot of the typical *Cracidæ* should hitherto have been completely overlooked, even by those who have speculated so much on the mode by which the *Rasores* and *Insessores* are united, is somewhat extraordinary. We can only account for it by the custom of examining specimens set up in cases, or on branches, instead of preserving them in skins, in which state they can be handled in all directions. But however this may be, the fact itself decides the long-contested question as to which family of the *Rasores* makes the nearest approach or rather forms the passage to the *Insessores*; while, if this question be reversed, and it is asked which of the *Insessores* makes the nearest approach to the *Rasores*, we need only direct our search among some of the long-legged Brazilian cuckoos, or at once point to the singular genus *Opisthocomus*."

Ourax (*Pauxi*, Temm.).—Bill short, strong, compressed, vaulted, convex, dilated at the base of the upper mandible into a horny, oval, hard, and elevated substance. Nostrils basal, pierced near the front, hidden, open beneath; head covered with short and close-set feathers. Feet (tarsi) long and smooth. This family consists of the following genera:—

O. Pauxi (Cuv.), the Galeated Curassow. Size about that of a small hen turkey. Head and neck covered with short velvety feathers of a rich black. All the rest of the plumage, with the exception of the white abdomen and under tail-coverts, brilliant black, exhibiting in certain positions a slight tinge of green. Tail-feathers tipped with white. Legs red, claws yellow. Iris brown. Bill bright red: the protuberance with which it is surmounted (which is rounded in the young birds, and pear-shaped with the narrow end directed forwards in the adult males) of a livid slate-colour; it is more than two inches in length when fully developed, hard and bony externally, and internally cellular, the cells communicating with the cavity of the mouth. This protuberance is not visible till after the first moulting, when it first appears in the form of a small tubercle, and becomes much larger in the male than in the female. In other respects there is little difference between the sexes, and the young are only distinguished by a browner tinge. The windpipe descends for a considerable distance in front of the sternum, immediately beneath the skin, and makes no less than three distinct convolutions before passing into the cavity of the chest. (E. T. Bennett.)

Galeated Curassow (*Ourax Pauxi*).

This bird is a native of Mexico, where the species lives in large companies perching upon the trees. Nest generally made on the ground. The young are led about by the female in the same manner as the hen pheasant and the common hen lead theirs. The first food of the chicks consists of worms and insects, but as they advance fruits and seeds are added. Hernandez gives a very good description of the bird in his 'Historia Avium Novæ Hispaniæ,' cap. ccxxii. The Galeated Curassow is easily domesticated, and is enumerated by M. Temminck among the birds which bred abundantly in the menagerie of M. Ameshoff before the French revolution.

Mr. Yarrell has pointed out the peculiarities of the very elongated trachea of another species, *Ourax Mitu*, Cuvier. This organ is produced between the skin and the muscles beyond the sternum, and reaches almost to the vent. It has been figured by Dr. Latham, M. Temminck, and others. The sterno-tracheal muscles extend along the whole of the tube, a disposition which, Mr. Yarrell remarked, prevails with one or two exceptions in all birds in which the fold of the trachea is not included in the bone. ('Zool. Proc.,' 1830-31.) Mr. Bennett ('Gardens and Menagerie of the Zoological Society') observes that the nostrils in *Ourax Pauxi* are seated behind the protuberance, and are perpendicular in their direction: the membranous cere which surrounds them, he adds, is covered with short velvety feathers.

Crax.—Bill moderate, long, compressed, higher than it is broad at the base, thick, carinated above, curved towards the end, surrounded at the base with a membrane; lore naked; nostrils lateral, longitudinal, pierced in the cere, and partially covered. Head crested with curled feathers. Tail spread out, inclined; tail-feathers 14. Sixth quill the longest. Hallux reaching the ground with the first phalanx.

C. Alector (Linnæus), the Crested Curassow. The plumage of the Crested Curassow is of a deep black, with a slight gloss of green upon the head, crest, neck, back, wings, and upper part of the tail; it is of a dull white beneath, and on the lower tail-coverts. Its crest is from 2 to 3 inches in length, and occupies the whole upper surface of the head; it is curled and velvety in its appearance, and capable of being raised or depressed at will. The eyes are surrounded by a naked skin which extends into the cere, and there assumes a bright yellow colour. Size about that of *Ourax Pauxi*. (E. T. Bennett.)

"This species," says Mr. Bennett, "is a native of Mexico, Guyana, and Brazil, and probably extends itself over a large portion of the southern division of the American continent. In the woods of Guyana it appears to be so extremely common that M. Sonnini regards it as the most certain resource of the hungry traveller whose stock of provisions is exhausted, and who has consequently to trust to his gun for furnishing him with a fresh supply. They congregate together in numerous flocks, and appear to be under little or no uneasiness from the intrusion of men into their haunts. Even when a considerable number of them have been shot the rest remain quietly perched upon the trees, apparently unconscious of the havoc that has been com-

Crested Curassow (*Crax Alector*).

mitted amongst them. This conduct is by no means the result of simplicity, but proceeds rather from the natural tameness and unsuspiciousness of their character. Those however which frequent the neighbourhood of inhabited places are said to be much wilder and more mistrustful, being kept constantly on the alert to avoid the pursuit of the hunters, who destroy them in great numbers. They build their nests on the trees, forming them externally of branches interlaced with the stalks of herbaceous plants, and lining them internally with leaves. They generally lay but once a year, during the rainy season; the number of their eggs being, according to Sonnini, five or six, and according to D'Azara as many as eight. They are nearly as large as those of a turkey, but are white like a hen's, and with a thicker shell." ('Gardens and Menagerie of the Zoological Society,' vol. ii.)

C. Yarrellii, the Red-Knobbed Curassow. The trachea of this species differs from all those previously known, but most resembles that of *C. Alector*, Linnæus, while in external characters the bird approaches *C. globicera*, Linnæus, from which it is distinguished by the redness of its cere, and by a prominence on each side under the base of the lower jaw, in addition to the globose knob near the base of the upper. The tube in *C. Yarrellii* is straight throughout its whole length, except a short convolution imbedded in a cellular membrane placed between the shafts of the os furcatorium. The trachea is narrow, and the fold, invested and supported by a membranous sheath, gives off one pair of muscles, which are inserted externally below the apex of the os furcatorium. The lower portion of the tube immediately above the bone of divarication sends off a pair of muscles to be inserted in the sternum. The upper pair of muscles (furculo-tracheal) influence the length of the tube above the convolution. The inferior pair (sterno-tracheal) have the same power over the bronchial tubes and that portion of the trachea which is below the convolution. ('Zool. Proc.,' 1830-31.)

Mr. Bennett, speaking of the Zoological Society's Menagerie, says:—"Of all the gallinaceous birds in the collection, the most interesting are those which hold out to us a prospect of supplying our farm-yards with new breeds of poultry of a superior kind. Such are especially the Curassows. In many parts of South America these birds have long been reclaimed; and it is really surprising, considering the extreme familiarity of their manners and the facility with which they appear to pass from a state of nature to the tameness of domestic fowls, that they have not yet been introduced into the poultry-yards of Europe. That with proper treatment they would speedily become habituated to the climate we have no reason to doubt; on the contrary, numerous examples have shown that they thrive well even in its northern parts; and Temminck informs us that they have once at least been thoroughly acclimated in Holland, where they were as prolific in their domesticated state as any of our common poultry. The establishment however in which this had been effected was broken up by the civil commotions which followed in the train of the French revolution, and all the pains which had been bestowed upon the education of these birds were lost to the world by their sudden and complete dispersion. The task which had at that time been in some measure accomplished still remains to be performed; and it may not be too much to expect that the Zoological Society may be successful in perfecting what was then so well begun, and in naturalising the Curassow as completely as our ancestors have done the equally exotic and in their wild state much less familiar breeds of the turkey, the Guinea-fowl, and the peacock. Their introduction would certainly be most desirable, not merely on account of their size and beauty, but also for the whiteness and excellence of their flesh, which is said by those who have eaten of it to surpass that of the Guinea-fowl or of the pheasant in the delicacy of its flavour." ('Gardens and Menagerie,' &c., vol. ii.)

Lieutenant Maw, who appears to have shot a Red-Knobbed Curassow on his passage from the Pacific to the Atlantic down the river Marañon, says that the native Peruvian name for the bird is Peury.

Penelope.—Bill moderate, naked at the base, entire, convex above, wider than it is high, bent at the point; lore and base of the bill naked. Under the throat a naked skin which is capable of being inflated or swollen. Nostrils pierced in the cere towards the middle of the bill, half closed. Foot (tarsus) slender, longer than the intermediate toe; nails somewhat curved, strong, compressed, and pointed. Fifth and sixth quill longest. Tail-feathers 12.

P. cristata (Gmelin), the Guan. Length about 30 inches, the tail being 13 or 14 inches. Upper parts dusky black or bronze, glossed with green, changing to olive in certain lights. A black stripe passes from the under part of the bill backwards, and surrounds the ear. Fore part of neck and breast spotted with whitish, each of the feathers being bordered by white; belly and legs, lower part of the back, and under tail-coverts, reddish. Cheeks naked and violet-purplish. Iris reddish brown. Bill blackish. Feathers of the back of the head long, forming a thick tufted crest, which the bird can raise or depress at pleasure. Naked part of the throat scarlet, with a contractile and extensile fold of depending skin. Mr. Bennett observes that this fold retains its elasticity after death. The female differs from the male principally in having her plumage, especially her under parts, more decidedly tinged with red.

Guan (*Penelope cristata*).

Mr. Yarrell states that the trachea of the Guan is uniform in size and substance throughout its whole length. After descending by the neck in the usual way, it is extended, and passes downwards under the skin, but over the outer surface of the pectoral muscle on the right side, to the extent of two inches beyond the angle formed by the junction of the two portions of the os furcatorium. The tube of the trachea is then reflected, and, ascending to the cavity of the thorax, again turns to be carried to the lungs as in other birds, and is provided with one pair of true muscles of voice, which have the usual origin and insertion. The loop or fold of the tube formed on the surface of the pectoral muscle is imbedded in cellular tissue, and further retained in its place by a strong ligament, which, firmly adhering to the loop, passes backwards to be first attached to the posterior angle of the sternum; and afterwards dividing once, and passing still farther backwards, the two slips are inserted on the two elongated pubic points of the pelvis. This structure in the Guan, Mr. Yarrell observes, has been noticed and figured by M. Temminck in his 'Histoire des Pigeons et Gallinacés.'

Mr. Bennett remarks that the manners of the Guan have little to distinguish them from those of the Curassows. Although to all appearance equally capable of domestication, they have not yet been introduced into Europe in equal numbers with the Curassows, nor has the same success attended the attempts to propagate them in this quarter of the globe. "We are told however," continues Mr. Bennett, "by M. Temminck, that the proprietor of a menagerie in the neighbourhood of Utrecht had bred them for several years; and there can be little doubt that with proper care and attention these birds might be added to the stock of our domesticated fowls. They are spoken of as furnishing an excellent dish for the table. In a wild state they inhabit Guyana and Brazil, and perhaps extend still farther to the north. Their food consists principally of seeds and fruits, which they search for and eat upon the ground; but the greater part of their existence is passed upon the trees, on the tops of which they perch, and in which they build their nests. They are often found in large bands, but generally pair together with the strictest constancy. The females lay from two to five eggs. Their flight, like that of most gallinaceous birds, in consequence of the shortness of their wings, is low and heavy; and in the performance of this action they derive much assistance from their tail, the feathers of which may be expanded in the shape of a fan. All the birds of this genus appear to be known in Brazil by the name of Jacu, pronounced Yacou, derived, according to Marcgrave, from their note. This, as might be expected from the conformation of their trachea, is extremely loud, insomuch that when a considerable number are collected near the same spot, the very woods, to use the expression of the scientific traveller just quoted, re-echo with their clamorous cries." The same author observes that M. Spix added very considerably to the difficulties that previously existed in distinguishing the species of this interesting group by the publication, in his 'Brazilian Birds,' of a series of figures representing apparently very slight modifications of the common form, but to each of which he has prefixed a peculiar specific name. Mr. Bennett expresses his belief that most of these will be found on further examination to be referrible to the present species, which, from its long domestication in the poultry-yards of South America, must necessarily be subject to very extensive variations. ('Gardens and Menagerie of the Zoological Society,' vol. ii.)

M. Lesson, on the authority of M. Goudot, mentions a species, *Penelope Aburri*, Goud., 2 feet 3 inches (French) long, the tail being 10 inches. M. Goudot states that this species seems peculiar to the mountains of New Granada, inhabiting temperate and cold districts; it is, he says, unknown in the great warm valleys and by the rivers. In the environs of the city of Muzo, celebrated for its mine of emeralds, this bird, he states, is known under the name of Pavo-ò-Guali. The inhabitants of the neighbourhood of Bogota and of the valley of Cauca designate it by the term Pava Burri, or Aburri Aburrida, which when slowly pronounced well expresses its cry. The male does not differ from the female; and those which M. Goudot opened had two cæcums analogous to *Penelope Parakona* and *Pavita* (*superciliaris?*). The trachea descended without any fold to the lungs. There was no gravel in the gizzard, the walls of which were thin, and nearly entirely covered by the proper muscles. M. Goudot states that the species lives solitary, perches upon high trees, flies but little, and suffers the hunter to approach easily within shot. It is never seen on the ground. The berries of trees compose its food. Its nest is formed in a mass of dry leaves, disposed between the forks of trees. The eggs are three in number, white, and 1 inch 8 lines in diameter. These birds, adds M. Goudot, are very common in the mountains of Quindiu, between Ilague and Carthagena. Their notes are the last that are heard on the approach of night, and the first that announce the dawn of day.

Ortalida.—Its characters are the same as those of *Penelope*, excepting that the head is completely feathered, and that there is no nakedness about the throat or round the eyes.

O. Motmot, *Phasianus Motmot*, Gmel., *Phasianus Parraqua*, Lath. Colour red-brown, bronzed above. Tail moderate. It inhabits Guyana.

Ortalida Motmot.

M. Goudot describes a new species from Santa-Fé de Bogota, which M. Lesson names *Ortalida Goudotii.* The bird it appears is found in the same places with the *Penelope Aburri*. Total length 23 inches, of which the tail is 9 inches. Feet red; tarsus 2 inches 5 lines; middle toe 2 inches 4 lines, the claw being 5½ lines (French). The bill is blackish, brown at its point; the upper mandible 1 inch 5 lines; cere and naked membrane round the eyes blue. All the upper plumage brown, with deep green reflections, or rather of a very deep greenish. Feathers of the throat gray. Bottom of the neck, belly, and abdomen, as well as the thighs, covered with ruddy. No crest nor nakedness about the throat. No fold of the trachea in either sex. It is found in the mountains of Quindiu.

M. Lesson observes that this bird approaches nearly to the last, but is clearly distinguishable from it, especially by the trachea, which does not descend upon the abdomen.

Opisthocomus, Hoffm. (Hoazin, Buff.; *Orthocorys*, Vieill.).—Bill thick, robust, short, convex, bent at the point, which is suddenly compressed, furnished with diverging bristles at the base, which is dilated laterally; lower mandible strong, terminated in an angle; edges dentelated towards the origin. Nostrils mesial on the surface of the bill, pierced (de part en part), covered above by a membrane. Feet robust and muscular; tarsus shorter than the middle toe, the lateral toes long, equal, entirely divided; sole broad; toes bordered with rudiments of membranes. Wings moderate, the first quill very short, the four following graduated, and the sixth the longest. Tail-feathers ten.

O. cristatus. This species, which appears to be the only one belonging to the genus, is the Hoatzin and Hoactzin of Hernandez; who describes it as an inhabitant of warm districts, where it was seen sitting on trees by the sides of rivers, and as having received its name from a supposed similarity of the shrieking cry of the bird to the intonation of the word 'hoatzin.' Hernandez relates some strange stories of cures effected by its bones and by a suffitus of its feathers; but says that the bird is deemed inauspicious by the natives. Sonnini states that it is known in Guyana by the name of Sasa.

Hoazin (*Opisthocomus cristatus*).

The Hoazins are said to live in pairs or in small troops, consisting of from six to eight individuals, in the flooded savannahs, which they prefer, and where they seek for their food the leaves of the *Arum arborescens*. Their flesh is not considered good, having a strong smell of Castoreum about it. These birds are by no means timorous. In stature and gait they resemble the peacock.

Megapodius.—Bill slender, straight, as wide as it is high, and flattened above at the base: upper mandible longer than the lower, slightly curved at its extremity; lower mandible straight, the point hidden by the edges of the upper mandible. Nostrils suboval, open, placed nearer to the point than to the base of the bill; nasal fossæ long, covered by a membrane furnished with small feathers. Space round the eye naked, head and neck well feathered. Feet large and strong, placed far backwards; tarsus large and long, and covered with large scales, compressed posteriorly; four very elongated toes, the three anterior ones nearly equal, united at their bases by a small membrane, which is more apparent between the inner and middle toe than between it and the outer one; posterior toe horizontal, touching the ground throughout its length; claws very long, very strong, flattened above, very little curved, triangular, obtuse at the point, nearly like those of *Menura*. Wings moderate, concave, rounded; third and fourth quills the longest. Tail small, wedge-shaped, scarcely exceeding the wings in length, and formed of twelve feathers. (Quoy and Gaimard, with slight alteration.)

M. Duperreyii. In size hardly so large as a partridge. Tarsi less elevated than they are in *M. Freycinetii* and *M. rubripes*. The bird is moreover altogether better proportioned. Total length, from the extremity of the bill to that of the wings, which are longer than the tail, rather less than a foot (French). Tarsi strong, covered with scales, and 20 lines in length; middle toe, including the claw, 17 lines; hind toe 14 lines; posterior claw 7 lines. Bill slightly swollen towards its extremity, yellow, 8 lines in length. Nostrils suboval, covered with a membrane clothed with very small rudimentary feathers. Space round the eyes naked, but less than in the other two species. Neck well clothed with feathers. Iris reddish. A very thick crest covers the head; the feathers which compose it are raised (se redressent) towards the occiput. The wings are concave, an inch longer than the tail, and terminated in a point: the fifth quill the longest. Tail suboval, pointed, very short, composed of 10 small feathers. Legs grayish, and feathered down to the tarsi; the claws slightly curved, pointed at the end, flat below, and of a brown colour. (Lesson.)

Mangoipe (*Magapodius Duperreyii*).

"The tuft," says M. Lesson, "of our *M. Duperreyii* is of a brown-yellow; the neck, the throat, the belly, and the lateral parts, are of a gray-slate colour. The feathers of the back and the wing-coverts large, and of a ruddy yellowish-brown. Rump, upper part of the tail, and vent-feathers, ochreous red. Quills yellow without, brown within, the shafts being ruddy brown.

"The middle toe is united to the inner one by a membranous border, which is wanting between the middle toe and the external one.

"In comparing our *Megapodius* with the *Menura* of New Holland, we cannot fail to perceive that it connects the last-mentioned genus with the gallinaceous birds, by forming a very natural passage. In fact, if we examine the position of the nostrils, the general form of the bill and legs, and the nakedness round the eyes—the membrane which unites the two external toes, but which is wanting between the middle toe and the inner one (an arrangement which is reversed in *Megapodius*)—the same length of the toes, the analogy in the form of the claws, the greater length of the posterior one, the concavity and the smallness of the wings—all these characters, in fine, coincide to confirm this passage, if we except the extraordinary grandeur and luxuriant form of the tail of *Menura*, a form without analogy among the other birds. *Megapodius* would thus belong to a small natural group, the *Lyriferi* of Vieillot (27th family); the name of which, in consequence of its having become improper, would have to be changed.

"The *M. Duperreyii*, the Mangoipe of the Papuans, inhabits the umbrageous forests of New Guinea, in the neighbourhood of the harbour of Doréry. The bird is timid, runs very fast among the bushes, like a partridge in standing corn, and utters a feeble cluck (un petit gloussement)."

M. Lesson states that he only observed *M. Freycinetii* in the Island of Waigiou, and that the attempt to preserve it alive in cages was vain, for the birds soon died. Their flesh, he says, is black, very hard, and not very agreeable as food, although possessing a fumet which the cooking developes. The Papuans brought them on board the Coquille daily, and called them (those of the harbour of Offack at least) Manesaqué.

Both Pigafetta and Gemelli Carreri speak of the Tavon (*Megapodius*), and it would seem that this, the *Megapodius* of the Philippines, leaves its eggs to the fostering heat of the sun. The habits of the *Megapodii* of New Guinea and the neighbouring islands are, according to M. Lesson, entirely unknown.

Alecthelia.—The characters of the genus *Megapodius*, observes M. Lesson, established by Messrs. Quoy and Gaimard in the Zoology of the voyage round the world performed by the Uranie, are in great measure applicable to the sub-genus *Alecthelia*, formed by M. Lessou for the position of a bird which differs from the true *Megapodii*, or Tavons, by many distinctive characters.

Bill short, compressed, pointed: the upper mandible prolonged, the lower mandible a little swollen and very short; nostrils at the base of the bill separated by a straight ridge; head and forehead abundantly covered with feathers down to the nostrils; space round the eyes furnished with short and close-set feathers; inner toe rather the shortest; membrane which unites the middle toe to the inner one almost absent; no tail; all the feathers of the body, except those of the wings, composed of loose barbs, very finely ciliated on each of the shafts.

A. Urvillii, Lesson. It is the only species known. Its total length from the extremity of the bill to that of the wings is 5 inches 4 lines. Tarsi 14 lines; middle toe 10, hind toe 8, claws 5, bill 6 lines (French). The bird is covered with loose and scanty feathers, but has upon the occiput a thick bunch of feathers. The general tint is brown, fuliginous, deepest above; belly and throat brown, slightly tinged with ruddy colour; throat ash-coloured; wings concave, rounded, the feathers entirely brown, the second, third, and fourth being equal: the upper part is brown sprinkled with zigzag or irregular lines, not well defined, of ruddy yellow. Place of the tail-feathers supplied by very loose plumes, composed of very fine barbs, bristled with very slender approximated barbules, presenting much analogy with those of the Cassowary (No. 6, pl. 67, 'Atlas de Peron'), and which, implanted in the rump in the same manner, form a feathery tuft as in the Cassowary; all the feathers of this bird, except those of the wings, are composed of multiple stems, very slender and soft, furnished with equal and very fine barbules which may be called multirachid. The bill is grayish, and so are the feet; the inner toe is a little more united to the middle one than to the external one; the claws are slightly curved, sharp, convex above, concave below, and of a brown colour; the iris is reddish.

Alecthelia Urvillii.

This species, which comes from the Isle of Guebé, placed immediately under the equator, is, no doubt, proper to the neighbouring lands such as the great and beautiful Isle of Halamiva or Golilo, so little known and so little studied by naturalists. (Lesson.)

CRAG, the uppermost of the distinctly Tertiary Strata of England —using this term in a sense which is perhaps gradually passing away, to be replaced by the larger meaning of Cainozoic, suggested in this work. The Crag of Norfolk and Suffolk is partly a calcareous mass rich in delicate corals; partly a subcalcareous sand rich in shells; and partly a rudely aggregated deposit of sand, shells, pebbles, and bones. To these divisions, whose origin is due to different local conditions, and successive times, Mr. Charlesworth has assigned the titles of Coralline Crag, Red Crag, aud Mammaliferous Crag. The position of these beds will be best seen from the following table of the classification of the Tertiary Rocks from Professor Ansted's 'Elemeutary Geology.'

Newer Tertiary, or Pliocene Series:—
1. Upper Gravel and Sand.
2. Till.
3. *Mammaliferous Crag.*
4. Fresh-Water Sand and Gravel.
5. *Red Crag.*

Middle Tertiary, or Miocene Series:—
6. *Coralline Crag.*

Lower Tertiary, or Eoceue Series:—
7. Fluvio-Marine Beds, &c.

For a further account of the Crag Formation, and its relation to the other members of the Tertiary Series, see Tertiary Strata.

CRAKE. [Rallidæ.]

CRAMBE, a genus of Plants belonging to the natural order *Cruciferæ*. It belongs to the sub-order *Lomentaceæ* and the tribe *Raphaneæ*. It has a 2-jointed silicle, upper joint globose, with 1 seed pendent from a long curved seed-stalk springing from the bottom of the cell; lower joint barren, stalk-like.

C. maritima, the Sea-Kail, or Sea-Kale, is a glaucous spreading plant, with broad-toothed sinuated leaves, and dense corymbs of large white flowers, found occasionally on the sea-coast of England, and now commonly cultivated in gardens for the sake of its delicate tender shoots. Naturally the flavour of the plant is strong, cabbage-like, and highly disagreeable, but in the state in which it is sent to the kitchen, it is merely a colourless mass of delicate fleshy vegetable tissue, with little or no flavour. This arises from the shoots that are to be cooked being grown in darkness, and with a little more speed than usual. For this purpose a garden-pot is inverted over the crown of an old sea-kail stock, in the winter before the leaves sprout. Over the pot is thrown a little litter, or some decaying leaves, or some old tan, so as to increase the temperature of the earth, and to exclude light; after a week or two the pot is examined from time to time, and when sprouts five or six inches long have been produced, they are cut off, and are fit for table.

Sea-Kail loves a light sandy soil, well drained in winter and richly manured. It will continue to bear cutting for twenty years together without suffering much; and is one of the most simple and useful of all culinary plants for a small garden. It is generally grown in rows eighteen inches or two feet apart.

CRAMBUS, a genus of Moths (*Lepidoptera nocturna*) of the family *Tineidæ* (Stephens). The type of this genus is the *Phalæna Pascuella* of Linnæus.

In crossing dry meadows during the summer time, we observe numerous little moths fly from the grass at every step we take; they soon settle again, and are then not easily detected, owing to their mode of folding their wings, which when shut almost inclose their slender bodies, and partly surround the blade of grass on which they rest; their form is then long and narrow, pointed at the head, and somewhat truncated at the opposite extremity. Their colouring is often brown and white, disposed on the upper wings principally in longitudinal lines. Very frequently however we find them adorned with beautiful metallic colours, generally of silvery or golden hues. Such are the insects which constitute the genus *Crambus*, and of which we possess about 40 species in this country. The characters of this genus are:—Proboscis distinct; wings convoluted round the body when at rest; superior wings narrow; palpi long, the inferior the longer; head furnished with short closely-applied scales.

When the wings are expanded, these moths commonly measure about an inch in width; they are called in England the Veneers, and sometimes Grass-Moths.

CRANBERRY. [Oxycoccus.]

CRANE-FLY. [Tipulidæ.]

CRANES. [Gruidæ.]

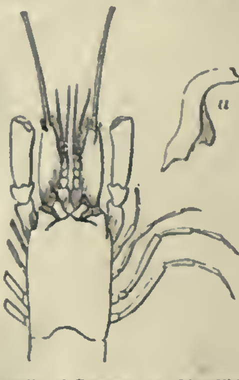
CRANE'S-BILL. [Geranium.]

CRANGONIDÆ, a family of *Crustacea* belonging to the division *Decapoda Macroura*. The type of this family is the Common Shrimp (*Crangon vulgaris*), and no other genera are included in it. It has the following characters:—

Internal antennæ inserted on the same line as the external antennæ; first pair of feet terminated by a subcheliform hand. Although there are a large number of *Crustacea* which are vulgarly called Shrimps which resemble in general form the Common Shrimp, the *Crangonidæ* differ too much from all these to be comprised in the natural tribes formed by them. It corresponds to the genus *Crangon* of Fabricius, which, in the opinion of M. Milne-Edwards, has been unnecessarily subdivided by Dr. Leach and M. Risso into the Crangons, properly so called, Egeons, and *Pontophili*.

Crangon comprises those shrimps whose anterior feet are terminated by a monodactylous and subcheliform hand.

Carapace much more depressed than in the other shrimps, and presenting anteriorly only the rudiment of a rostrum. Eyes short, large, and free. Antennæ inserted nearly on the same transversal line; the first pair dilated at their base, at the external side of which is a rather large scale; their peduncle is short, and they are terminated by two multi-articulate filaments. The external antennæ are inserted outwardly and a little below the preceding, and they offer nothing remarkable. The mandibles are slender, and without any palp. The external jaw-feet, which are pediform and of moderate length, terminate by a flattened and obtuse point; within, they carry a short palp, terminated by a small flagriform appendage directed inwards. The sternum is very wide backwards. The first pair of feet are strong, and terminate in a flattened hand, on the anterior edge of which a moveable claw is bent back: the internal angle of this hand, which corresponds to the point of the claw, is armed with a tooth representing an immoveable rudimentary finger. The two succeeding pairs of feet are extremely slender; the second terminate generally in a very small didactylous claw; and the third are monodactylous, like those of the fourth and fifth pairs; but these four posterior feet are much stronger. The abdomen is very large, but presents nothing remarkable in its conformation. The branchiæ are only seven in number on each side of the thorax. (Milne-Edwards.)



Details of *Crangon*. *a*, Mandible.

The genus is divided by M. Milne-Edwards into the following sections:—

1. Species having the second pair of feet nearly as long as the third pair.

In this section are comprised *C. vulgaris*, *C. fasciatus*, and *C. Boreas*.

2. Species with the second pair of feet much longer than the third. Example, *C. septemcarinatus*.

C. vulgaris, the Common Shrimp. Carapace and abdomen almost entirely smooth, with the exception of one small median spine on the stomachal region, and one lateral above each branchial region. Terminal filaments of the internal antennæ more than twice as long as their peduncle. Lamellar appendage of the external antennæ large and elongated (about twice as long as the peduncle of the internal antennæ). Last joint of the external jaw-feet long and narrow. Two last pairs of feet of moderate size. A strong spine inserted on the sternum between the second pair of feet, and directed forwards. Abdomen smooth, and without any keel. Median blade of the caudal fin pointed, and without a furrow above. Length rather more than two inches. Colour greenish-gray, dotted with brown.

Common Shrimp (*Crangon vulgaris*). *a*, anterior foot or claw.

It is common on the coasts of England and France.

It is the Crevette of the French, and Shrimp of our markets, and is one of the most delicious (Pennant thinks the most delicious) of the macrurous crustaceans.

The shoals of these creatures which frequent our coast give employment to a great number of persons, who are engaged in catching them. They are abundant at the mouth of the Thames, from whence the London market is principally supplied. They are caught by a large open net, which is attached to a long stick and pushed through the water. They are most plentiful on sandy shores. They are used also for bait.

C. fasciatus, the Banded Shrimp, is found in the Mediterranean. It has also been taken in England at Salcombe Bay.

C. spinosus, the Spiny Shrimp. It is the *Pontophilus spinosus* of Leach; *Egeon loricatus* of Guerin. This shrimp has been taken in several places on the south coast of England.

C. sculptus is a British species, described by Professor Bell in his 'History of the British Stalk-Eyed Crustacea.' It was taken at Weymouth by Mr. Bowerbank.

C. trispinosus and *C. bispinosus* are also British species, and have been taken on the coast of Hastings.

CRANIA. [BRACHIOPODA.]

CRASSAMENTUM. [BLOOD.]

CRASSATELLA. [CONCHACEA.]

CRASSINA. [VENERIDÆ.]

CRASSULA, a genus of Plants, the type of the natural order *Crassulaceæ*. It has a 5-parted calyx, much shorter than the corolla; sepals flattish; the petals 5, stellate, spreading, distinct; the stamens 5, filaments awl-shaped; scales 5, ovate, short; carpels 5, many-seeded. The species are very numerous. They are succulent herbs or shrubs, and are mostly natives of the Cape of Good Hope. Their leaves are opposite and entire, or nearly so. The flowers are mostly white, rarely rose-coloured. Upwards of fifty species have been described; and many of them, on account of their grotesque appearance, are cultivated in our gardens. They are greenhouse plants. One species, *C. tetragona*, is used at the Cape of Good Hope as a remedy in dysentery. Any medicinal properties they possess is probably owing to the presence of tannin.

CRASSULA'CEÆ, *House-Leeks*, a natural order of Polypetalous Exogenous Plants. It consists of succulent plants, with herbaceous or shrubby, and annual or perennial roots, growing in hot dry exposed places in the more temperate parts of the Old World chiefly. On the sun-scorched cliffs and volcanic soil of the Canaries, and on the dry sterile plains of the Cape of Good Hope, they are most abundant. Their flowers are arranged in panicles, spikes, cymes, and corymbs; each has a calyx of several divisions, alternating with which is the like number of petals, alternating with which is the like number of stamens, or twice as many, alternating with which are as many

Crassulaceæ.

A, a portion of a branch of *Sempervivum villosum*; 1, a calyx of *S. montanum*; 2, a part of the petals and stamens laid open, and adhering by the tube of the calyx; 3, a calyx with the ovaries projecting—the hypogynous scales are seen at the base of some of these; 4, a ripe follicle; 5, a section of a seed showing the embryo in the albumen.

distinct carpels as there are segments of the calyx. The stamens arise from the tube of the calyx; there is usually a hypogynous gland at the base of each carpel; the carpels are often of the same colour as the petals; and sometimes, in monstrous cases, the anthers bear ovules as well as the ovaries. The fruit consists of a number of distinct follicles, each containing numerous minute seeds; the embryo lies in the axis of fleshy albumen. The affinities of this order, according to Dr. Lindley, are with *Sauvagesiaceæ*, *Caryophyllaceæ*, *Saxifragaceæ*, and *Turneraceæ*.

Many species of *Crassula*, *Rochea*, *Sempervivum*, *Sedum*, &c., are cultivated for the beauty of their flowers; the various annual Tillæas, &c., are obscure weeds; house-leeks (different sorts of *Sempervivum*) are grown for their refrigerant qualities; and the leaves of *Sempervivum arboreum* possess powerful tanning qualities. This order contains 22 genera and 450 species. [SEDUM; SEMPERVIVUM; COTYLEDON; ECHEVERIA; TILLÆA; ROCHEA; RHODIOLA; UMBILICUS; BRYOPHYLLUM.]

All the hardy species may be grown on old walls, roofs, rock-work, or other places thoroughly drained of moisture; the greenhouse kinds require what is called a dry-stove treatment—that is, they must be potted in a mixture of lime, rubbish, broken pots, and earth; in summer they are freely exposed to the weather in sunny situations without protection, and in winter they are kept moderately cool, and nearly without water.

CRATÆ'GUS, a genus of Plants belonging to the natural order *Rosaceæ* and the sub-order *Pomeæ*. This genus is very nearly allied to the Apple (*Pyrus*), from which it differs in the fruit containing a variable number of stones, as the Medlar does; from the Medlar it is known by its fruit being closed, not spread open, at the apex.

The species inhabit woods and hedges throughout the northern hemisphere, from Barbary and Palestine to about 60° N. lat. in the east, and from Mexico to a similar latitude in the west. South of these limits they do not occur in a wild state. The flowers appear in the greatest profusion, usually in terminal cymes, in the early months of the year, and are succeeded by small round fruits, coloured yellow, red, purple, or black. Most of them are merely haws, and fit only for the food of birds; a few are larger and more fleshy, but none of them have been found worth cultivating for the fruit, except the Azarole (*Cratægus Azarolus*), which is eaten in Italy, and the Aronia, which is sold in the markets of Montpellier under the name of Pommettes à Deux Closes.

Between sixty and seventy well-marked species and varieties are known in the gardens of this country. Into extensive collections they are all worth introduction, except *C. parvifolia* and those immediately allied to it; and for the ornament of park-scenery there is probably no genus of flowering trees at all to be compared with *Cratægus* for variety, fragrance, and beauty. Our limits prevent our noticing all these at length; we therefore confine ourselves to a brief indication of those which are most valuable for ornamental purposes.

C. oxyacantha, the Hawthorn, White Thorn, or May. The leaves are obovate, 3-4-lobed, cut and serrate, cuneate at the base; the flowers corymbose; calyx not glandular; styles 1-3. The branches are spinose. This plant is one of the most common in the British Flora, being used throughout the kingdom for forming quickset hedges. Babington mentions two varieties, expressing an opinion that they are not improbably distinct species—*C. oxyacantha* (Linnæus and Jacquin), with the peduncles and calyx glabrous, and *C. monogyna* (Jacquin), with the peduncles and calyx villose. The latter is the more common form.

The Hawthorn not only grows in the form of a shrub or bush in our hedges, but is not unfrequently seen in the form of a tree. It is of slow growth, and many individuals have attained celebrity for their antiquity. There are several in Bushy Park said to be above two centuries old. The wood of the Hawthorn is hard, takes a fine polish, and is used by cabinet-makers.

Under the name of Hawthorns may be comprehended all the numerous sorts which are either varieties of *Cratægus oxyacantha* or nearly related to it. They have all deeply-lobed rather shining leaves, so little hairy that their bright green colour is not deadened, small fragrant flowers, and small shining haws. They are distinguished for the graceful manner in which they generally grow in rich soil and unharmed by the pruning-knife. Thirty feet is not an unusual height for very fine specimens, and when of that size their appearance is exceedingly graceful and picturesque. *C. oxyacantha* itself produces varieties with double flowers, bright crimson flowers, yellow fruit, black fruit, and fruit downy when young; the latter is called *C. oxyacantha eriocarpa*, and is one of the most beautiful of the genus.

Very nearly allied to these are the Oriental Thorns, species which have their deeply-cut leaves covered so closely with hairs as to have a dull gray or hoary aspect, large fragrant flowers, and large succulent rather angular fruit. These are less graceful in their manner of growth than the true Hawthorns, some of them, especially *C. tanacetifolia* and *C. odoratissima*, having a round formal head; but their flowers are even more fragrant than the May-bush, and their fruit renders them striking objects in the autumn. The Azarole is one of them; but it does not fruit or flower readily, and is the least worth having of the group. We should recommend *C. odoratissima*, with its red fruit, *C. tanacetifolia* with its yellow fruit, *C. orientalis* with purple fruit, and *C. Aronia* with its light orange-coloured fruit.

The American Thorns are species with leaves but little lobed, usually broad, shining, and toothed unequally, often having exceedingly long spines, and having fruit generally of an intermediate size

They are not quite so handsome as the species of the two former groups; but the following, nevertheless, have sufficiently ornamental features, namely—*C. Crusgalli*, or the Cockspur Thorn, with very long strong spines and shining deep green leaves; of this we have a broad-leaved variety called *C. splendens*, and a narrow-leaved variety called *C. salicifolia*; *C. prunifolia*, *C. ovalifolia*, and *C. Douglasii*, with dark handsome leaves; *C. punctata*, with large yellow or red haws; *C. cordata*, with brilliant scarlet fruit; and *C. microcarpa*, with very small beautiful vermilion fruit and graceful pendulous shoots.

The Small-Leaved Thorns are all North American: they form small straggling bushes, and are not worth cultivation.

Finally, the Evergreen Thorns consist of *C. Mexicana* and *C. pyracantha*. The former is a small tree with lance-shaped bright green leaves, and large round yellow fruit; it is probably too tender for hardy cultivation north of London. The latter, an inhabitant of rocks and wild places in the south of Europe and the Caucasus, has been long cultivated in this country for the sake of its flame-coloured berries and evergreen leaves.

All these plants may be budded or grafted upon the Common Hawthorn, so that persons whose means do not allow them to purchase the plants may nevertheless ornament their gardens with them by providing hawthorn stocks, upon which they may work them themselves; or a very small garden might exhibit a good many sorts, if each of the groups here pointed out were intermixed upon the same plant. This might be easily effected by a skilful budder. It would not however do to intermix the different groups upon the same plant, because the species would not harmonise, and consequently a bad appearance would be the result.

(London, *Arboretum et Fruticetum Britannicum*; *Botanical Register*, vols. xxi. and xxii.)

CRATÆVA, a genus of Plants belonging to the natural order *Capparidaceæ*. It has 4 sepals; 4 unguiculate petals larger than the calyx, and not closing over the stamens during æstivation; 8-28 stamens; the torus elongated or hemispherical; the berry stalked, between ovate and globose, pulpy within; a thin pericarp. The species are unarmed shrubs or trees with trifoliate leaves and terminal cymes or racemes of large flowers.

C. gynandra, Garlic Pear, has 20-24 stamens inserted on the cylindrical receptacle, longer than the petals; the berry ovate; the leaflets ovate, acute; the petals lanceolate. It is a native of bushy places and thickets near the sea-side in Jamaica. The whole plant has a nauseous smell and a burning taste. The bark of the root is said to blister like cantharides.

C. Tapia, the Tapia, or Common Garlic-Pear, has 8-16 stamens, declinate, about three times as long as the petals; the stipe of the ovary as long as the stamens; the stigma sessile, capitate; the fruit globose. This plant is a tree about 20 feet high. Its fruit is the size of a small orange. It is brought both from the West India Islands and from South America. The fruit has the smell of garlic, and communicates its odour to animals that feed on it. The bark is bitter and tonic, and has been employed in the cure of intermittent fevers.

C. Marmelos, the Bilva, or Mahura, is a small tree bearing a large spheroidal berry with a hard shell, and 10-15 cells which contain, besides the seeds, a large quantity of a tenacious transparent gluten, which on drying becomes very hard, but continues transparent; when fresh it may be drawn out, before it breaks, into threads of one or two yards in length, and so fine as scarcely to be perceptible to the naked eye. This plant is now however transferred to the family *Aurantiaceæ*, under the generic name *Ægle*. It is the *Feronia pellucida* of some authors. It is found in all parts of the East Indies. The fruit is nutritious and aperient, and very delicious to the taste. It is recommended by European physicians in the East as a valuable remedy in habitual costiveness, and it is said never to fail in producing its aperient effects. The root, bark, and leaves are also used in fevers by the Malabar physicians.

(Lindley, *Flora Medica*; Don, *Dichlamydeous Plants*.)

CRAW-FISH. [ASTACUS.]

CRAX. [CRACIDÆ.]

CRAY-FISH. [ASTACUS.]

CREAM-FRUIT, a kind of eatable Fruit found at Sierra Leone, and said to be produced by some Apocynaceous Plant.

CREEPERS. [CERTHIADÆ.]

CRENATULA. [MALLEACEA.]

CRENELLA. [MYTILIDÆ.]

CRENILA'BRUS (Cuvier), a genus of Fishes belonging to the section *Acanthopterygii* and family *Labridæ*. The species of this genus have all the general characters of the true *Labri*, or Wrasses, but are distinguished by their having the margin of the pre-operculum denticulated: the cheeks and operculum are scaly.

C. melops (*Labrus melops*, Linnæus), *C. tinca* of others, the Gilt-Head, Connor, Golden Maid. This fish is found on various parts of the coast; it is about six inches in length, and the depth is nearly one-third of the length. The general colour of the body is obscure red and green; these colours are arranged in longitudinal stripes on the upper parts, and beneath the lateral line the red is disposed in spots. The Gilt-Head mostly frequents deep water, where the bottom is rocky; its food is chiefly *Crustacea*.

C. Norvegicus (Cuv. et Val.), *C. Cornubicus* (Risso), the Goldfinny or Goldsinny, and Corkwing, somewhat resembles the last, but may always be distinguished by a black spot on each side near the base of the tail, and situated on the lateral line; its general colour is yellowish green, darkest on the back; the sides are usually adorned with longitudinal lines of a deeper hue. Length about three or four inches.

C. gibbus, the Gibbous Wrasse, may be readily distinguished from either of the known British species of this genus by its comparatively shorter and more elevated form. The depth of the body is considerably more than one-third of the length: the colours are chiefly orange and blue; the gill-covers and sides of the body are spotted, and the back is striped. The ventral fins are green, the pectorals are yellow, with transverse red stripes at their base.

Pennant obtained a specimen of this fish off the coast of Anglesey; and this is we believe the only instance on record of its capture off the British coasts.

C. luscus (Couch), *Acantholabrus Couchii* (Cuv. et Val.), the Scale-Rayed Wrasse, has been caught by Mr. Couch off the coast of Cornwall: the specimen was 22 inches in length. The tail is round, and consists of 15 rays; "between each ray of the dorsal, anal, and caudal fins, is a process formed of firm, elongated, imbricated scales. Colour, a uniform light brown, lighter on the belly; upper eye-lid black; at the upper edge of the base of the caudal fin is a dark brown spot. Pectorals yellow: all the other fins bordered with yellow."

C. multidentatus (Thompson), *Turdus minor* (Ray), *Labrus pusillus* (Jenyns), the Corkling, Ball's Wrasse. This fish was originally taken on the British coast by Professor Henslow at Weymouth. It has since been taken in Cornwall and Ireland. It is about four inches in length. Mr. Jenyns says, "It is quite distinct from any of those described by other authors. Though belonging to the present section (*Labrus*) which it is convenient to retain, it would seem to form the transition to the *Crenilabri*, to which its near affinity is indicated by the rudimentary denticulations on the margin of the pre-opercle."

C. rupestris, Jago's Goldsinny (Selby). It has been referred by various writers to the genera *Sciæna*, *Labrus Perca*, and *Lutjanus*. Several specimens of this fish have been taken in Great Britain. It is found occasionally in the Baltic, in Sweden, Denmark, and Norway. Its prevailing colour is orange, the free edge of each scale being of a light golden-yellow colour; the colour is darkest over the three or four lines of scales along the highest part of the back, and lightest on the lower part of the sides and belly; the body is indistinctly marked with five transverse bands. In northern localities it is tinged with green.

C. microstoma, the Small-Mouthed Wrasse, or Rock-Cook (Thompson). It is the *Acantholabrus exoletus* (Cuv. and Val.), the *Labrus exoletus* of other authors. This fish is occasionally caught in Cornwall, and has been taken at Antrim in Ireland. It is immediately known amongst its congeners by its very small mouth. It is found on the coasts of Sweden, Denmark and Norway. [LABRIDÆ.]

CREPIDO'PTERIS, a genus of Fossil Ferns, which Presl substitutes for *Pecopteris* of Brongniart, in the case of two species, one from Stuttgardt, the other from Newcastle.

CREPIDULA. [CALYPTRÆIDÆ.]

CREPIS, a genus of Plants belonging to the natural order *Compositæ*, the division *Cichoraceæ*, and section *Lactuceæ*. It has many-flowered heads; a double involucre, the inner of one row, the outer of short lax scales; the fruit terete, narrowed upwards or obscurely beaked. Most of the species of this genus are common weeds in the hedges of Europe. Five of the species are found in Great Britain. The most common is the *C. virens*, which has the outer involucral scales adpressed, linear, the inner ones glabrous within: the leaves lanceolate, remotely dentate, runcinate, or pinnatifid, the uppermost leaves linear, arrow-shaped, clasping with flat margins; the stem subcorymbose; the fruit shorter than the pappus, oblong, slightly attenuated upwards, with smooth ribs. This is the *C. tectorum* of Smith; but the true *tectorum* has revolute margins to its upper leaves, and other points of difference, and has never been found in Great Britain.

The other British species are—*C. pulchra*, a rare plant found in Scotland; *C. biennis*, also rare, found in chalky places in England; *C. succisæfolia*, common in woods in the north of England; *C. paludosa*, not uncommon in damp woods and shady places. *C. lacera* is considered to be a venomous plant in Naples, where it grows.

(Babington, *Manual of British Botany*.)

CREPUSCULA'RIA (Latreille), a section of Lepidopterous Insects, corresponding with the genus *Sphinx* of Linnæus. These insects occupy an intermediate station between the *Lepidoptera Diurna*, or Butterflies, and the *Lepidoptera Nocturna*, commonly called Moths. They have the following characters:—Antennæ growing gradually thicker towards the apex, at which part they are furnished with an elongated club, either fusiform or prismatic. Inferior wings furnished with a rigid bristle-like process at their base, which passes into a hook on the under surface of the superior wings, and serves to retain them. The larvæ are furnished with 16 legs, and many of them have a long horny process on the last segment of the body. The chrysalides are smooth, or sometimes furnished with small spines (but destitute of the points and angles usually observed in those of butterflies). They are either inclosed in a cocoon or buried in the earth. The larvæ sometimes feed upon wood, in which case they assume the pupa state within the tree or branch.

The families contained in this section are the *Sphingidæ*, *Sesiidæ*, *Ægeriidæ*, and the *Zygænidæ*.

CRESCENTIA, a genus of Plants, the type of the natural order *Crescentiaceæ*. It has a 2-leaved equal deciduous calyx; the corolla campanulate, with a fleshy tube much shorter than the ventricose 5-cleft unequal crisped limb; 4 stamens, didynamous, with the rudiment of a fifth; the fruit gourd-like, 1-celled, with a solid shell, internally pulpy, many-seeded. The species are large spreading trees, with solitary flowers rising from the trunk or branches.

C. Cujete, Cujete or Common Calabash-Tree, has oblong acute or obtuse leaves, cuneate at the base, and in fascicles. This plant is a native of the West India Islands and Spanish Main. It is a tree about 20 feet high, and is readily distinguished from all others by its habit. It sends out large horizontal branches, which bear fascicles of leaves at various distances. These leaves are from 4 to 6 inches long. The flowers are scattered over the older branches; the corolla is large, somewhat campanulate and constricted below the middle, which gives the upper part a ventricose character. It does not wither up as other corollas, but becomes putrid, giving out a nauseous and intolerable odour. The form and size of the fruit is very variable, being from 2 inches to 1 foot in diameter. It is covered with a thin skin, of a greenish-yellow colour when ripe, and under this is a hard woody shell which contains a pale yellowish soft pulp, of a tart unpleasant flavour, surrounding a great number of flat seeds. The shell is of great use to the inhabitants; the smaller oblong ones are formed into spoons and ladles, the larger ones form drinking cups, basins, and bowls for every variety of domestic purposes. They will even bear fire, and are used for boiling water in. The Caribs generally carve the outside of these vessels with a variety of grotesque figures. The pulp is sometimes eaten by the natives, but it is not much sought after. A syrup is prepared from it in the West Indies, which has a great reputation as a cough medicine. The pulp is also used as a poultice in cases of abscess or bruises. The leaves and branches and pulp of the fruit are eaten by cattle in times of scarcity. The wood of the tree is tough and flexible, and well adapted for the work of the coachmaker. There are three or four other species, natives of the West Indies and South America, having the same general characters as the above.

The species of *Crescentia* will grow in a mixture of loam, peat, and sand, and woody cuttings will grow when placed in sand in heat under a hand-glass. They do not however blossom in this country, as they require first to arrive at the full size.

(Don, *Dichlamydeous Plants*; Loudon, *Encyclopædia of Plants*; Lindley, *Flora Medica*.)

CRESCENTIACEÆ, a natural order of Plants formerly included in the *Solanaceæ*, allied to *Gesneraceæ* and *Bignoniaceæ*. The species are trees of small size, with alternate or clustered simple leaves without stipules. The flowers grow out of the old stems or branches; the calyx free, undivided, eventually splitting into irregular pieces; the corolla monopetalous, irregular, somewhat 2-lipped, with an imbricated æstivation. The stamens are four in number, growing on the corolla, didynamous, with the rudiment of a fifth between the posterior pair, which are the longest; anthers 2-lobed, bursting longitudinally; ovary free, surrounded by a yellow annular disc, 1-celled, composed of an anterior and posterior carpellary leaf, with 2 or 4 equidistant parietal placentæ, which sometimes meet and produce additional cells; ovules 0-0, horizontal; stylo 1; stigma of 2 plates. Fruit woody, not splitting, containing a multitude of large amygdaloid seeds buried in the pulp of the placentæ; skin leathery, loose; embryo straight, without albumen, with plano-convex fleshy cotyledons, and a thick short radicle next the hilum.

CRESS, the name given to various Plants with acrid or pungent leaves. Common Cress is *Lepidium sativum*; Water-Cress, *Nasturtium officinale*; Belleisle or Normandy Cress, *Barbarea præcox*; Indian Cress, *Tropæolum majus*. [LEPIDIUM; NASTURTIUM; BARBAREA; TROPÆOLUM.]

CRETACEOUS GROUP or FORMATION. [CHALK FORMATION.]

CREUSIA. [CIRRIPEDIA.]

CREX. [RALLIDÆ.]

CRIBELLA. [SOLASTERIÆ.]

CRICACANTHUS, a genus of Fossil Fishes, from the Mountain Limestone of Armagh. (Agassiz.)

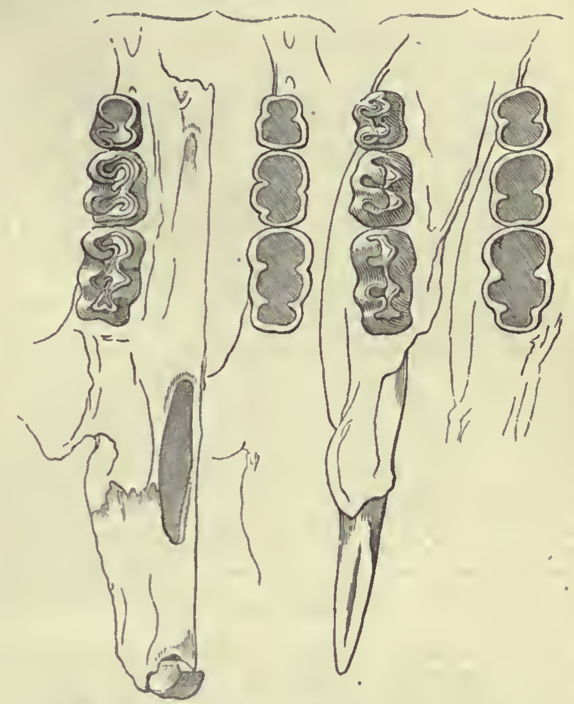
CRICETUS, the name of a genus of Rodents, whose economy makes them one of the most interesting of the great Linnæan genus *Mus*, or the family of *Muridæ* in its most extensive sense. The species have the following characters:—

Molar teeth simple; their crown furnished with blunt tubercles. Four toes and the vestige of a thumb on the fore feet; five toes on the hind feet; nails robust. Tail short and hairy.

$$\text{Dental Formula :—Incisors, } \frac{2}{2}; \quad \text{molars, } \frac{3\text{—}3}{3\text{—}3} = 16.$$

The species are found over all the north of Europe and of Asia, the temperate countries of Persia, and the deserts of Astrakhan. If the Canada Pouched Rat (Hamster du Canada, *Cricetus bursarius* of Desmarest, *Mus bursarius* of Shaw) is to be considered a Hamster, Canada and the borders of Lake Superior must be added; and it must be remembered that the Tucan of Hernandez, an inhabitant of New Spain, is considered by some to be identical with this Canada Rat (Sir John Richardson thinks on insufficient grounds). But the last-mentioned zoologist places Desmarest's Canada Hamster under the genus *Geomys*, with a note of interrogation; and Say has given it a generic distinction under the name of *Pseudostoma*.

C. vulgaris, the Common Hamster, *Mus Cricetus* of Pallas, Le Hamster of Buffon and the French authors.



Teeth of Common Hamster (*Cricetus vulgaris*). F. Cuvier.

It is reddish-brown above; black below, with three great whitish spots on the sides; feet white; a white spot on the throat, and another on the breast. Length about 9 inches; tail 3 inches. Males bigger than females. Weight of some males from 12 to 16 ounces; weight of females seldom exceeding from 4 to 6 ounces.

Common Hamster (*Cricetus vulgaris*). F. Cuvier.

Variations in colour are not uncommon. There is one variety entirely black. Pennant figures one which is entirely black, with the exception of the edge of the ear, the muzzle, the under-jaw and feet.

It is found in the north of Europe and Asia (Lesson), Austria, Silesia, and many parts of Germany, Poland, and the Ukraine; all the southern and temperate parts of Russia and Siberia; and even about the river Yenesei, but not farther to the east. In the Tartarian deserts, in sandy soil: they dislike moist places. Swarming in Gotha. (Pennant.)

The Common Hamsters are ill friends to the farmers. The quantity of grain which they consume is very great, nor does the destruction stop with mere satiety of appetite; the animal never forgets its hoard, and fills its two cheek-pouches till they seem bursting with the booty. They are also said to be very fond of the seeds of liquorice. Their dwellings are under the earth; their mode of forming them, and the purposes to which they apply them, have been thus described:—They first form an entrance, burrowing down obliquely. At the end of this passage one perpendicular hole is sunk by the male; the female sinks several. At the end of these they excavate various vaults, some as lodges for themselves and young, some as storehouses for their food. Every young one is said to have its separate apartment; each sort of grain its different vault. The 'living apartments,' as they may be called, are lined with straw or grass. The vaults are said to be of different depths, according to the age of the constructor: a young hamster, it is stated, makes them scarcely a foot deep, an old one sinks to the depth of four or five feet; and the whole 'curtilage,' so to speak, is sometimes eight or ten feet in diameter. From the mode of proceeding in their work, the reader will be prepared for the statement that the male and female live in separate apartments; and indeed it appears that, excepting at the short season of courtship, they have very little or no intercourse. Pennant gives them a very unamiable character. "The whole race," says that zoologist, "is so malevolent as to constantly reject all society with one another. They will fight, kill, and devour their own species, as well as other lesser animals; so may be said to be carnivorous as well as granivorous. If it happens that two males meet in search of a female, a battle ensues; the female makes a short attachment to the conqueror, after which the connection ceases. She brings forth two or three times in a year, and produces from 16 to 18 young ones at a birth: their growth is very quick, and at about the age of three weeks the old one forces them out of the burrows to take care of themselves. She shows little affection for them; for if any one digs into the hole, she attempts to save herself by burrowing deeper into the earth, and totally neglects the safety of her brood; on the contrary, if she is attacked in the season of courtship she defends the male with the utmost fury."

The harvest of these animals commences in August. Grains of corn, ears of corn, peas and beans in the pods, all find their way into their cheek-pouches, which will hold a quarter of a pint English. This forage is carefully cleaned in their burrows, and the husks and chaff carried out. When all is in order, they stop up the entrance and prepare for their hybernation, which lasts during the whole of the severe season; the provision they have made having been collected for the purpose of their support before their torpidity actually commences, and also in the spring and summer before the season has produced a supply for them in the fields. If all tales be true, they are a bold generation, and will jump at a horse if he tread near them, and hang by its nose so as to be disengaged with difficulty. Their voice is said to be like the barking of a dog. Fierce as they are, they quail before their deadly enemy the pole-cat, which, chasing them into their holes, destroys them unrelentingly. Notwithstanding this check, they are said to be so numerous in some seasons as to occasion a dearth of corn.

The fur of the animal is said to be valuable; and the peasant, when he 'goes a Hamster-nesting' in the winter, not only possesses himself of the skin of the plunderer, but of the plunder, which is said commonly to amount to two bushels of good grain in each magazine. Buffon, quoting Sulzer, says that in Gotha, where these animals were proscribed on account of their vast devastations among the corn, 11,564 of their skins were delivered at the Hôtel-de-Ville of the capital in one year, 54,429 in another, and 80,139 in a third.

There are four or five other species of this genus.

Professor Kaup records *Cricetus vulgaris fossilis*, from the Epplesheim sand.

CRICHTONITE. [TITANIUM.]

CRICKET, FIELD. [GRYLLIDÆ.]

CRICKET, HOUSE. [GRYLLIDÆ.]

CRICOPORA, a genus of Corals formed by Blainville out of a subdivision of the *Milleporidæ*, including some fossil species, which chiefly occur in the Oolitic Formations. *C. straminea* is found near Scarborough; *C. cæspitosa* near Bath.

CRINOIDEA. [ENCRINITES.]

CRINUM, a genus of Plants belonging to the natural order *Amaryllidaceæ*. It has a tubular long perianth, with a spreading reflexed or equal limb; 6 stamens, spreading or declinate, inserted into the orifice of the tube; the ovules hardly separable from their fleshy placentæ; the capsule membranous, bursting irregularly; the seeds globose, with a fleshy testa, giving them the appearance of small tubes. The species are handsome plants, and many of them form the greatest ornaments of our gardens.

C. Asiaticum, Poison Bulb (*Radix toxicaria*, Rumph.), has a cylindrical bulb above ground; the leaves lanceolate, smooth at the edge, longer than the scape, flowers on stalked umbels, the segments long, linear, reflexed; the ovary inferior; the style as long as the stamens, declinate; the fruit membranaceous, subglobose. The bulbs of this plant are powerfully emetic, and are used in Hindustan for the purpose of producing vomiting after poison has been taken, especially that of the Antiaris. It is a native of the East Indies.

C. amabile has a very large bulb with a long red neck, the leaves broad, glaucous, smooth at the edge; the umbels many-flowered; the tube shorter than the limb. This plant is a native of the East Indies, but is now common in our greenhouses. Many of the species have been lately introduced. They grow best in a rich loam mixed with a little rotten dung. They should be potted in large pots, where they will flower abundantly. They may be propagated by suckers from the roots, or they may be raised from seed. Should the plant show any indisposition to put out suckers it should be cut down near to the root, when it will put out plenty.

(Lindley, *Flora Medica*; Loudon, *Encyclopædia of Plants*; Herbert, *Amaryllidaceous Plants*.)

CRIOCERATITES. The discoidally spiral *Ammonitidæ*, whose whorls do not touch each other, receive this generic title. The species occur in the Oolitic and Lower Cretaceous Strata. [AMMONITES.]

CRIOCERIDÆ (Leach), a family of Coleopterous Insects, of the sub-section *Eupoda* and section *Tetramera*, distinguished by the following characters:—Mandibles truncated at the apex, or presenting two or three notches; labium generally entire, or but slightly emarginated; antennæ of moderate length, filiform, somewhat thickened towards the apex; the joints mostly of an obconic form; tarsi with the penultimate joint bilobed; femora often thick, especially towards the apex.

The principal genera contained in this family are—*Donacia*, *Hæmonia*, *Plauristes*, *Crioceris*, *Zeugophora*, *Auchenia*, and *Megacelis*.

The species of the genus *Crioceris* have the posterior femora of the same thickness as the others; the antennæ gradually enlarged towards the apex, the joints of which are scarcely longer than broad; the eyes are emarginated on the inner side: the thorax is narrower than the elytra, short, and usually of a somewhat cylindrical form: the elytra are elongate.

About eight species of this genus have been found in England, of which the most common is the *Crioceris Asparagi*, sometimes called the Asparagus Beetle, which is nearly a quarter of an inch in length, and of a blue-black colour; the thorax is red, with two black spots; the elytra are yellow, with the suture, two transverse bands, and a spot at the base, black.

This pretty little beetle is found in abundance in the south of England on asparagus plants; the larvæ are of a greenish hue, resemble little masses of jelly, and inhabit the same situations as the perfect insect. They subsist upon the leaves and soft part of the stalk of the asparagus plant.

CRIOCERUS. [EUPODA.]

CRISIA. [CELLARIÆA; POLYZOA.]

CRISTATELLA. [POLYZOA.]

CRITHMUM, a genus of Plants belonging to the natural order *Umbelliferæ*. The margin of the calyx is obsolete; petals roundish, entire, involute, ending in an obovate segment; transverse section of fruit nearly terete; mericarps with 5 elevated sharp rather winged ribs, lateral ribs a little broader than the rest, and marginating; pericarp spongy, with large cells; seed semi-terete, constituting a free nucleus which is covered with copious vittæ in every part. A suffruticose glabrous fleshy herb; petioles sheathing at the base; leaves bipinnate; leaflets oblong linear; umbels compound; involucre and involucels of many leaves; flowers white.

C. maritimum, Samphire, is a well known native of rocky seashores and cliffs along the Black Sea, in Tauria, the Mediterranean Sea; and of Europe, along the shores of the Western Ocean, from Spain to Britain, and of the Canary Islands; in Britain on the rocky sea-shore and cliffs. The root is branched and creeping extensively; the plant is greenish, salt, and pungently aromatic in flavour; the leaves biternate, the stems ascending; the flowers are white, anthers yellow. Samphire is a favourite ingredient in pickles. It is generally gathered in places where it is found wild, and the allusion to the practice by Shakespere in his description of the cliffs of Dover is well known. The plant is also used medicinally. Samphire is cultivated artificially in many places for the purposes of diet.

CROCIDOLITE, a Silicate of Iron of a lavender-blue or leek colour. It is called Blue Asbestus. It comes from Southern Africa.

CROCODILE. [CROCODILIDÆ.]

CROCODILIDÆ, *Crocodile-Tribe*, Crocodiles, a family of Saurians, comprising the largest living forms of that order of Reptiles. Duméril and others distinguish the family by the appellation of Aspidiot (shielded) Saurians; while many modern zoologists have considered them as forming a particular order. They form the *Loricata* of Merrem and Fitzinger, and the *Emydosaurians* of De Blainville.

Cuvier in his 'Règne Animal' describes the peculiarities of the family. The tail is flattened at the sides; there are five anterior and four posterior toes, of which the three inner ones only on each foot are armed with claws; all the toes are more or less joined by membranes. There is a single row of pointed teeth in each jaw, and the tongue is fleshy, flat, and attached very nearly up to the edges, which made the ancients believe that the Crocodile wanted that organ. The intromittent male organ of generation is single; the opening of the vent longitudinal. The back and tail are covered by great and strong squared scales, elevated into a ridge on their middle. There is a deeply dentilated crest on the tail, at the base of which the crest becomes double. The scales of the belly are squared, delicate, and smooth. The nostrils are opened at the end of the muzzle by two small crescent-shaped slits, closed by small valves, and lead by a long and straight canal pierced in the palatine and sphenoidal bones to the bottom of the back part of the mouth. As the lower jaw is prolonged behind the skull, the upper jaw has the appearance of mobility, and so the ancients wrote; but it only moves in concert with the whole of the head. The external ear is shut at will by means of two fleshy lips; and the eye has three lids. Under the throat are two small glandular orifices, whence issues a musky secretion.

The vertebræ of the neck bear upon each other by means of small false ribs, which render lateral motion difficult. Crocodiles therefore change their direction not without trouble, and they may be easily avoided by doubling, and escaping while they are employed in the laborious operation of turning round. They have no true clavicles; but their coracoid apophyses are attached to the sternum, as in all the other Saurians. Besides the ordinary and the false ribs, there are a set which protect the abdomen without reaching up to the spine, and which appear to be produced by the ossification of the tendinous portions of the recti muscles. Their lungs are not sunk in the abdomen like those of other reptiles, and there are fleshy fibres adhering to the part of the peritoneum which covers the liver, and which present the appearance of a diaphragm, which, joined to their trilocular heart, where the blood which comes from tho lungs is not mingled with that venous portion of it which comes from the body so completely as it is in the other reptiles, slightly approximates the Crocodiles to the warm-blooded quadrupeds. The auditory bone (caisse) and the pterygoid apophyses are fixed to the skull as in the tortoises.

The eggs of the Crocodiles are hard, and as large as those of the goose; and these reptiles are considered to be animals in which the extremes of size, taking that of the newly-hatched young and that of the full grown adult as the most remote points, present the widest difference. The females guard their eggs, and when they are hatched take care of the young during some months. (Cuvier.)

The dentition of the Crocodiles is peculiar. The teeth are numerous, large, of unequal length, conical, hollow at the base, disposed in a single row, and planted in the thickness of the edges of the superior and inferior maxillary bones, in separate cavities which may be considered as true alveoli. These teeth are hollowed at the base in such a manner as to serve for the case or sheath of the germ of the tooth destined to replace it, and which is to be of greater volume; so that, in Crocodiles, the number of the teeth does not vary with age as in many other animals.

Tooth of Crocodile, showing the incipient absorption of the hollow basal cone from the effect of the rising pressure of the advancing tooth.

Great solidity and strength are the results of this double gomphosis, and the alveoli are moreover directed obliquely from front to rear. The bony edges of the jaws whence these insulated teeth spring, are covered by a kind of gum. Another peculiarity of admirable adaptation to the necessities of the animal, may be observed in the interior of the mouth of the Crocodiles. Their palatine vault is nearly flat, and is not pierced by the extremities of the nasal fossæ, as in the majority of other reptiles. The posterior nasal apertures open in the pharynx behind the velum palati, which is sufficiently long to overspread that portion of the roof which is in front of the orifice of the glottis. They are probably the only reptiles which have a true pharynx, that is to say, a vestibule common to the posterior nostrils, the mouth, the larynx, and the œsophagus. This conformation, joined to the muscular structure of the tongue, and a peculiar expansion of the body of the os hyoides, produces a kind of cartilaginous disc or valve, which can be raised and applied to the velum palati above, so as to protect tho glottis, to which it serves tho office performed by the epiglottis in mammifers, while it confers on the reptile a peculiar power of deglutition and respiration, of the greatest consequence to its economy when it is below the surface of the water and has seized its prey in that situation; or, when the muzzle alone is above the surface, in carrying on respiration.

The following is a summary of the characters of the family *Crocodilidæ*.—Body depressed, elongated, protected on the back with solid and carinated scutcheons or shields; tail longer than the trunk, compressed laterally, annulated, and furnished with crests above; feet four, short, tho toes of the posterior feet united by a natatory membrane: each foot with three claws only; head depressed, elongated into a muzzle, in front of which are the nostrils approximated upon a fleshy tubercle, furnished with moveable suckers (soupapes): gape of the mouth extending beyond the skull; tongue fleshy, adherent, entire, not protractile; teeth conical, simple, hollowed at the base or towards the root, unequal in length, but placed in a single row; male genital organ simple, having its exit from the cloaca, which opens longitudinally. (Duméril and Bibron.)

No living species of this family is found in Europe, nor has any been yet detected in Australasia. The Alligators are peculiar to America; the species of *Crocodilus* are distributed in the Old and New World; those of *Gavialis* seem to be limited to the Ganges and the other large rivers of continental India.

Asia, besides the Gavial of the Ganges, produces at least three true crocodiles, viz. *Crocodilus vulgaris*, *C. galeatus* (*C. Siamensis*, Schneid.; *C. Siamensis*, Gray?), and *C. biporcatus*. Siam seems to be the principal, if not the only locality, where the first of these has been found; while the other two appear to be natives of those rivers which have their mouths in tho Indian Ocean and tho Ganges.

Africa, where neither Caimans (*Alligator*) nor Gavials have yet been discovered, is tho native country of the Crocodile à Bouclier, and *Crocodilus vulgaris*: it may also be the locality of *C. planirostris* of Graves and of Gray (*C. Gravesii*, Bory de St. Vincent); and *C. intermedius* of Graves and of Gray (*C. Journei*, Bory de St. Vincent), though their geographical position does not seem to be determined: these may perhaps come from the coast of Guinea. The only part of Africa whence the Crocodile à Bouclier has been received is Sierra Leone; while *Crocodilus vulgaris* seems to be spread over the whole of Africa, and is also an inhabitant of Madagascar. Numbers have been taken in the Nile, and one in the river Senegal. (Duméril and Bibron.)

America is most fruitful in Crocodiles, and possesses more species than Asia and Africa put together. True Crocodiles have never been detected on the continent. *C. acutus* has been found at Martinique and St. Domingo, and *C. rhombifer* at Cuba. The northern part of America is inhabited by one species only, *Alligator Lucius*, while four species, viz. *Alligator palpebrosus*, *A. sclerops*, *A. punctulatus*, and *A. cynocephalus*, inhabit the south. (Duméril and Bibron.)

Cuvier says that the *Crocodilidæ* inhabit fresh-water, that they cannot swallow while in the water, but drown their prey and place it in some nook under water, where they suffer it to putrefy before they eat it. This account seems to require some modification. Sir Charles Lyell, in his 'Principles of Geology,' observes that the larger Gangetic species descends beyond the brackish water of the Delta into the sea: and other instances are recorded of the true Crocodiles (but not of the Alligators) frequenting the mouths of large rivers, and even passing between different islands at considerable distances from each other. [ALLIGATOR.] This should be remembered by geologists. Then, as to their inability to swallow while in the water, those authors who describe their collective fishing expeditious, entirely contradict it. True it is, according to them, that the Alligators, after they have seized the fish from below, rise to the surface and toss the fish into the air to get rid of the water which they have taken in with it, catching it again in its descent: but it is clear that they swallow it without resorting to the land, though they go thither for the purpose of devouring those land animals which they have succeeded in capturing and drowning, after they have undergone some degree of decomposition.

"The laying of the eggs," says M. Ricord, "takes place in April and May, and the number amounts from 20 to 25, more or less, laid at many times. The female deposits them in the sand with little care, and scarcely covers them. I have met with them in the limo which the masons had left on the bank of the river. If I have reckoned right, the young come forth on the fortieth day, when the temperature is not too cold. At their birth they are 5 or 6 inches in length. They are hatched alone, and as they can do without nourishment while coming out of the egg, tho female is in no haste to bring it to them: she leads them towards the water and into the mud, and disgorges for them half-digested food. The male takes no account of them." The young preserve for some time the umbilical mark or cicatrice on the abdomen, whereby the vitellus was absorbed.

The *Crocodilidæ* are generally considered as forming a natural passage from the Saurians to the Chelonians, the last genera of which, in certain points of their conformation and habits, approximate nearly to the family under consideration.

The following is a synopsis of the species from the 'Catalogue of the Species in the British Museum':—

Fam. I. CROCODILIDÆ (Crocodiles).

The lower canines fitting into a notch in tho edge of the upper jaw. The hind legs with a fringe of compressed scales behind.

Synopsis of Genera.

* Teeth all uniform; nose of the male very large, inflated.

Gavialis.—Jaws very long, slender, sub-cylindrical. Cervical and dorsal discs united together.

** The ninth upper and eleventh lower teeth longer, like canines. Nose of both sexes simple.

Mecistops.—Jaws oblong, slender, depressed. Cervical and dorsal discs united. Hind feet webbed.

Crocodilus.—Jaws oblong, depressed. Nuchal, cervical, and dorsal discs separated from each other by small scales.

Gavialis.—Jaws very long, subcylindrical, slender, rather dilated and convex at the end. Teeth, canines two, quite anterior, small; lower canines shutting into a notch in the edge of the upper jaw. Feet fringed; toes webbed to the tip. The cervical plates united to and forming a disc with the dorsal ones. Males with a large swelling in front of tho nostrils. Native of Asia.

G. Gangeticus, the Gavial, or Nakoo.

Mecistops (Gray), *Gavialis* (Müller).—Jaws oblong, slender, depressed, flat, without ridges. Teeth unequal, lower canines fitting into a notch in the side of the upper jaw. Feet fringed; toes webbed to tho tip. The cervical plates in three or four cross series united to the dorsal shield. Males without any swelling in front of the nostrils.

M. Bennettii, Bennett's False Gavial.

M. cataphractus (*Crocodilus cataphractus* of Cuvier), the False Gavial.

M. Journei (*Crocodilus intermedius* of Graves), Journey's False Gavial.

Crocodilus.—Jaws oblong, depressed, tapering, rather dilated at the end. Teeth unequal, lower canines fitting into a notch in the side of the upper jaw. Feet fringed; toes webbed to the tip. Nuchal and cervical plates forming a disc separated from the dorsal one by small granular scales. The head of the newly hatched specimens is short, but it gradually elongates, and after a short time attains the form proper to the species; and, through the bones becoming more solid by increasing age, they only slightly alter the relative proportions of the different parts, so that the form of the head, taken with the shielding of the back, affords good characters for the determination of the species.

C. porosus, the Indian Crocodile.
C. bombifrons, the Large-Headed Indian Crocodile.
C. rhombifer, the Aque Palin.
C. Americanus, the American Crocodile.
C. marginatus, the Margined Crocodile.
C. vulgaris, the Egyptian Crocodile.
C. palustris, the Muggar, or Goa Crocodile.
C. trigonops, the Wide-Faced Crocodile.
C. planirostris, Graves's Crocodile.
C. Siamensis, the Siamese Crocodile.

Fam. II. Alligatoridæ (Alligators).

Synopsis of the Genera.

Canine teeth of the lower jaw fitting into a pit in the edge of the upper jaw. It is a native of the New World.

Jacare.—Jaws oblong, depressed, with a ridge across the face between the eyes. Hind feet scarcely webbed. Nostrils with a cartilaginous septum. Eyelids fleshy.

Alligator.—Jaws oblong, depressed, with a small longitudinal rib between the orbits. Hind feet webbed. Nostrils separated by a bony septum.

Caiman.—Jaws oblong, depressed. Hind feet scarcely webbed. Nostrils a cartilaginous septum. Eyelids with three bony plates.

Jacare.—Head oblong, depressed, with a ridge across the face before the eyes, rounded in front. Teeth unequal, canines of lower jaw each fitting into a pit in the upper jaw. Toes scarcely webbed. Nuchal and cervical plates united into one group. Eyelids fleshy, only partially bony. Nostrils only separated by a cartilage.

J. fissipes, the Broad-Headed Yacare.
J. sclerops, the Yacare.
J. nigra, the Black Yacare.
J. punctulatus, the Spotted Yacare.
J. vallifrons, Natterer's Yacare.

Alligator.—Jaws oblong, very depressed, broad, nearly parallel, rounded in front. Forehead with a small longitudinal ridge between the orbits. Teeth unequal, the lower canines received into a pit in the edge of the upper jaw. Nuchal and cervical plates separate. Feet fringed behind; toes half webbed, the outer front toe free. Nostrils separated by a bony septum arising from the outer edge. North America. The muzzle elongates by age.

A. Mississipensis (Gray), *A. Lucius* of others, the Alligator.

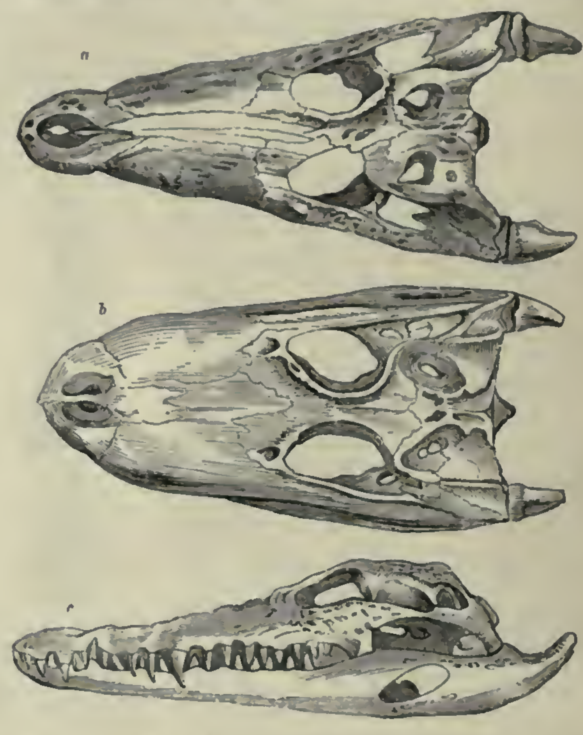
Caiman.—Jaws oblong, depressed, subpyramidical, rounded, and swollen at the end, without any frontal ridges or maxillary pits. Forehead flat and smooth. Teeth $\frac{19}{21}$, unequal, lower canine teeth fitting into a pit in the inner edge of the upper jaw. Eyebrows defended with three bony plates. Toes scarcely webbed. Nuchal and cervical plates united into one group (?). Tropical America.

C. trigonatus.—The Trigonal Caiman.
C. palpebrosus.—The Eyebrowed Caiman.
C. gibbiceps.—The Swollen-Headed Caiman.

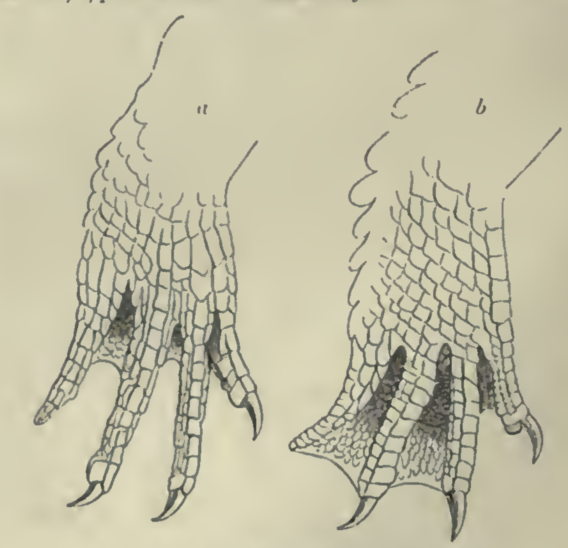
With regard to the differences between the above-named genera, Duméril and Bibron observe that nothing better distinguishes the Crocodiles from the Alligators than the narrowness of the muzzle behind the nostrils, a narrowness which is produced by the deep notch on each side of the upper mandible serving for the passage of the fourth lower tooth. The Gavials, it is true, have similar notches, which are destined for the same purpose; but at the extremity of the muzzle they have also two others for the reception of the front lower teeth; in lieu of this the front lower teeth in the Crocodiles pierce the upper mandible through and through. The horizontal contour of the head of the Crocodiles represents in general the figure of an isosceles triangle more or less elongated, depending upon the size of the jaws; but in no case is the muzzle wider than that of the Caimans, nor more slender than that of the Gavials. The Crocodiles have, like the former, their jaws festooned, as it were, on their sides, and their teeth unequal, but in less number, because they have never been observed with more than 19 on each side above, and 16 on each side below. The cranial holes are larger than they are in the Caimans, and less wide than they are in the Gavials. Their diameter is always found to be less than that of the orbits. The nasal aperture is oval or subcircular. There a very small bony plate in the thickness of the upper eyelid.

The same remark, as to the length of the head in proportion to its width at the three principal epochs of life, applies to the Caimans as well as to the Crocodiles.

The greater part of the Saurians of this group have the hind toes, the three external ones at least, united up to their extremity by a wide natatory membrane. There are indeed some nevertheless in which it is shorter, and one species, *Crocodilus rhombifer*, wants the membrane almost entirely, in the interval of the two inner toes. With about two exceptions, all the Crocodiles have the posterior border of the leg furnished with a dentilated crest formed of flattened scales. The two species which are said not to present this character are *Crocodilus planirostris* and *C. rhombifer*.



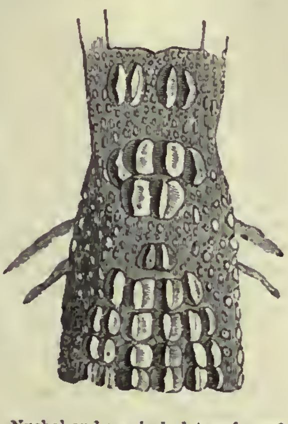
a, Skull of *Crocodilus vulgaris*, seen from above; *b*, skull of *Alligator Lucius*, same view; *c*, profile of skull of *Crocodilus vulgaris*.



a, hind foot of Caiman; *b*, hind foot of Crocodile.

Only one species among the Crocodiles (*Mecistops Bennettii*, *C. cataphractus*) has its cervical scales similar, in regard to the extent which they occupy on the neck, to those of the Caimans; that is to say, they form a long band commencing behind the nape, and prolonging themselves to the first dorsal plates. In the others, the cervical armour occupies about the middle of the neck; so that there remains before and behind it a considerable space devoid of bony pieces. The scales which cover the sides of the body are flat in some, carinated in others, and there are some which are provided with both sorts. The carinæ springing from the tail-plates to form the crest which surmounts that part are in general lower, of less consistence, and less stiff than those in the Caimans. *Crocodilus rhombifer* must however be excepted; for the caudal crest of that species is very low, and, so to speak, osseous.

Zoologists seem to be agreed in allowing that there is scarcely any genus of Reptiles the species of which are so difficult to be distinguished from each other as those of *Crocodilus. Crocodilus vulgaris*, the Egyptian Crocodile, may be taken as a type of the genus to which it belongs and of the whole family. It has the following characters:—Jaws not elongated into a narrow beak. Hind feet largely palmated, and with a festooned crest along their posterior border. Six cervical plates. Dorsal scutcheons or shields quadrangular, and surmounted by six longitudinal rows of carinæ but little elevated.



Nuchal and cervical plates, &c., of *Crocodilus vulgaris*.

It is the *Crocodilus amphibius Niloticus*, Loch.; Le Crocodile du Nil, Daud.; *Crocodilus vulgaris*, Cuv.; *Crocodilus vulgaris*, Tiedm.; Le Crocodile Vulgaire, Cuv.; the Common Crocodile, Griff., 'Animal Kingdom;' *Lacerta Crocodilus*, Linn.; *C. Champses*, Bory; *C. lacunosus*, Geoff.; *C. complanatus*, Geoff.

Messrs. Duméril and Bibron make four varieties of this species. The first variety has the following characters:—Muzzle a little narrowed, rather flat than arched across, with small hollows and channelings, which are now and then worm-shaped, on its surface. Table of the skull entirely flat. Back green, speckled with black; two or three oblique bands of the last-mentioned colour on each flank. The authors give the following synomyms:—

Crocodilus vulgaris, Geoff., 'Ann. Mus.' tom. x. p. 67; 'Descript. Egyp.' ('Hist. Nat.') tom. i. p. 8; Atlas, pl. 2, fig. 1, 2: *C. vulgaris*, 'Merr. Amph.' p. 37, spec. 9; *C. Champses*, Bory de St. Vincent, 'Dict. Clas.' tom. v. p. 105; *C. vulgaris*, Geoff., 'Crocod. d'Egypte,' p. 159; *C. lacunosus*, Geoff., 'Croc. d'Egypte,' p. 167; *C. vulgaris*, Gray, 'Synops. Rept.' part i. p. 57, spec. 1.

This, as well as the following variety, is that to which those individuals whose jaws are the least narrowed belong. The jaws have not indeed the same width in all, but it may be said generally that their width, when measured at the ninth upper tooth, is only one-seventh of the length of the head measured from the end of the nose to the occiput. There are some individuals of this variety whose upper mandible presents a nearly flat surface; that is to say, the extreme edge of its contour is the only part which declines towards the lower jaw. As an example of this group Messrs. Duméril and Bibron refer to the individual brought from Egypt by M. Geoffroy, and which both Cuvier and himself have taken as the type of *Crocodilus vulgaris*.

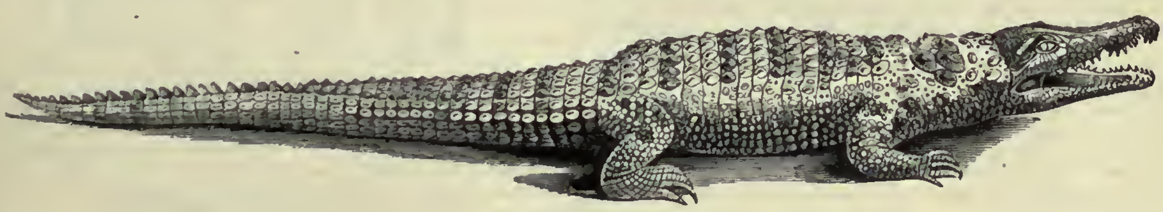
that historian to the locality of Elephantine alone, nor to any particular species. Geoffroy observes that the Crocodile still bears in Egypt the name of Temsa, which M. Champollion thought he recognised upon many papyri, as msbab, a word which he regarded as formed of the preposition 'm,' 'in,' and the substantive 'sah,' 'egg.' With regard to the Suchus, M. Champollion, the younger, states that the Egyptians gave the name of Souk to a deity which they represented as a man with a Crocodile's head. We refer those who wish to follow out this part of the subject more especially to the ancient authors above mentioned, to M. Geoffroy St. Hilaire, to Cuvier, and to the volume on Egyptian Antiquities in the 'Library of Entertaining Knowledge;' observing only that the Egyptians ornamented their tame Crocodiles by hanging rings of gold and precious stones in the opercula of their ears, which they pierced for the purpose, adorned their fore feet with bracelets, and presented them in this finery to the veneration of the people. They also fed them well. Cake, roast meat, and mulled wine were occasionally crammed and poured down their throats. Pliny, Ælian, and others, did little but copy what preceding writers had written upon this subject; but we learn from the former that the Romans first saw them in the ædileship of Scaurus, who showed five. Augustus introduced thirty-six of them into an amphitheatre at one time, where they were all killed by gladiators.

It is said that *Crocodilus vulgaris* is no longer seen in the Delta, but that it is found, sometimes in great numbers, in the Thebaid and the Upper Nile.

The characters of the genus *Gavialis* are given above.

The upper mandible of the Gavials is never pierced for the intromission of the teeth of the lower jaw, as it is in *Crocodilus;* but there are four large notches which serve as lodgments for the first and fourth pair of lower teeth. The Gavials are besides distinguished by the narrowness and length presented by the anterior part of their head and jaws, which resemble a sort of straight beak spread out at its origin, subcylindrical for the greatest part of its length, and terminating in a slight circular enlargement at its extremity. These jaws are rectilinear, and not undulated as in Alligator and *Crocodilus*. The number of teeth with which these narrow mandibles are armed is also greater than in either of the last-mentioned genera, amounting ordinarily in *Gavialis* to 118 or 120, all of which are equal, with the exception of those which compose the five or six first pairs above as well as below. The post-orbito-cranial holes are oval, and larger than they are in *Crocodilus*, for their diameter approaches that of the orbits themselves. The external orifice of the nasal fossæ, or rather of the long canal, which M. Geoffroy St. Hilaire has termed cranio-respiratory, is triangular. The membrane which closes this orifice has a considerable development in the males, and forms a large oval cartilaginous mass. This prominence is a kind of sac divided into two portions internally, the aperture of which is backwards and a little below. As in the Crocodiles, the eyelid contains in its substance a rudiment of a bony plate.

The hind feet of the Gavials are formed for the most part in the same manner as those of the majority of species of *Crocodilus;* that is to say, there are long and wide webs between the toes, and the posterior part of the leg is furnished with a dentilated crest. The cervical plates of the Gavials form a long band on the neck, as in the Caimans, and in one species only of Crocodile. The scales of the flanks are flat and



Egyptian Crocodile (*Crocodilus vulgaris*).

The second variety is the *C. palustris*, Less., 'Voy. Ind. Orient.'; Bell, 'Zool. Rept.' p. 305: *C. vulgaris*, var., E., Gray, 'Synops. Rept.' p. 58.

The third variety is *C. marginatus*, Geoff., 'Crocod. d'Egypte,' p. 165; *C. vulgaris*, var., B., Gray, 'Synops. Rept.' part. i. p. 58.

The fourth variety is the *C. complanatus, C. Suchus*, Geoff.

It may be expected that we should notice the ancient history of an animal held sacred by the Egyptians, and even elevated by them to the rank of a deity, for it was certainly one of the symbols of Typhon. Herodotus, Aristotle, Diodorus, Strabo, and Plutarch, will be read with interest on this subject. While it was worshipped in one part of Egypt under the name of Suchus or Souchis, it was eaten at Elephantine. Cuvier observes that the term Σοῦχος, or Σοῦχις, was only applied to the sacred individual, as Apis, Mnevis, and Pacis were appellations of the deified bulls of Memphis, Heliopolis, and Hermonthis respectively, and not intended to designate particular races of oxen. Geoffroy St. Hilaire is of a different opinion from Cuvier, who considered that Champsa,* as used by Herodotus, was not applied by

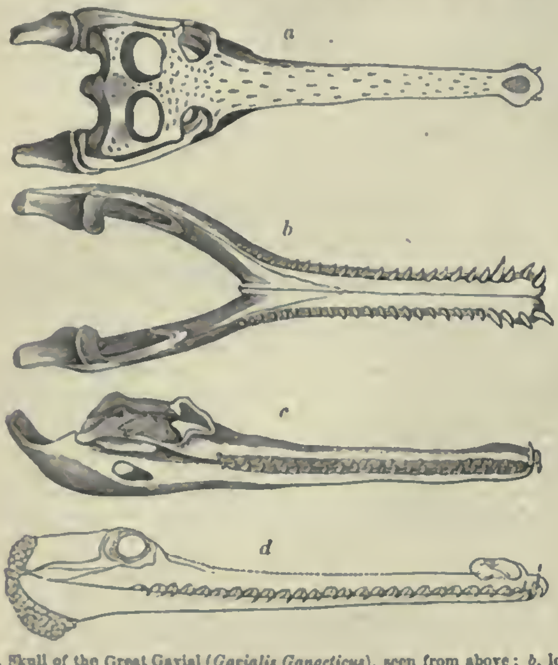
* Καλέονται δὲ οὐ κροκόδειλοι, ἀλλὰ χάμψαι—But they are not called Crocodiles, but Champsæ.

oval. The carinæ which surmount the bony pieces forming the dorsal cuirass are low, but the crest of the tail is very much elevated throughout the whole of its length.

The Caimans and Crocodiles, in their youth, have the head short in proportion to the size which it exhibits at their full growth. The contrary obtains among the Gavials, for in them the head is proportionally longer in youth than it is in age, so that it has the appearance of becoming shorter as the animal increases in size. (Duméril and Bibron.)

G. Gangeticus, the Narrow-Beaked Crocodile of the Ganges, Edw., 'Phil. Trans.' It is the *Crocodilus maxillis teretibus subcylindraceis*, 'Gronov. Zooph.;' *Crocodilus*, Merck, 'Hess. Beytr.'; *Lacerta Gangetica*, Gmel.; Le Gavial, Lacép., 'Hist. Quad. Ovip.;' Le Gavial, Bonn., 'Encyc. Méth.;' Crocodile du Gange ou Gavial, Fauj. Saint Fond, 'Hist. Mont. Saint-Pierre;' *Crocodilus longirostris*, Schneid., 'Hist. Amph.;' Le Gavial, Latr., 'Hist. Rept.;' Gangetic Crocodile, Shaw, 'Gener. Zool.;' *Crocodilus arctirostris, C. longirostris*, Daud., 'Hist. Rept.;' *C. longirostris, C. tenuirostris*, Cuv., 'Ann. Mus. Hist. Nat.;' *C. Gangeticus, C. tenuirostris*, Tied., Opp. und Liboschb, 'Naturg. Amph.;' *Gavialis longirostris, G. tenuirostris*, Merr., 'Amph.;' *Crocodilus* *longirostris*, *C. tenuirostris*, Cuv., 'Oss. Foss.;' Le Grand Gavial, Le Petit Gavial, Bory de St. Vincent, 'Dict. Class. d'Hist. Nat.;' *Crocodilus Gangeticus*, *C. tenuirostris*, Geoff., 'Mém. Mus. d'Hist. Nat.;' Le Gavial du Gange, Cuv., 'Reg. Anim.;' *Gavialis tenuirostris*, Guer., 'Icon. Reg. Anim.;' *Rhamphostoma tenuirostre*, Wagl., 'Naturl. Syst. Amph.;' *Gavialis Gangeticus*, Gray, 'Synops. Rept.;' the Gavial of the Ganges, Griff., 'Anim. Kingd.'

The head of the Gavial may be considered as framed of two parts; one anterior and long, almost cylindrical in form, more or less flattened; the other posterior and short, presenting the figure of a depressed hexahedron, wider behind than before. The jaws constitute the anterior part or beak, which is long, straight, and of extreme narrowness, but not, properly speaking, cylindrical. It is 4-sided, but the angles are rounded. It spreads out at its base and terminates in front, so as to recal to the observer the beak of the Spoonbill. Its vertical diameter is throughout less than its transversal diameter.



a, Skull of the Great Gavial (*Gavialis Gangeticus*), seen from above; *b*, lower jaw of Gavial, another individual; *c*, profile of the skull of Gavial; *d*, outline of the head covered with the integuments.

The head, properly so called, that is, the part situated behind the beak, has its sides straight and perpendicular. The upper surface is quadrilateral. The post-orbital portion is flat and smooth, except that one can perceive through the skin the subtriangular or ovoid holes with which the skull is dotted. The other portion is considerably inclined forwards, and mostly occupied by the eyes, the interval between which forms a slight gutter-like depression. The mandible is not continued from the forehead by a gradual slope as it is in the Crocodiles, but sinks suddenly to follow a straight and nearly horizontal direction, on a line with the inferior edge of the orbit. At the extremity of this upper mandible are the four notches for the passage of the first and fourth lower teeth when the mouth is shut. Two of these notches are very deep, and situated quite in front: the other two are moderate, and placed one on the right, the other on the left, behind the spatuliform termination of the beak, where it is slightly constricted.

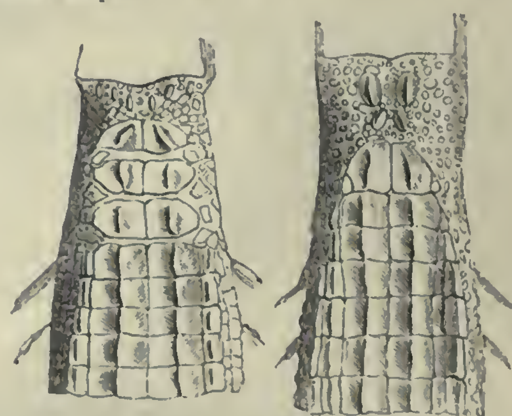
The division of the lower jaw into two branches does not commence till towards the twenty-second or twenty-third tooth. The first ten upper teeth, among which the two anterior teeth are the least separated, are implanted in the intermaxillary bone, and the greater portion of the teeth of the upper mandible are longer than the corresponding teeth of the lower jaw. Up to the nineteenth or twentieth pair they are turned a little outwards, so that when the mouth is shut the upper teeth pass over the sides of the lower jaw, and the lower teeth over the sides of the upper. The last six pairs are straight or nearly so, so that the points of the one set correspond exactly with the intervals of the other. The first, the third, and the fourth above, and the first, second, and fourth below, are the longest. They are in general a little curved and slightly compressed from before backwards, and are very slightly trenchant right and left. Hardly more than the last eight or nine on each side are nearly conical. Slight vertical ridges show themselves on the surface of the teeth of old individuals.

Under the throat, about the middle of the branches of the maxillary bone, are situated, one on the right and the other on the left side, the musky glands.

The external orifice of the nostrils opens on the upper side of the beak, at a small distance from its terminal border. The aperture is semilunar, at the bottom of which may be perceived a cartilaginous plate, which divides it longitudinally in two. The edges of this opening form two lips, which appear to have the power of approaching each other, so as to close the aperture hermetically. The anterior of these is curvilinear, and the posterior rectilinear; in the females and in young subjects they are very delicate and quite soft; but in the old males the anterior lip not only arrives at a cartilaginous consistence, but a development that carries it backwards as far as the seventh pair of teeth, and triples the thickness of the muzzle. This pouch, or cartilaginous sac, with two compartments, is of a sub-oval form, and is notched behind so as to form two very thick rounded lobes. Above these is, on the mesial line and in front, a cordiform prominence, on each side of which is a deep fold in the form of the letter S. This sac has its opening, which is common to it and the nostrils, below. This apparatus is the nasal purse or pouch (bourse nasale) of M. Geoffroy, and in his opinion performs the office of a reservoir of air for the animal when plunged beneath the surface of the water.

The anterior limb is nearly one-half longer than that part of the body which lies between the anterior and posterior limbs of the same side. The hinder limb is about two-thirds of the same interval. The third toe is longest in all the feet. The three middle toes of the fore foot are united at their base by a very short membrane: the other two toes are free, as well as the first toe of the posterior feet; but the second, third, and fourth of these last are united by a thick membrane with a free border, which is notched as it were semicircularly between the toes. The nails are slightly arched.

The nape supports two strong scutcheons, surmounted by a carina, more compressed behind than it is before. Their form is oval, and their height nearly equal to their width. There is sometimes a small scutcheon on each side of these. This is the case in one of the largest individuals; namely, that described by Lacépède, and figured by Faujas de Saint-Fond in his 'History of St. Peter's Mountain,' at Maestricht. The cervical scutcheons, to the number of four pairs, form a longitudinal band, which extends from two-thirds of the length of the neck to the dorsal shield. The first two are triangular, the six others quadrilateral. Each of them has a longitudinal carina on their mesial line, and there is a large scale on the left and on the right of the last pair.



Nuchal and cervical plates, &c., of two individuals of *Gavialis Gangeticus*, from Cuvier.

The upper part of the body is transversely cut by eighteen bands of osseous plates, with equal carinæ, which consequently form four longitudinal rows all down the back. The plates of the two lateral rows are squared, and rather smaller than those of the mesial rows, which are also four-sided; but their longitudinal diameter is less than their transversal. A longitudinal row of other carinated scutcheons borders this dorsal cuirass on the right and on the left for a part of its length. The flanks, the sides of the neck, and a portion of its upper part are covered with oval flat scales of moderate size. The tail is surrounded by from thirty-four to forty scaly circles, the number varying in different individuals. The dentilated crest does not become very perceptible till towards the sixth or seventh circle: its double portion terminates at the eighteenth or nineteenth. This crest is highest towards the middle of the tail, elsewhere it is delicate and flexible. The scales which clothe the lower parts of the body are quadrilateral, oblong, and perfectly smooth: there are nearly sixty transverse rows from the chin to the vent, and, like those of the flanks, they are all pierced with a small pore on the middle of their posterior border.

The limbs are protected above with rhomboidal scales: the anterior limbs on their external edge; the posterior limbs from the hock (jarret) to the little toe have a row forming a serrated edge. The surface of the natatory membranes is covered with granulous scales.

The ground-colour of the upper parts is a deep water-green, on which are often scattered numerous oblong irregular brown spots.

In young subjects the back and limbs are transversely banded with black. The lower region of the body is very pale yellow or whitish. The jaws are sprinkled with brown. The nails are of a clear horn colour. (Duméril and Bibron.)

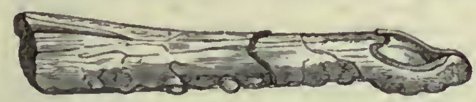
The Gavial of the Ganges is supposed to be the largest of the living Saurians. The measurement of the largest mentioned by Messrs. Duméril and Bibron is given at 5 metres, 40 centimetres (17 feet 8 inches).

Cuvier was led to think, principally from the figures published by Faujas de Saint-Fond, that there was more than one species of Gavial, and on subsequent inquiry distinguished two, the Great Gavial and the Little Gavial; but he was afterwards satisfied, from the examination of numerous specimens, that age alone made the difference between them.

Fossil Crocodilidæ.

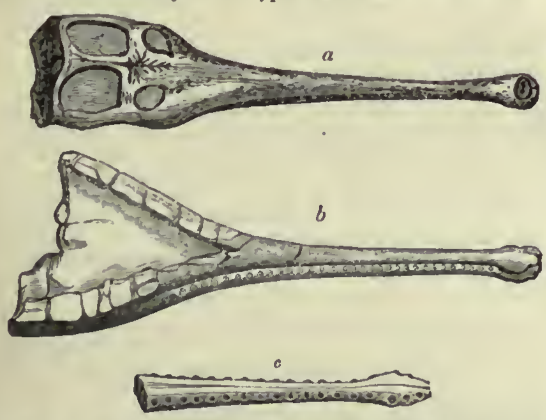
"In the living sub-genera of the Crocodilean family," observes Dr. Buckland ('Bridgewater Treatise,' p. 250), "we see the elongated and slender beak of the Gavial of the Ganges constructed to feed on fishes; whilst the shorter and stronger snout of the broad-nosed crocodiles and alligators gives them the power of seizing and devouring quadrupeds that come to the banks of rivers in hot countries to drink. As there were scarcely any *Mammalia* during the secondary periods, whilst the waters were abundantly stored with fishes, we might, à priori, expect that if any crocodilean forms had then existed, they would most nearly have resembled the modern Gavial: and we have hitherto found only those genera which have elongated beaks in formations anterior to and including the chalk; whilst true crocodiles with a short and broad snout like that of the caiman and the alligator appear for the first time in strata of the tertiary periods, in which the remains of *Mammalia* abound."

The genus *Steneosaurus* of Geoffroy St. Hilaire appears to come the nearest in its conformation to the living Gavial, and a general idea of the structure of the muzzle and anterior nasal aperture will be derived from the following cut of a specimen from Havre; whilst



Muzzle of *Steneosaurus*, from Dr. Buckland, who quotes De la Beche.

in *Teleosaurus* (Geoff.), though there is considerable similarity in the general contour of the head and jaws, the conformation of the muzzle and nasal aperture is very different from that of the living Saurian, the anterior termination of that aperture forming almost a vertical section of the extremity of the upper mandible.



a, head of *Teleosaurus Chapmanni*, seen from above; *b*, head of another individual of the same species seen from below, showing the lower jaw: locality of both, Lias in the neighbourhood of Whitby; *c*, inside view of anterior extremity of lower jaw: locality, Great Oolite at Enslow near Woodstock, Oxon. From Dr. Buckland.

Anterior extremities of the beak or jaws of *Teleosaurus*. Locality, Great Oolite, Stonesfield, Oxon. From Dr. Buckland.

In his monograph on the 'Fossil Reptilia' of the London Clay, published by the Palæontographical Society, Professor Owen describes the following species of extinct Emydosaurians.

Crocodilus Toliapicus. It is the Crocodile de Sheppey of Cuvier; *C. Spenceri* of Buckland, in his 'Bridgewater Treatise,' and of Rose in the 'Reports of the British Association,' 1841.

It was found originally in the Eocene beds of Sheppey, and was first described by Baron Cuvier from a specimen in the collection of M. Deluc of Geneva. Professor Owen doubts if the skull figured by Dr. Buckland (and given below) as *C. Spenceri* is identical with a more perfect specimen of this species now in the British Museum, from which he has given his own description.

Skull of *Crocodilus Spenceri*. Buckland.

C. Champsoides (Owen). This species seems also to have been included in Buckland's *C. Spenceri*, and Cuvier's Crocodile de Sheppey. This species has been established from a skull in the possession of Mr. Bowerbank, and although not to be clearly identified with Buckland's *C. Spenceri* more nearly resembles it than *C. Toliapicus.*

"The evidences," says Professor Owen, "of Crocodilean Reptiles from the deposits at Sheppey, less characteristic than those above described, are abundant. Mr. Bowerbank possesses numerous rolled and fractured vertebræ, condyloid extremities, and other portions of long bones, with fragments of jaws and teeth." In relation to the two Sheppey species he says, "Amongst the existing species of Crocodile, the *C. acutus* of the West Indies offers the nearest approach to the *C. Toliapicus*; and the *C. Schlegelii* of Borneo most resembles the *C. Champsoides.*"

C. Hastingsiæ (Owen). The specimen upon which this species is established was discovered by the Marchioness of Hastings in the Eocene Fresh-Water deposits of the Hordwell Cliffs in Hampshire, which her ladyship has described in the volume of 'Reports of the British Association' for 1847.

Alligator Hantoniensis (Searles Wood). The specimens of this fossil differ from the last in the exposed condition of the inferior canines when the mouth is shut. Although this distinction is sufficient to separate the existing species of Crocodiles and Alligators, Professor Owen is inclined to doubt whether it may not be in this case a mere accidental variety.

Gavialis Dixoni (Owen). The remains on which this species is established were discovered by the late Mr. Frederick Dixon in the Eocene deposits of Bracklesham.

In concluding the monograph in which these Fossil Crocodiles are minutely described and figured, and the skeletal anatomy of the family treated at large, Professor Owen says, "On reviewing the information which we have derived from the study of the fossil remains of the Procœlian *Crocodilia* that have been discovered in the Eocene deposits of England, the great degree of climatal and geographical change, which this part of Europe must have undergone since the period when every known generic form of that group of reptiles flourished here, must be forcibly impressed upon the mind.

"At the present day the conditions of earth, air, water, and warmth, which are indispensable to the existence and propagation of these most gigantic of living Saurians, concur only in the tropical or warmer temperate latitudes of the globe. Crocodiles, Gavials, and Alligators now require, in order to put forth in full vigour the powers of their cold-blooded constitution, the stimulus of a large amount of solar heat, with ample verge of watery space for the evolutions which they practise in the capture and disposal of their prey. Marshes with lakes, extensive æstuaries, large rivers, such as the Gambia and Niger that traverse the pestilential tracts of Africa, or those that inundate the country through which they run, either periodically, as the Nile for example, or with boundless forest and savannahs, like those ploughed in ever varying channels by the force of the mighty Amazon or Orinoco,—such form the theatres of the destructive existence of the carnivorous and predacious Crocodilean Reptiles. And what then must have been the extent and configuration of the Eocene continent which was drained by the rivers that deposited the masses of clay and sand accumulated in some parts of the London and Hampshire basins to the height of 1000 feet, and forming the graveyard of countless Crocodiles and Gavials. Whither tended that great stream once the haunt of alligators and the resort of taper-like quadrupeds, the sandy bed of which is now exposed on the upheaved face of Hordwell Cliff? Had any of the human kind existed and traversed the land where now the base of Britain rises from the ocean, he might have witnessed the Gavial cleaving the waters of its native river with the velocity of an arrow, and over and anon rearing its long and slender snout above the waves, and making the banks re-echo with the loud and sharp snapping of its formidably armed jaws. He might have watched the deadly struggle between the Crocodile and Palæothere, and have been himself warned by the hoarse and deep bellowings of the Alligator from the dangerous vicinity of its retreat. Our fossil evidences supply us with ample materials for this most strange picture of the animal life of ancient Britain; and what adds to the singularity and interest of the restored 'tableau vivant' is the fact, that it could not now be presented in any part of the world. The same forms of Crocodilean Reptile it is true still exist, but the habitats of the Gavial and the Alligator are wide asunder, thousands of miles of land and ocean intervening: one is peculiar to the tropical rivers of continental Asia, the other is restricted to the warmer latitudes of North and South America; both forms are excluded from Africa, in the rivers of which continents true Crocodiles alone are found. Not one representative of the Crocodilean order naturally exists in any part of Europe: yet every form of the order once flourished in close proximity to each other in a territory which now forms part of England."

CROCOISITE, a native Chromate of Lead. [LEAD.]

CROCUS, a beautiful genus of Iridaceous Plants, consisting of many hardy species, some of which are among the commonest ornaments of gardens. Crocuses are chiefly found in the middle and southern parts of Europe and the Levant, three only being wild with us, namely *Crocus nudiflorus*, which is abundant in the meadows near Nottingham, *C. vernus* and *C. sativus*. Botanists have found it extremely difficult to ascertain by what precise technical marks the species are to be distinguished. We do not propose to occupy ourselves with that subject, but shall rather enumerate briefly the names and localities of such as are apparently distinct; so that those who wish to form a complete collection of these pretty flowers may know where to look for them, and when their task is accomplished.

* Vernal Species.

C. vernus. This is the common Purple or White Crocus of our gardens in the spring. It has produced a multitude of florists' varieties, some of which are extremely beautiful and well marked. Its root-coats are finely netted, its flowers scentless, and the throat of the tube of the flower covered with hairs. *C. albiflorus* and *C. obovatus* are varieties of it. It is said to be wild in some parts of England, but it may have been introduced. It is certainly wild on the Alps, particularly of the Tyrol, Piedmont, Switzerland, Salzburg, and Carinthia, descending to the sea-coast at Friuli. It is also found on the mountains of the Abruzzi and elsewhere, in similar situations in the kingdom of Naples, associating itself with oaks, chestnuts, and similar trees, and not existing at elevations exceeding 6000 feet.

C. versicolor, the common Sweet-Scented Variegated Spring Crocus. There are not many varieties of it, all of which are recognised by the root-coats not being cut circularly, the yellow tube of the flower hairless, and the sweet scent. It grows wild about Nizza (Nice), and in all the eastern parts of Provence.

C. biflorus, the Scotch Crocus. The beautiful pencilled sepals and clear or bluish-white petals of this species distinguish it at once; added to which the root-coats are cut round into circular segments, a circumstance that occurs in no other species. It is a native of the most southern parts of Italy; growing wild in sterile subalpine pastures in the kingdom of Naples, and in similar situations in Sicily. Our garden plants are merely a cultivated state of the *C. pusillus* of the Italians.

C. Imperati. This is little known in England. Its leaves appear long before the flowers, and are glaucous and spreading. The petals and sepals are a delicate violet inside, but externally white; the petals are almost whole-coloured and pale purple, except at the base; the sepals are strongly feathered with rich purple. A white and a whole-coloured variety of it are said to exist. It differs from *C. biflorus* in its root-coats being membranous, and not cut circularly, and from *C. versicolor* in the tube of the flower not being hairy. It inhabits low hills and woods in the kingdom of Naples, on Capri, on Mount S. Angelo di Castellamare, and elsewhere. It is supposed that *C. suaveolens* is at most only a variety of this.

C. luteus or *mæsiacus*, the Large Yellow Crocus. It is characterised by very large whole-coloured flowers, and large roots, with coarsely netted coats. It is an oriental plant, but its exact locality is unknown.

C. aureus, the Small Yellow Crocus, by no means so common as the last, of which it is probably a variety. Its flowers are smaller and deeper coloured, and it has a pale cream-coloured variety. Dr. Sibthorp found it wild on the hills of the Morea.

C. susianus, the Cloth-of-Gold Crocus. This species is well known for its coarsely-netted root-skin, and small deep yellow flowers, the sepals of which are feathered with dark chocolate brown, and are rolled back when expanded under sunshine. It is a native of the Crimea, the Ukraine, and the other parts of south-western Russia: it is also believed to be a Turkish plant; and localities are given for it under the name of *C. reticulatus*, on mountains near Trieste, in woods near Lippizza, in Friuli, and in Hungary, in the lordship of Tolna. A remarkable variety with deep purple flowers exists, but it is extremely rare.

C. stellatus and *C. sulphureus* are pale and probably hybrid varieties of *C. luteus*. They have never been seen except in gardens, and are the least pretty of the genus.

* * Autumnal Species.

C. sativus, the common Saffron Crocus, an eastern plant, cultivated from time immemorial for the sake of its long reddish-orange drooping stigmas, which, when dried, form the saffron of the shops. Its Asiatic localities are not known; in Europe it grows apparently wild in the south of Tyrol, and is said to have been found near Ascoli, and on the Alps of Savoy. Its British station is in all probability to be ascribed to accident.

C. odorus, the Sicilian Saffron. This species, which has also been named *C. longiflorus*, is found in mountain pastures in Calabria, and in both mountainous and maritime situations through all Sicily, where its stigmas are collected instead of those of the true saffron. Its blossoms are sweet-scented, and are known at first sight from the stigmas not hanging out of the flower, but standing upright and inclosed within it. The tube of its flower is very long.

C. Thomasii, a Calabrian plant, found in mountain woods. It is said to have coarsely-netted root-coats, fragrant saffron-like truncated stigmas inclosed within the flower, which appears long after the leaves, and has a bearded throat. It exists in English gardens, but is very rare.

C. nudiflorus. The flowers appear without the leaves, and the root-coats are slightly netted. The stigmas are divided into many deep narrow segments. The plant is not rare in many parts of Europe, flowering about the time of the *Colchicum*, to a small species of which it at first sight bears much resemblance. *C. speciosus*, *C. multifidus*, *C. medius*, are mere varieties or synonymous names of this plant.

C. serotinus. This requires to be compared with *C. odorus*, to which it approaches very nearly, if it be not the same thing.

The Crocus delights in a dry situation and a rich light sandy soil. In such a place and soil it flowers profusely and produces large roots; but in a wet poor soil it dwindles away. Slugs are the chief enemies of this plant, which may be destroyed by watering the beds or clumps with lime-water.

For a florist's account of the varieties of spring Crocuses cultivated in the gardens of this country, see the 'Transactions of the Horticultural Society of London,' vol. vii.

CRONSTEDTITE, a hydrous Silicate of Iron, occurring both massive and crystallised. Its primary form is a rhomboid, in small thin hexagonal prisms, and in radiating groups. The cleavage is perpendicular to the axis, distinct. The colour is black and brownish-black; streak, dull green. Hardness 2·0 to 2·5. Specific gravity 3·3 to 3·36. Lustre vitreous. Opaque. This mineral is found in Cornwall, Brazil, and Przibram in Bohemia. It has the following composition:—

Silica	22·45
Oxide of Iron	58·85
Oxide of Manganese	2·89
Magnesia	5·68
Water	10·70

CROSSARCHUS. [VIVERRIDÆ.]

CROSSBILL. [LOXIADÆ.]

CROSS-STONE. [STAUROTIDE.]

CROSSWORT. [GALIUM.]

CROTALIDÆ, a family of Reptiles belonging to the order Serpents or Snakes, and including those species known by the name of Rattle-Snakes. In the 'Catalogue of the British Museum' Dr. J. E. Gray constitutes *Crotalidæ* a family of his sub-order *Viperina*. The family has the following distinctions:—Face with a large pit on each side, placed between the eye and the nostril. The head large behind, crown flat, covered with scales or small shields; the jaws weak, the upper with long fangs in front and no teeth. The belly covered with broad band-like shields: anal spurs none. The species are all of them venomous and viviparous.

The following is a synopsis of the genera and species:—

A. Head covered with scales, having small shields on the edge of the forehead and eyebrows; tail ending in a spine; cheeks scaly.

a. Subcaudal plates two-rowed to the tip. *Craspedocephalina.*

Craspedocephalus.—Superciliary shield single, hinder labial shields large; scales lanceolate, keeled. America.

Species—*C. Brasiliensis*; *C. lanceolatus*; *C. atrox*; *C. elegans*; *C. trilineatus.*

Trimesurus. — Superciliary shield single, hinder labial shields smallest; scales lanceolate, keeled. Asia.

T. viridis; *T. albolabris*; *T. carinatus*; *T. purpureus*; *T. maculatus*; *T. subannulatus*; *T. Philippensis*; *T. strigatus*; *T. Sumatranus*; *T. formosus*; *T. Ceylonensis.*

Parias.—Superciliary shield single, hinder labial shields smallest; scales lanceolate, of head and body smooth, of crown unequal. Asia.

P. flavomaculatus; *P. ornatus*; *P. variegatus.*

Megæra.—Superciliary shield double, hinder labial shields smallest; scales lanceolate, of head and body smooth. Asia.

M. trigonocephala; *M. olivacea.*

Atropos.—Superciliary shields many, forming a prominent arched series. Asia.

A. acontia.

b. Subcaudal plates four-rowed at the tip. America. *Lachesina.*

Lachesis.—Head ovate; crown scaly.

L. mutus; *L. pictus.*

B. Head more or less shielded.

c. Subcaudal plates two-rowed; tail ending in a spine; cheeks not scaly; head-shields with some additional plates in front. *Trigonocephalina.*

Trigonocephalus.—Dorsal scales keeled.

T. Halys; T. affinis; T. Bromhoffi; T. rhodostoma; T. Hypnale; T. Azara.

d. Subcaudal plates one-rowed; tail ending in a spine; cheeks not scaly; head shielded. America. *Cenchrina.*

Cenchris.

C. contortrix; C. atrofuscus; C. piscivorus.

e. Subcaudal plates one-rowed; tail ending in a rattle; cheeks scaly; head more or less shielded. America. *Crotalina.*

Crotalophorus.—Head with nine large shields extending behind the eyes.

C. miliaris; C. tergeminus; C. Kirtlandi.

Uropsophus.—Head with scales behind; temporal scales and labial shield moderate.

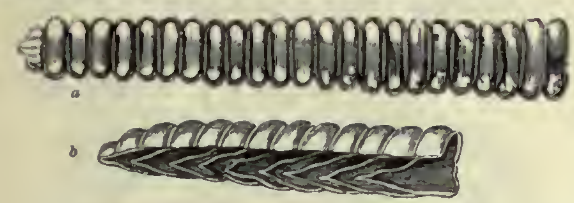
U. decussus.

Crotalus.—Head with scales behind; temporal scales and labial shields very small, convex.

C. horridus.

The last species, *C. horridus*, the Rattle-Snake, may be taken as a type of the whole family.

The colour of the head is brown; eye red; upper part of the body yellowish-brown, transversely marked with irregular, broad, black lists. Rattle brown, composed of several horny membranous cells, of an undulated pyramidal figure, articulated one within the other, so that the point of the first cell reaches as far as the basis or protuberant ring of the third, and so on; which articulation, being very loose, gives liberty to the parts of the cells that are inclosed within the outward rings to strike against the sides of them, and so to cause the rattling noise which is heard when the snake shakes its tail. (Catesby.)



a, Rattle of twenty-four joints; *b*, section of rattle.

It is a native of Virginia, the Carolinas, and other parts of America.

Lawson, in his 'History' (1714), says, "The Rattle-Snakes are found in all the main of America that I ever had any account of; being so called from the rattle at the end of their tails, which is a connection of jointed coverings of an excrementitious matter, betwixt the substance of a nail and a horn, though each tegmen is very thin. Nature seems to have designed these on purpose to give warning of such an approaching danger as the venomous bite of these snakes is. Some of them grow to a very great bigness, as six feet in length, their middle being the thickness of the small of a lusty man's leg. We have an account of much larger serpents of this kind; but I never met them yet, although I have seen and killed abundance in my time. They are of an orange-tawny and blackish colour on the back; differing (as all snakes do) in colour on the belly, being of an ash-colour inclining to lead. The male is easily distinguished from the female by a black velvet spot on his head; and besides his head is smaller shaped and long. Their bite is venomous if not speedily remedied; especially if the wound be in a vein, nerve, tendon, or sinew; when it is very difficult to cure. The Indians are the best physicians for the bite of these and all other venomous creatures of this country. There are four sorts of snake-roots already discovered, which knowledge came from the Indians, who have performed several great cures. The rattle-snakes are accounted the peaceablest in the world; for they never attack any one, or injure them, unless they are trod upon or molested. The most danger of being bit by these snakes is for those that survey land in Carolina; yet I never heard of any surveyor that was killed or hurt by them. I have myself gone over several of this sort, and others; yet it pleased God I never came to any harm. They have the power or art (I know not which to call it) to charm squirrels, hares, partridges, or any such thing, in such a manner, that they run directly into their mouths. This I have seen by a squirrel and one of these rattle-snakes; and other snakes have in some measure the same power. The rattle-snakes have many small teeth, of which I cannot see they make any use; for they swallow everything whole; but the teeth which poison are only four; two on each side of their upper jaws. These are bent like a sickle, and hang loose as if by a joint. Towards the setting on of these, there is, in each tooth, a little hole wherein you may just get in the point of a small needle. And here it is that the poison comes out (which is as green as grass) and follows the wound made by the point of their teeth. They are much more venomous in the months of June and July, than they are in March, April, or September. The hotter the weather the more poisonous. Neither may we suppose that they can renew their poison as oft as they will; for we have had a person bit by one of these who never rightly recovered it, and very hardly escaped with life; a second person bit in the same place by the same snake, and received no more harm than if bitten with a rat. They cast their skins every year, and commonly abide near the place where the old skin lies. These cast-skins are used in physic, and the rattles are reckoned good to expedite the birth. The gall is made up into pills with clay, and kept for use, being given in pestilential fevers and the small-pox. It is accounted a noble remedy, known to few, and held as a great arcanum. This snake has two nostrils on each side of his nose. Their venom, I have reason to believe, effects no harm any otherwise than when darted into the wound by the serpent's teeth."

Catesby thus notices this species in 1771:—"Of these vipers," says he, writing of all the American venom-snakes under that name, "the rattle-snake is most formidable, being the largest and most terrible of all the rest: the largest I ever saw was one about eight feet in length, weighing between eight and nine pounds. This monster was gliding into the house of Colonel Blake of Carolina; and had certainly taken his abode there undiscovered, had not the domestic animals alarmed the family with their repeated outcries; the hogs, dogs, and poultry united in their hatred to him, showing the greatest consternation, by erecting their bristles and feathers, and, expressing their wrath and indignation, surrounded him, but carefully kept at a distance; whilst he, regardless of their threats, glided slowly along.

"It is not uncommon to have them come into houses, a very extraordinary instance of which happened to myself in the same gentleman's house, in the month of February, 1723: the servant in making the bed in a ground-room (but a few minutes after I left it), on turning down the clothes discovered a rattle-snake lying coiled between the sheets in the middle of the bed.

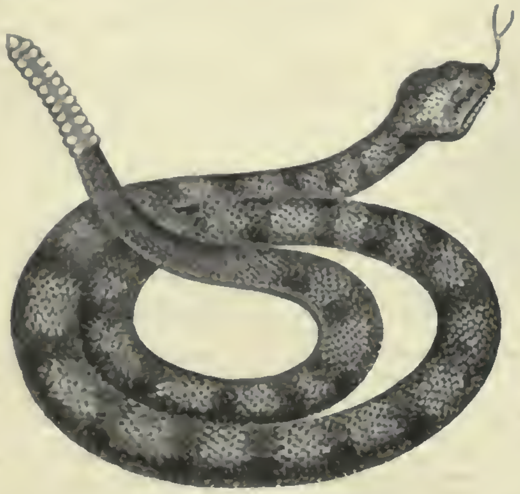
"They are the most inactive and slow-moving snake of all others, and are never the aggressors except in what they prey upon; for unless they are disturbed they will not bite; and, when provoked, they give warning by shaking their rattles. These are commonly believed to be the most deadly venomous serpent of any in these parts of America: I believe they are so, as being generally the largest, and making a deeper wound, and injecting a greater quantity of poison; though I know not why any of the other kinds of vipers may not be as venomous as a rattle-snake, if as big, the structure of the deadly fangs being alike in all. The most successful remedy the Indians seem to have, is to suck the wound, which, in a slight bite, has sometimes a good effect; though the recovered person never fails of having annual pains at the time they were bit. They have likewise some roots which they pretend will effect the cure; particularly a kind of *Asarum*, commonly called Heart Snake-Roots, a kind of *Chrysanthemum* called St. Anthony's Cross, and some others; but that which they rely on most, and which most of the Virginian and Carolina Indians carry dry in their pockets, is a small tuberous root, which they procure from the remote parts of the country; this they chew, and swallow the juice, applying some to the wound. Having, by travelling much with Indians, had frequent opportunities of seeing the direful effects of the bites of these snakes, it always seemed and was apparent to me that the good effects usually attributed to these their remedies is owing more to the force of nature, or the slightness of the bite of a small snake in a muscular part, &c. The person thus bit I have known to survive without any assistance for many hours; but where a rattle-snake with full force penetrates with his deadly fangs, and pricks a vein or artery, inevitable death ensues; and that, as I have often seen, in less than two minutes. The Indians know their destiny the minute they are bit; and when they perceive it mortal, apply no remedy, concluding all efforts in vain. If the bite happeneth in a fleshy part, they immediately cut it out to stop the current of the poison. I could heartily wish that oil of olives applied to the wound might have as good success against the venom of these snakes as it hath been found in England to have had against the poison of the adder." (Catesby, 'Natural History of Carolina.')

Lawson, it appears, was an eye-witness of the fascination, if so the effect of terror on the victim is to be termed, of the Rattle-Snake; and though Catesby never saw it, he thus details the evidence of the fact known to him:—

"The charming, as it is commonly called, or attractive power this snake is said to have of drawing to it animals and devouring them, is generally believed in America. As for my own part, I never saw the action, but a great many from whom I have had it related all agree in the manner of the process; which is, that the animals, particularly birds and squirrels (which principally are their prey), no sooner spy the snake, than they skip from spray to spray, hovering and approaching gradually nearer their enemy, regardless of any other danger; but with distracted gestures and outcries descend, though from the top of the loftiest trees, to the mouth of the snake, who openeth his jaws, takes them in, and in an instant swallows them."

There can be little doubt that this supposed power is greatly exaggerated. That a suddenly-surprised animal should be arrested by terror and easily fall a victim to the serpent, is highly probable; but that it should descend to its destruction from the top of the loftiest trees, is almost incredible.

That the secretion of the poison may be greatly increased by local irritation would be expected; and Mr. Bell, in his 'History of British Reptiles,' adduces the following as evidence of the fact. He was dissecting very carefully and minutely the poison-apparatus of a large rattle-snake which had been dead for some hours; the head had been taken off immediately after death; yet as Mr. Bell continued his dissection the poison continued to be secreted so fast as to require to be occasionally dried off with a bit of rag or sponge. He states his belief that there could not have been less altogether than six or eight drops at the least.



Rattle-Snake (*Crotalus horridus*).

The same scientific and entertaining author relates, as a proof that the effect of wounds inflicted by venomous serpents subsequently to the first is greatly lessened, either by the diminution of the quantity of venom or of some deterioration of its strength, the following anecdote:—A gentleman of his acquaintance had received a living rattlesnake from America. Intending to try the effect of its bite upon some rats, he introduced one of those animals into the cage with the serpent, which immediately struck the rat, and the latter died in two minutes. Another rat was then placed in the cage, and ran to the farthest corner from the snake, uttering cries of distress. The serpent did not attack it immediately; but after about half an hour, on being irritated, struck the rat, which exhibited no symptoms of being poisoned for several minutes, nor did it die till twenty minutes after the bite had been inflicted. A third rat, remarkably large, was then introduced into the cage, and exhibited no signs of terror, nor was it apparently noticed by its dangerous companion. After watching for the rest of the evening, Mr. Bell's friend retired, leaving the rattle-snake and the rat together. He rose early the next morning, and visited the cage: there lay the snake dead, and the rat had supped upon the muscular part of its back. Mr. Bell does not remember at what time of the year this took place, but he expresses his belief that it was not during very hot weather.

The length of time during which a man will linger after being bitten by one of these deadly snakes was manifested in a very distressing case. Some years ago a carpenter came to see a rattle-snake which was publicly shown for money in London. The man endeavoured to excite it, probably to hear its rattle, with his rule, which he dropped into the serpent's cage. As he was trying to recover it the snake bit him in the hand. He was taken to one of the hospitals (St. George's, if we recollect right), and bore up so long that hopes were entertained of his recovery; but his constitution gave way at last, and after many days he fell a victim to the poison. [VIPERINA.]

CROTON, a genus of Plants belonging to the natural order *Euphorbiaceæ*, comprehending a large number of species, many of which have important medical properties. It is distinguished from other genera of its order by monœcious flowers; the males with a 5-parted valvular calyx, 5 petals, 5 glands alternate with the petals, and a definite number of distinct stamens; the females with a 5-parted calyx, no petals, 3 bifid or multifid styles, 5 glands surrounding the ovary, and a tricoccous fruit. The species are extremely diversified in appearance, some being trees, others bushes, others herbaceous plants; many with serrated or lobed leaves, many with entire ones; sometimes covered with hair, sometimes naked; and now with a small compact inflorescence, now having it long and lax. The following are a few of the more remarkable species:—

C. Cascarilla. Leaves lanceolate, acute, quite entire, stalked, downy on the under surface. Stem arborescent. A native of the Bahamas, St. Domingo, and Florida. Fée considers it quite certain that this species is that which furnishes the Cascarilla Bark of commerce; but others ascribe it to *C. Eleutheria*; and Schlede suspects that it may be rather the produce of *C. Pseudo-China*, which he found to be the real Quina Blanca of the apothecaries of Jalapa. Dr. Lindley considers that the true Cascarilla Bark is not yielded by this species but by *C. Eleutheria*.

C. Tiglium. Leaves ovate, smooth, acuminate, serrated. Stem arborescent. Flowers in terminal spikes. Fruit smooth, the size of a hazel-nut. An inhabitant of the Moluccas, Ceylon, and other parts of the East Indies. This plant is at once the most active and dangerous of drastic purgatives; every part—wood, leaves, and fruit—seems to participate equally in the energy. The leaves are so acrid as to inflame the mouth, lips, and fauces of those who merely chew them, bringing on swelling and producing a sensation of burning as far as the anus. The seeds thrown into water intoxicate fish. Ten or twenty fruits bruised with honey have been known to kill a horse by the violent diarrhœa they have produced. Hence the oil obtained from the seeds, which is known by the name of Croton Oil, when used medicinally, has to be administered with extreme care.

Croton Tiglium.

C. lacciferum. Leaves ovate, downy, serrulated, stalked; calyxes downy; flowers in terminal spikes; fruits small and velvety. A native of the East Indies. This species is said to furnish the finest of all the sorts of lac, but scarcely ever to find its way to England. It is very pure, of a bright red, and furnishes a brilliant varnish in Ceylon.

C. Draco, a Mexican plant, with long heart-shaped woolly leaves, with *C. sphærocarpum*, and *C. sanguifluum*, yields, when wounded, a resinous substance of a deep red colour, resembling dragon's blood. Others are merely aromatic. From *C. balsamiferum* the liquor called Eau de Mantes is distilled; *C. aromaticum*, *C. niveum*, *C. fragrans*, and *C. coriaceum* have similar qualities; and *C. thuriferum* exudes a fragrant resin analogous to incense.

The bark of these trees occurs in pieces about a foot long, which are tubular or overlapping, externally covered with a cuticle which easily peels off, so that the liber or bark is often exposed, in which case it feels soft and cork-like. The colour externally is yellowish, ash-gray, or varying to reddish-brown: this last colour is mostly owing to the presence of lichens. The surface is also marked by irregular deep longitudinal furrows. The inner surface is a dirty or rusty-brown colour. Odour faintly aromatic; taste bitter, not unpleasant, and stimulating. No alkaloid has been detected in it; but it possesses much volatile oil. One pound of bark yields one drachm and a half of volatile oil. This bark is sometimes mixed with the cinchona barks, being called Gray Fever-Bark—a substitution in no respect hurtful.

For the medical properties of this genus see CASCARILLA and CROTON OIL, in ARTS AND SC. DIV.

CROTO'PHAGA (Linn.), *Crotophagus* (Browne, Brisson), a genus of Birds placed by Lesson under the third family, Hétéroramphes, of the order Grimpeurs (*Scansores*), Cuvier; *Zygodactyli*, Temminck; Sylvains Zygodactyles, Vieillot.

The bill short, very much compressed, arched, without dentilations, elevated, and surmounted by a vertical and trenchant crest; nostrils basilary, open; fourth and fifth quills longest; tail-feathers long, rounded.

These birds are called Ani and Anno in Guyana and Brazil, and Anno in Paraguay. In Mexico they are named, according to Hernandez, Cacalotototl, and in the Antilles Bouts de Petun, Amangoua, Diables de Savannes, and Perroquets Noirs. In Cayenne their common name is Bouilleur de Canari. Their general colour is black, with more or less of metallic reflections.

A considerable portion of the species are found in America—principally the hot and humid parts, but the south more especially—and the Antilles.

The Anis live in flocks, and are so far from timid that when they see their companions fall before the gun, the survivors fly but a short way, and then again settle. Bushes, the skirts of woods, and the borders of flooded savannahs, are their favourite haunts. Their food consists of small lizards, insects, and seeds. Many pairs are said to use the same nest, built on the branches of trees, and of large dimensions, when considered in relation to the number of couples occupying it, where they lay and hatch their young in concert.

C. Ani is a blackbird with bronzed tints in some lights. Size rather larger than that of the common blackbird; less than that of a jackdaw. Locality, moist savannahs and the neighbourhood of water, in the West India Islands, Carolinas, Brazil, Paraguay, &c. It is the Razor-Billed Blackbird of Jamaica of Catesby, the Savannah Blackbird of the English colonists, and the Great Blackbird of Sloane.

Jamaica Blackbird (*Crotophaga Ani*).

Browne ('Hist. of Jamaica') thus describes it:—"This bird is about the size of a Barbary dove, or something larger, black all over, and splay-footed like a parrot. It has a long square tail, a broad compressed bill, and a short thin tongue: but the beak or upper part of the bill is flatted on the sides, arched and sharp above, and straight at the edges below. They live chiefly upon ticks and other small vermin, and may frequently be seen jumping about all the cows and oxen in the fields; nay, they are often observed to fly on their backs unless they lie down for them, which if much troubled with ticks they generally do when they see the birds about them; but if the beast be heedless they hop once or twice round it, looking it very earnestly in the face every time they pass, as if they seem to know that it was only requisite to be seen to be indulged. They are very noisy birds, and one of the most common sorts in all the pastures of Jamaica. Their flight is low and short."

Sloane thus describes his specimen, under the name of the Great Blackbird:—"This was thirteen inches long from the end of the bill to the end of the tail, and about fifteen inches from the end of one wing to the end of the other, both being extended; the bill was three-quarters of an inch long, and black, the under mandible being straight, the upper of a singular make, distinguishing it from other birds; for it was arched or round, raised high, flat and thin on the upper round edge. The feet have three toes before and one behind (though Marcgrave says otherwise). The legs are two inches long, and black as jet; the middle toe before is one inch and a half long, armed with a pretty sharp claw, and the other toes proportionable. The colour of the feathers all over is black. The stomach of this bird was pretty thick; it was very full of grasshoppers, beetles, &c., disjointed and partly dissolved.

"It haunts the woods on the edges of the savannahs, and is very common, making a loud noise upon the sight of mankind, which alarms all the fowls in their neighbourhood, so that they are very prejudicial to fowlers; but on the other hand, when negroes run from their masters and are pursued by them in the woods to be brought back to their service, these birds, on sight of them as of other men, will make a noise, and direct the pursuers which way they must take to follow their blacks, who otherwise might live always in the remoter inland woods in pleasure and idleness.

"Perhaps this bird may have the toes sometimes two before, at other times two behind."

Sloane's doubt may have arisen from a casual examination of dead specimens. The fact is that the external toe in some scansorial birds can be directed backwards, but not forwards to any extent.

These birds are easily tamed, and may be taught to speak. Their flesh is said to have a bad odour.

CROUGER, a local name for the Prussian or Gibel Carp. [CYPRINIDÆ.]

CROW. [CORVIDÆ.]

CROW-BERRY. [EMPETRUM.]

CROW-FOOT. [RANUNCULUS.]

CROZOPHORA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. The flowers are monœcious. Calyx of male flowers 5-parted; petals 5; stamens 5-10, with unequal connate filaments. Calyx of female flowers 10-parted; petals absent; styles 3-bifid; capsule 3-coccous.

C. tinctoria is a small prostrate hoary annual, with slender cylindrical stems about a foot long; soft, oval, alternate, almost rhomboidal leaves, which are plaited and curled at their edge; small flowers arranged in short clusters, and drooping fruit composed of three blackish rough cells. It is a native of barren places all over the south of Europe, and is cultivated about Montpelier for the sake of the deep purple dye called Tournesole, which it produces. Its properties are acrid, emetic, corrosive, and drastic, like the most virulent Euphorbiaceous Plants.

Crozophora tinctoria.

1, a male flower cut open, showing the stamens; 2, a closed flower; 3, a nearly ripe fruit; 4, 5, different kinds of starry scales, with which all the green parts are covered.

CRUCIAN CARP. [CYPRINIDÆ.]

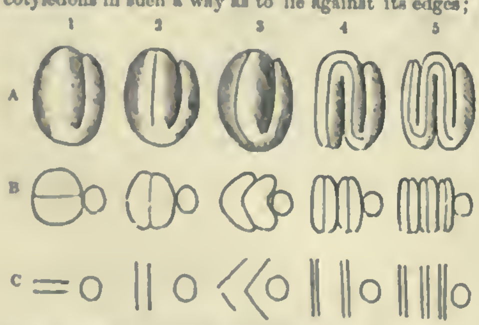
CRUCIFERÆ, *Crucifers*, the Cabbage Tribe, a very extensive and most natural assemblage of Plants, called *Tetradynamia* and *Cruciatæ* by Linnæus, and *Brassicaceæ* by others. It comprehends the Mustard, Cress, Turnip, Cabbage, Scurvy-Grass, Radish, Horse-Radish, and similar plants, having a pungent principle diffused more or less in their sap, and giving them valuable antiscorbutic qualities. All the species have an inflorescence without bracts; a calyx of 4 sepals; 4 petals with long claws, and their blades placed something like the arms of a Maltese cross, whence their name; 6 stamens, 4 of which are longer than the other 2; and a fruit consisting of 2 cells, with a central frame, to which is fitted a pair of deciduous valves, and from the sides of which under the valves is stretched a thin double transparent diaphragm. In each cell are two or more seeds, with an embryo folded upon itself, and destitute of albumen. The form of the fruit is extremely variable: when it is long and slender it is called a Silique, and when short and round a Silicle; hence the two divisions of the *Tetradynamia* of Linnæus into *Siliquosæ* and *Siliculosæ*.

About a couple of thousand species are dispersed over the milder parts of the world, refusing alike to exist beneath the severe cold of the arctic zone and the excessive heats of the tropics. A large proportion consists of inconspicuous and useless weeds; many are objects of beauty from the size and gay colours of their petals; and the names already mentioned show that another part of the order consists of plants useful to man.

Cheiranthus Cheiri.

1, a flower from which the petals have been removed; 2, the stamens; 3, a section of the ovary; 4, a ripe fruit, from which the valves are separating; 5, an embryo.

Owing to the number of the species, and the great resemblance between them, the systematic arrangement of Cruciferous Plants was until late years exceedingly unsatisfactory. It has however been discovered that the embryo presents the most constant character, and that by five modifications of the manner in which it is folded up five precisely limited divisions of the order are secured. The following cut illustrates them. Let A 1 be an embryo with the radicle applied to the cotyledons in such a way as to lie against its edges; then B 1



will be the appearance of such an embryo when cut across, and C 1 will be a sign expressing the mutual positions of the radicle and cotyledons by a circle and two bars: these are *Pleurorhizeæ*. Then *fig.* A 2 will be the same embryo with the radicle applied to the back of the cotyledons; and B 2 and C 2 will give the section and sign of what are called *Notorhizeæ*. When the cotyledons instead of being flat are channeled so as to receive the radicle in a kind of groove, as at A 3, it gives the division *Orthoploceæ*. If the cotyledons are so long as to be doubled twice, A 4, they constitute *Spiroloberæ;* and if, as at A 5, the cotyledons are doubled three times, they indicate the division *Diplecolobeæ*. Upon these distinctions all recent arrangements of *Cruciferæ* have been formed.

The affinities of this order are with *Papaveraceæ*, *Cistaceæ*, *Capparidaceæ*, and *Fumariaceæ*. There are 173 genera and above 1600 species described. It is eminently a European order: 166 species are found in Northern and Middle Europe, and 178 on the northern shore or islands of the Mediterranean; 45 are peculiar to the coast of Africa between Mogadore and Alexandria; 184 to Syria, Asia Minor, Tauria, and Persia; 99 to Siberia; 35 to China, Japan, or India; 76 to Australia and the South Sea Islands; 6 to Mauritius, and the neighbouring islands; 70 to the Cape of Good Hope; 9 to the Canaries or Madeira; 2 to St. Helena; 2 to the West Indies; 41 to South America; 48 to North America; 5 to the islands between North America and Kamtchatka; and 35 are common to various parts of the world. This being their general geographical distribution, it appears that, exclusive of the species that are uncertain or common to several different countries, about 100 are found in the southern hemisphere and about 800 in the northern hemisphere; or 91 in the New and the rest in the Old World. Finally, if we consider them with regard to temperature, we shall find that there are—

In the frigid zone of the northern hemisphere		205
In all the tropics (and chiefly in mountainous regions)		30
In the temperate zone—		
Of the northern hemisphere	548	634
Of the southern hemisphere	86	

Such were the calculations of De Candolle in 1821. Although requiring considerable modification, especially in the Asiatic and North American numbers, which are much too low, they serve to give a general idea of the manner in which this order is dispersed over the globe.

The character of the genera of this order is antiscorbutic and stimulant, combined with an acrid flavour. The officinal species are among the commonest of all plants, and will be found treated of under their respective heads. A large number of genera are natives of Britain. The following is a synopsis of the British genera, according to Babington's 'Manual of British Botany:'—

Sub-Order I. Siliquosæ.

Pod (silique) linear or linear-lanceolate, opening by two valves; dissepiment narrow, but in its breadest diameter.

Tribe I. Arabideæ.

Cotyledons accumbent, parallel to the dissepiment; radicle lateral; seed compressed.

1. *Matthiola.*
2. *Cheiranthus*
3. *Nasturtium.*
4. *Barbarea.*
5. *Turritis.*
6. *Arabis.*
7. *Cardamine.*
8. *Dentaria.*

Tribe II. Sisymbrieæ.

Cotyledons incumbent, contrary to the dissepiment; radicle dorsal seed compressed.

9. *Hesperis.*
10. *Sisymbrium.*
11. *Alliaria.*
12. *Erysimum.*

Tribe III. Brassiceæ.

Cotyledons conduplicate, longitudinally folded in the middle; radicle dorsal within the fold.

13. *Brassica.*
14. *Sinapis.*
15. *Diplotaxis.*

Sub-Order II. Latiseptæ.

Pouch (silicle) short, opening with two valves; dissepiment in its breadest diameter.

Tribe IV. Alyssineæ.

Cotyledons accumbent.

16. *Alyssum.*
17. *Koniga.*
18. *Draba.*
19. *Cochlearia.*
20. *Armoracia.*

Tribe V. Camelineæ.

Cotyledons Incumbent.

21. *Camelina.*

Tribe VI. Velleæ.

Cotyledons conduplicate.

22. *Vella.*

Sub-Order III. ANGUSTISEPTÆ.

Pouch (silicle) short, laterally compressed, opening with two boat-shaped valves, keeled or winged on the back; dissepiment narrow, linear, or lanceolate.

Tribe VII. THLASPIDEÆ.

Cotyledons accumbent.

23. *Thlaspi.*
24. *Hutchinsia.*
25. *Teesdalia.*
26. *Iberis.*

Tribe VIII. LEPIDINEÆ.

Cotyledons incumbent.

27. *Lepidium.*
28. *Capsella.*

Tribe IX. SUBULARIEÆ.

Cotyledons incumbent, long, linear, curved back above their base; cells many-seeded.

29. *Subularia.*

Tribe X. SENEBRIEREÆ.

Cotyledons incumbent, long linear, curved back above their base; cells one-seeded.

30. *Senebriera.*

Sub-Order IV. NUCAMENTACEÆ.

Pouch (silicle) scarcely dehiscent, often 1-celled, owing to the absence of the dissepiment.

Tribe XI. ISATIS.

Cotyledons incumbent.

31. *Isatis.*

Sub-Order V. LOMENTACEÆ.

Silicle or silique dividing transversely in single-seeded cells; the true silique often barren, all the seeds being in the beak.

Tribe XII. CAKILINEÆ.

Cotyledons accumbent.

32. *Cakile.*

Tribe XIII. RAPHANEÆ.

Cotyledons conduplicate.

33. *Crambe.*
34. *Raphanus.*

CRUCIROSTRA. [LOXIADÆ.]

CRUSTA'CEA, Crustacés of the French, Krustenthiere of the Germans, Μαλακόστρακα of Aristotle and the ancient Greeks, a class of Articulated Animals, whose external covering is less solid than that of the majority of Testaceous Mollusks, but much firmer and harder than the skin of the Naked Mollusks; and whose conformation is essentially distinguishable from other classes, especially in the circulating, respiratory, and locomotive organs. The Common Crab [CRAB], the Lobster, and Crayfish [ASTACUS], the Common Shrimp [CRANGONIDÆ], and the Water-Fleas [BRANCHIOPODA], may be taken as types of different sections of this family.

As in many of the Testaceous Mollusks, the skeleton of the *Crustacea* is external. It is made up of the tegumentary envelope, which, in some of the class, always continues soft, but in the greater portion is very firm, forming a shelly case or armour, in which all the soft parts are contained. In the more perfect Crustaceans it is complex. The following description of its component parts is from the pen of M. Milne-Edwards, who, in his 'Histoire Naturelle des Crustacés' (Paris, 1834, &c., 8vo), and in the article 'Crustacea' in the 'Cyclopædia of Anatomy and Physiology (Loudon, 1836, &c.), has given the most complete view of the organisation of this family. Taking the *Brachyura*, or Short-Tailed Crustaceans, as his instance of the more highly developed forms of the class in which the complex structure is exhibited, he thus proceeds, "The integument consists of a corium and an epidermis, with a pigmentary matter of a peculiar nature, destined to communicate to the latter membrane the various colours with which it is ornamented. The corium or dermis, as among the *Vertebrata*, is a thick, spongy, and very vascular membrane; on its inner surface it is intimately connected with a kind of serous membrane, which lines the parietes of the cavities in the *Crustacea* in the same manner as the serous membranes line the internal cavities among the *Vertebrata*; these two membranes, divided in the latter order by the interposition of muscular and bony layers, which cover and protect the great cavities, become closely united when these layers disappear, as they do in the *Crustacea*, in consequence of the important changes that take place in the conformation of the apparatus of locomotion. The corium again, among the *Crustacea*, is completely covered on its outer surface by a membranous envelope unfurnished with blood-vessels, and which must be held in all respects as analogous to the epidermis of the higher animals. It is never found in the properly membranous state, save at the time of the *Crustacea* casting their shell; at this period, it is interposed between the corium and the solid covering ready to be cast off, and has the appearance of a pretty dense and consistent membrane, in spite of its thinness. It forms, as among animals higher in the scale, a kind of inorganic lamina, applied to the surface of the corium, from which it is an exudation. After the fall of the old shell it becomes thicker and very considerably firmer, owing to the deposition or penetration of calcareous molecules within its substance, as well as by the addition of new layers to its inner surface. The degree of hardness finally acquired, however, and the amount of calcareous matter deposited within it, vary considerably; in many members of the class, it remains semicorneous, in a condition very similar to that of the integuments of insects, with which, moreover, it corresponds very closely in point of chemical composition; in the higher crustaceans, again, its composition is very different: thus, whilst chitine in combination with albumen is the principal element in the tegumentary skeleton of some species, this substance scarcely occurs in the proportion of one or two tenths in the carapace of the Decapods, which, on the contrary, contains 60 and even 80 per cent. of phosphate and carbonate of lime, the latter substance particularly occurring in considerably larger proportion than the former. With regard to the pigmentum, it is less a membrane or reticulation than an amorphous matter diffused through the outermost layer of the superficial membrane, being secreted like this by the corium. Alcohol, ether, the acids, and water at 212° Fahr., change it to a red in the greater number of species; but there are some species in which it may be exposed to the action of these different agents without undergoing any perceptible change. The epidermic layer hardened in different degrees is the part which mainly constitutes the tegumentary skeleton of the *Crustacea*. In its nature it is obviously altogether different from that of the internal skeleton of the *Vertebrata*; still its functions are the same, and this physiological resemblance has led naturalists to speak of these two pieces of organic mechanism, so dissimilar in their anatomical relations, under the common name of skeleton. The tegumentary skeleton of the *Crustacea* consists, like the bony skeleton of the *Vertebrata*, of a great number of distinct pieces connected together by means of portions of the epidermic envelope which have not become hardened, in the same way as, among the higher animals, certain bones are connected by cartilages, the ossification of which is only accomplished in extreme old age."

This skeleton, or crustaceous frame-work, consists of a series of rings varying in number, the normal number of the body-segments being twenty-one. Instances of a larger number are rare, and a less number seldom occurs; one or more rings may be apparently absent, but in such cases they will generally be found consolidated as it were. In the embryo the segments are developed in succession from before backwards; the posterior rings therefore are generally absent when the number is defective. Each ring is divisible into two arcs, one upper or dorsal, the other lower or ventral. Each arc may present as many as four elementary pieces. Two of these united in the mesial line form the tergum; the sides of this upper arc are framed of two other portions denominated flanks or epimeral pieces. The lower arc is a counterpart of the upper. Two of the four pieces into which it is divisible constitute the sternum, situated in the mesial line, and are flanked by two episternums. These two arcs do not cohere at their edges, but a space is left for the insertion of the lateral appendages or extremities which correspond with them. (Milne-Edwards; Audouin.)

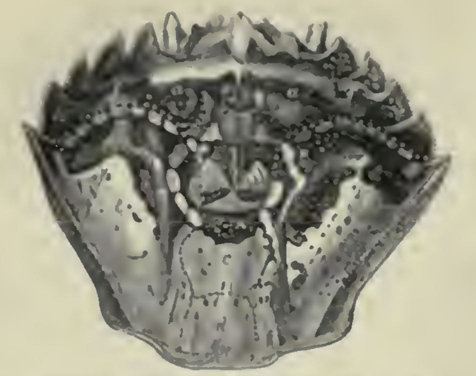
The one-and-twenty rings above mentioned are generally divisible into three sections of seven each, and may be considered as corresponding with the three regions which zoologists have generally consented to recognise in the bodies of the crustaceans, under the denominations of a head, a thorax, and an abdomen; but the student should be on his guard against the false impressions which, as M. Milne-Edwards observes, are likely to arise from these terms, by their leading the mind to liken them to the grand divisions in the *Vertebrata*, which are defined by the same expressions.

The cephalo-thoracic portion and carapace first claim our attention, and the latter acquires its greatest development in the Decapods. "In these animals," says M. Milne-Edwards, "the frame-work of the body does not appear at first sight to consist of more than two portions, the one anterior, formed by the carapace, and representing the cephalic and thoracic segments conjoined; the other posterior formed by the abdomen. In reality, the first fourteen rings of the body are covered by this enormous buckler, and are so intimately conjoined as to have lost all their mobility; the whole of the thoracic segments thus hidden below the carapace are connected with it in their superior parts; they are only joined with one another underneath and laterally; and their tergal parts having, in consequence of this, become useless, are no longer to be found, being in some sort replaced by the great cephalic buckler; thus the whole of these rings, in conformity with this arrangement, are imperfect and open above."

The subjoined cut represents the carapace of a Brachyurous or Short-Tailed Crustacean, and the regions of which it is composed, named after the viscera and organs protected by them.

The succeeding figure represents the carapace of a Macrourous or Long-Tailed Crustacean.

The abdomen is most fully developed in the *Macroura*, or Long-Tailed Crustaceans, in many of which it becomes a very important organ of motion, and in them there is a comparatively small development of the carapace; while in the *Brachyura*, or Short-Tailed Crustaceans,



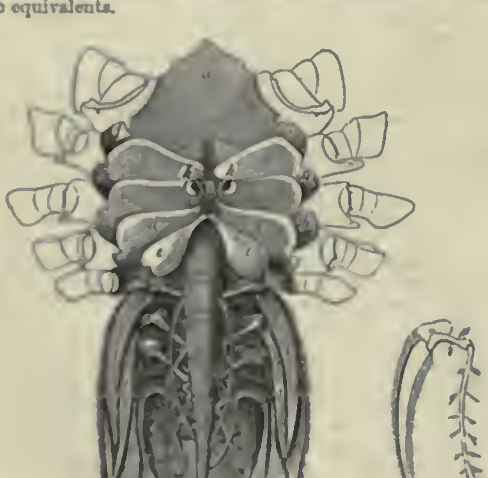
Carapace of *Carcinus mænas* (*Cancer mænas*, Linn.)

a, a, Region of the stomach, or gastric region; *b*, genital region; *c*, cardiac region; *d*, posterior cardiac region; *e, e*, branchial regions; *f, f*, hepatic region.

Carapace of common Crawfish (*Astacus fluviatilis*).

a, Gastric region; *b*, genital region; *c*, cardiac region; *d*, posterior cardiac region; *e, e*, branchial regions.

this rule is reversed, the abdomen being comparatively small, and the great development taking place in the carapace, illustrating the "loi de balancement organique" of M. Geoffroy St. Hilaire. The Common Crab and Common Lobster afford striking examples of this law of organic equivalents.



View of the under side of the female of *Thelphusa fluviatilis*, with the tail or abdomen extended.

a, b, c, d, e, sternal pieces; *f, g, h, i*, latero-sternal pieces; *k, k*, external apertures of the female organs of generation; *l, l, l*, abdominal appendages, or false feet. The detached figure represents one of these appendages removed from the abdomen; the palp marked *m* carries the ova during incubation.

View of the under side of the male of *Thelphusa fluviatilis*, with the male organs. The detached figure represents one of these organs.

On this subject Professor Bell remarks:—" When we consider the almost endless diversity of form under which the species composing this class of animals appear, the astonishing discrepancy which exists in the forms and relative proportions of the different regions of the body, and other parts of their organisation for the performance of offices and functions equally various, and see that all these diversities are produced only by modifications of a typical number of parts, we cannot but be struck by so remarkable and interesting an illustration of the great economical law, as it may be termed, that *the typical structure of any group being given, the different habits of its component species or minor groups are provided for, not by the creation of new organs or the destruction of others, but by the modification in form, structure, or place, of organs typically belonging to the group.*"

One of the necessary consequences of the condition of these animals inclosed in a hard shell is the power they possess of throwing it off. If this were not the case all growth would be stopped, excepting increase of thickness in the shell by a succession of secretions from below. To allow therefore room for the expansion and growth of the body and limbs, a provision for their increase is made by means of moulting, which, as a general rule, is more frequent the younger the animal is, as indeed might be expected. Thus eight moults in the short space of seventeen days have been observed in a young *Daphnia*. [BRANCHIOPODA.] It can be easily observed in the Common Crab. [CANCER.]

In *Astacus fluviatilis*, the moult, or Ecdysis, as this process is called, is preceded by a few days of fasting and sickness, and at that time the carapace becomes loosened from the corium to which it was attached. The corium begins forthwith to secrete a new shell, which is at first soft and membranous, becomes gradually harder and harder, and is at last calcareous. When all connection with the old shell is broken off, and the corium has completely secreted the new membranous envelope, the animal begins to set about freeing itself from the old incumbrance, and becomes very restless, the symptoms of inquietude increasing in proportion as the time for emancipation draws nigh. It rubs its legs one against the other, and finally throws itself on its back. In that situation it begins to shake itself and swell itself out, till it tears the membrane which connects the carapace with the abdomen, and begins to raise the former: then it rests a while. Alternations of agitation and rest succeed each other at intervals of longer or shorter duration, the carapace is completely raised, the head, the eyes, the antennæ, are extricated. The greatest difficulty occurs in freeing the extremities, nor could they be extricated at all did not the old covering split longitudinally: and indeed it frequently happens that the Crawfish leaves a limb or two behind; and is sometimes so fettered, that it perishes from inability to extricate itself. The abdomen is the last division of the body freed, and the whole change generally takes place in half an hour. Four-and-twenty-hours, or two or three days at furthest, are necessary for the conversion of the soft and membranous integument which sheathes the corium or naked body into a firm calcareous case similar to the last, and presenting the same appendages, even to the hairs; although M. Milne-Edwards has stated that these last organs are not formed within the old ones, as supposed by Réaumur, but exist ready-formed in the new envelope, turned in towards the interior like the fingers of a glove turned in upon itself.

Mr. Spence Bate of Plymouth, who has very successfully studied the *Crustacea*, states that he has confirmed the original observation of Réaumur.

M. Milne-Edwards observes that the time occupied in the business of throwing off the shell varies considerably in different species, and that it also depends on atmospheric influences; and this observation applies equally to the number of days required for giving the new tegumentary sheath the consistency of the old shell; and he adds, that in the whole of the species which have been duly watched, especially those found on the French shores, the period which precedes and that which follows the Ecdysis is a period of inquietude and disorder. The muscles are then flaccid, the flesh is soft and watery, and the animals are considered unwholesome and unfit for food. An exception to this remark occurs in the Land-Crabs (*Gecarcinus*), which, according to the testimony of all who have spoken and written on the subject, are never so delicious as during the season of change.

At the period of Ecdysis, rounded flattened calcareous concretions (carbonate of lime), commonly called Oculi Cancrorum, are formed at the sides of the stomach of the common river crawfish. (Prep. 406, Mus. Coll. of Surg.)

Every one has occasionally been struck with the difference of size in the members of crabs and lobsters. One claw of these, and other crustaceans which have the claws, when perfect, nearly equal, is often found of its full volume, while the other is comparatively diminutive; for the animal, upon the limb receiving any injury, has the power of suddenly throwing it off, and the effort does not appear to be attended with pain, though it is frequently made when the system receives a severe shock. [ASTACUS.] The point at which the separation takes place is always in the second articulation, near the basis of the limb, and from the stump, which speedily cicatrises, a new claw buds forth with all the proper articulations, and with an entire though miniature resemblance to the rejected member. This new claw is formed within the old shell and lies folded up until the exuvia are shed, when it appears as a part of the new skeleton. If one of the limbs be severed in any other place than the usual point of separation the stump goes on bleeding, nor does it heal. In such cases the renovating process does not commence until the animal succeeds in separating the remains of the member at the proper point, and this it does by a violent muscular contraction. Some years ago there were some Land-Crabs (*Gecarcinus*) at the Garden of the Zoological Society, and the apparent ease with which they parted with their smaller legs in order to escape from any one who injudiciously took them up by those members was very remarkable. They did not seem to regard the loss at all, and ran away on the remainder of their legs as if nothing had happened. Mr. Harry Goodsir has pointed out that this power of renewing the members in the *Crustacea* depends on a small glandlike body seated at the base of each limb. This body consists of a great number of large nucleated cells, which are interspersed throughout a fibro-gelatinous mass. It is supplied by a vessel and a nerve. Mr. Spence Bate describes the development of the shell as follows:—

"Immediately above the heart, a pulp consisting of nucleated cells, areolar tissue, (and blood vessels?), is formed, extending to the internal surface of the shell, from which it is separated by a layer of pigment which gives colour to the new formation. Towards the base, that is, immediately above the heart, the cells are uniformly large and distinct, while an areolar tissue ramifies throughout the whole. As advance is made from the base, cells of less size mix with them, which increase in number as they diminish, in diameter, until they approach the layer of pigment, immediately beneath which they adapt themselves by mutual pressure into a polygonal form. The pulp extends over the whole periphery of the crab, immediately beneath the shell; the thickness of the pulp decreases with the distance from the centre; and the larger cells become fewer in number, the mass being made of the smaller cells which become the secreting organs of the future shell, which process commences previously to and is completed after the removal of the exuviæ." ('Annals of Nat. Hist.,' vol. vii.)

Of the nature of the organs of locomotion developed by the external skeleton, Milne-Edwards has given the best account:—

"The kind of solid sheath formed by the tegumentary skeleton of the *Crustacea*, and which includes in its interior the whole of the viscera and other soft parts of these animals, is required to be so constructed as not to oppose locomotion; consequently there exist, either between the different rings of the body or the various constituent elements of the limbs, articulations destined to admit of motion to a greater or less extent between these different pieces. The structure of these articulations is of the most simple kind; the moveable piece rests upon that which precedes it by two hinge-like joints, situated at the two extremities of a line perpendicular to the plane in which the motion takes place. In the internal portion of the edge of the moveable piece comprised between the joints there exists a notch of greater or less depth, destined to admit of flexion, whilst on the opposite or external side the same edge generally glides under that of the preceding piece. This kind of articulation, whilst it is the most favourable to precision of movement and to strength, has the disadvantage of admitting motion in one plane only; therefore the whole of the rings of the body, the axis of motion being entirely parallel, cannot move save in a vertical plane; but nature has introduced a kind of corrective of this disadvantage in the structure of the limbs, by changing the directions of the articular axis, whence ensues the possibility of general motions being performed in every direction. Between the two fixed points two opposed empty spaces are observed, left by the rings severally, and destined to admit of the occurrence of motions of flexion and extension. The tegumentary membrane which fills it never becomes incrusted or calcareous, but always continues soft and flexible.

"The tegumentary skeleton supplies the apparatus of locomotion with fixed points of action as well as with the levers necessary to motion. The immediate or active organs of this apparatus are the muscles, the colour of which is white, and the structure of which presents no peculiarity worthy of notice. They are attached to the pieces which they are required to move either immediately or by the intermedium of horny or calcareous tendons, which are implanted upon the edge of the segment to which they belong. To the fixed point they are most commonly attached immediately. Their structure is simple, and each segment in fact, as has already been said, being contrived to move in one fixed and determinate plane, the muscles which communicate motion to it can constitute no more than two systems antagonists to each other, the one acting in the sense of flexion, by which the segment moved is approximated to that which precedes it, the other in the sense of extension, by which the segment is brought into the position most remote from the centre of motion. The muscles that produce these opposite effects, as might have been concluded, are found implanted into the opposite arms of the lever upon which their energy is extended.

"The motions in flexion tend universally to bring the extremities and the different rings towards the ventral aspect of the body; it is consequently upon this aspect that the flexor muscles are inserted, and these are in general the more powerful. On the contrary, and in accordance with the nature of the motion produced, it is upon the superior or dorsal aspect of the segments that the extensor muscles are attached. In the trench the two orders of muscles generally form two distinct layers, the one superficial, the other deep; the former thin and sometimes absent, the second on the contrary very powerful wherever powerful motions are required. The muscles generally extend from the arc above to the one immediately below, passing for the most part from the anterior edge of the upper to the anterior edge of the lower segment. The extent and the direction of the flexion of which any segment is susceptible depend on the size of the interannular spaces above or below the ginglymoid joints; and as these spaces are in general of considerable magnitude on the ventral aspect, whilst the superior arcs are in contact, and can only ride one over another in a greater or less degree, it is only downwards that the body can be bent upon itself, while upwards, or in the sense of extension, it can hardly in general be brought into the horizontal line.

"Thus far what has been said applies more especially to the rings of the body, but the extremities present nothing that is essentially different, either as regards the mode in which the tubular segments are articulated to one another, or as regards the mode in which the muscles are inserted. Each of these indeed having but one kind of motion, and even that very limited in its extent, nature has aided the deficiency, as has been stated, by increasing the number of articulations, by which extent of motion is conferred, and in varying the direction of the articular axes, an arrangement by which the animal obtains the ability of moving in every direction, but at the expense of power, rapidity, and precision in its motions. Each segment of a limb incloses the muscles destined to move that segment which succeeds it, unless it be too short and weak for this end, in which case the muscles themselves have their origin at some point nearer to the medium plane of the body. As a general law the muscles are observed to be more powerful in proportion as they are nearer to the centre, which is to be explained by the fact that each motion they then communicate is transmitted to a larger portion of a limb, to a lever longer in that sense in which it is disadvantageous to the power. Occasionally however the two last segments of a member are converted into a sort of hand, and in this case the penultimate segment sometimes includes a muscular mass, which may surpass in power the same system in the whole of the limb besides. Those muscles that put an extremity generally into motion are attached to the sides of the thoracic cavity, and the apodemata supply them with surfaces of insertion of great extent, and very favourably situated as regards their action. They occupy the double rank of cells formed by these laminæ, but they vary too much in their mode of arrangement to admit of our saying anything generally upon this head. The motion of translation or from place to place, the only kind upon which it seems necessary to say anything here, is effected in two modes, either by the alternate flexion and extension of the trunk, or by the play of the limbs.

"In those *Crustacea* which are formed essentially for swimming, the posterior part of the body is the principal agent in enabling the animal to change its place; but here the motions, instead of being lateral, are vertical; and instead of causing the creature to advance they cause it to recede: it is by bending the abdomen suddenly downwards, and bringing it immediately under the sternum, that it strikes the water, and consequently by darting backwards that the animal makes its way through the liquid. [ASTACUS.] From what has now been said it may be imagined that the *Crustacea* whose conformation is the best adapted for swimming have the abdomen largely developed, and this is in fact what we always observe; the *Amphipoda* and *Decapoda Macroura* are examples; whilst in the walking *Crustacea*, such as the Crabs, the *Caprella*, the *Oniscus*, &c., this portion of the body attains but very insignificant dimensions. In the swimming *Crustacea* the appendages of the penultimate segment of the abdomen also become important organs of locomotion, inasmuch as they for the most part terminate in two broad horizontal plates, which, with the last segment, also become lamelliform, constitute an extensive caudal fin arranged in the manner of a fan. We have already said that the thoracic extremities alone constitute true ambulatory limbs. When destined for swimming only, their segments are lamelliform, and the palp, as well as the stem, contributes to form the kind of oar which each of them then constitutes.

"To conclude, the stemmatous portion of the thoracic extremities, whilst it still preserves the general form which we have assigned it, is modified in some cases to serve for walking as well as swimming, or to aid the animal as an instrument for burrowing with facility, and making a cavity for shelter among the sand. Thus in the Decapods that burrow, the last segment of the tarsus assumes a lanceolated form; and in the swimming *Brachyura*, the same segment, especially of the last pair of extremities (*Matuta*, for example), appears entirely lamellar."

Any one who will take the trouble of going over this excellent description with a common crab and lobster before him, will have a clear idea of the locomotive system in these animals.

We have only further to add, that in a great number of species one or several pairs of the thoracic extremities are modified so as to become instruments of prehension; sometimes it is the last segment of the limb which, acquiring more than usual mobility, bends in such a manner as to form a hook with the preceding segment; sometimes it is this penultimate segment which extends below or by the side of the last, so as to form a kind of immoveable finger with which it is placed in opposition. In the first instance these instruments are denominated subcheliform claws, in the second chelæ simply, or cheliform claws.

Claw (cheliform) of *Thelphusa fluviatilis*.

a, moveable finger; *b*, hand (manus) and immoveable finger; *c*, carpus, or wrist.

Posterior foot of *Thelphusa fluviatilis*.

a, Haunch (hanche); *b*, trochanter; *c*, thigh (femur); *d*, leg; *e*, metatarsus; *f*, tarsus, or nail.

We come now to the organs of digestion. The cheliform or subcheliform claws may be considered as ancillary to this important part of the organisation of the *Crustacea*; and there are other parts, the details of which we proceed to give before we enter at large into this part of the subject.

Jaw-feet (pieds machoires), &c., of *Thelphusa fluviatilis*.

1, right external jaw-foot; A, its internal blade, or tige; *a*, *b*, *c*, *d*, *e*, its various articulations; B, its external blade, or palp; 2, jaw of the fourth pair with its palp; 3, jaw of the third pair with its palp; 4, jaw of the second pair; 5, jaw of the first pair; 6, mandible with its palp; 7, upper lip; 8, tongue (langue) or lower lip.

The maxillary limbs above represented, which constitute the jaws in the Masticating Crustaceans, reach in them their highest development; whilst in the Sucking Crustaceans, which are parasites, and feed on the juices of other animals, a great difference of structure is, as might be expected, observable; certain parts of the apparatus being elongated into a proboscis or tube of longer or shorter dimensions adapted for sucking, and in the interior of which are two slender pointed processes that act as lancets for the purpose of perforation, in lieu of the true mandibles.

The basilar articulations of the anterior thoracic extremities in many species are employed to seize, hold fast, and in a considerable degree comminute, the food; and the most perfect development of this design is manifested in the cheliform claws of the lobsters and crabs, with all their admirable modifications for powerful prehension.

The mouth is a mere opening of the short œsophagus; nor is it furnished with a tongue—the organ so named (langue and languette) is no more than a horny and lamellar process, performing in a degree the functions of a lower lip. The œsophagus, which terminates without any interruption in the stomach, and both parts, with one striking exception in the case of the latter, which we shall presently mention, present nothing remarkable, consisting, as well as the whole of the intestinal canal, of two membranous layers, and presenting a considerable resemblance to the same part of the organisation of the higher animals. The stomach is globular and capacious, occupying much of the area of the cephalic cavity, and consisting of two distinct portions: 1, the cardiac region, surmounting the mouth and œsophagus; 2, the pyloric, placed behind the cardiac region.

Around the pylorus is situated that extraordinary apparatus of hard tubercles or sharp teeth which operate as grinding or tearing organs on the food submitted to the action of this animal mill; and though the different pieces vary considerably in different species, their greater or less development depending upon the nature of the food taken by those species, they may be traced in all the *Brachyura* and *Macroura*. In *Squilla* this masticatory framework is reduced to two half-horny pieces, with rounded projections; and, to make up for this deficiency, a branch of each mandible reaches down to the pyloric orifice.

From the pylorus the intestine proceeds direct to the vent, there being no convolution; but in the higher Crustaceans it is distinguishable into two portions, to which the names of duodenum and rectum have been applied, and which are sometimes, in the lobster for instance, separated by a valve, but more frequently are without defined limits. In the lower Crustaceans the intestine is cylindrical, and offers no difference throughout its whole length from the stomach to the vent, which is always situated in the last ring, and has its orifice closed by muscular fibres which perform the functions of a sphincter.

The liver is largely developed in many of the *Crustacea*, especially in the Decapods; indeed, no one can eat a crab or a lobster without being struck with the large proportions of this viscus, which in those species is considered so delicious. In the Edriophthalmians, on the contrary, it is almost rudimentary, there being in them only three pairs of biliary vessels, much resembling those of insects. The organ, when well developed, consists of two symmetrical portions, generally separated from each other, and composed of a collection of cæcums, which at one of their extremities discharge their secretion into excretory ducts, which being converted by their union into longer and larger vessels, pour the bile ultimately through a double channel into the pylorus. The nature of the whitish fluid secreted by the two, and, as it is said, in some cases three, elongated blind tubular worm-like organs—the first two situated on each side of the pylorus, and the third on the middle of the intestine a short way below them—is not known, nor is its use.

The two green glandular organs placed on each side of the œsophagus are supposed to act in some degree as substitutes for salivary glands.

Much has been written on the subject of the vascular system of the *Crustacea*. The following are the conclusions to which Milne-Edwards and V. Audouin came, after a careful study, as well of the anatomical disposition of the circulating apparatus of the *Crustacea*, as of the progress of the blood through its interior:—

"The circulation of the blood in these animals is accomplished in a manner very similar to what takes place in the *Mollusca*. The blood, pushed forward by the heart, is distributed to every part of the body, from whence it is returned into large sinuses situated at no great distance from the base of the branchiæ; from these sinuses it is sent on to the respiratory apparatus, which it traverses, and from which it finds its way to the heart, to recommence the same circle anew. The heart is consequently aortic and single. The heart is always found in the median line of the body, and lying over the alimentary canal, near the dorsal aspect. Its form is various; in the Decapods it is nearly square, and lies in the middle and superior part of the thorax, being separated from the carapace by tegumentary membranes only, and may be seen in the space included between the two vaults of the flanks. In structure it appears to be composed by the interlacement of numerous muscular fibres, fixed by their extremities to neighbouring parts, and passing to some distance over the aggregate at either end, so that the whole organ brings to mind such a figure as would be formed by the superposition of a number of stars the rays of which do not correspond. In the other orders this general form of the heart varies considerably, from the figure of an oblong square of rather inconsiderable size, as it occurs in the *Decapoda*, to that of a long cylindrical vessel extending through the whole length of the body, as it appears in the *Stomapoda* and the Edriophthalmians. In the former of these it gives origin to six vascular trunks, three of which issue from the anterior edge, and three from the posterior surface;

each of the six openings is closed by a valvular apparatus, which prevents the regurgitation of the blood.

"The first of the three anterior vessels is situated in the median line, and is distributed to the eyes, in consequence of which we have entitled it the ophthalmic artery. Lodged within the substance of the general tegumentary membrane, it continues its course without undergoing any subdivision along the median line through the whole length of the thorax, until, arrived opposite the eyes, it subdivides and terminates in two branches, which penetrate the ocular peduncles. On the two sides are the two antennary arteries. They run obliquely towards the antennæ, sending off numerous branches to the tegumentary membrane, in which they are at first lodged; they then plunge more deeply, sending branches to the stomach and its muscles, and to the organs of generation, between which they insinuate themselves by following the folds of the same membrane which parts them. Lastly, each of these vessels subdivides into two branches, one of which proceeds to the internal and the other to the external antenna.

"Two hepatic arteries arise from the fore part of the inferior surface of the heart, and penetrate the liver, there to be ramified; but they are only found double and distinct from one another so long as the liver is met with divided into two lobes, as it is in the crawfish and lobster.

"From the posterior part of the same surface of the heart there proceeds a large trunk, which, from its importance, might be compared with the aorta. This is unquestionably the vessel which many authors have spoken of as a great vena cava; we have entitled it the sternal artery. It bends forward, giving origin to two abdominal arteries, dips into the sternal canal, distributing branches to the different thoracic rings, as also to the first five cephalic rings, which it passes over in its course. Meeting with the œsophagus, it bifurcates, but still sends branches to the mandibles and the whole of the anterior and inferior parts of the head.

"The bulb presented by the sternal artery at its origin, in the *Macroura*, is the part which Willis characterised as auricle of the heart. As concerns the two abdominal arteries, which may be distinguished into superior and inferior, and which arise from the kind of cross which it forms almost immediately after its exit, they are in precise relationship in point of size with the magnitude and importance of the abdomen itself. In the *Brachyura* they are mere slender twigs; in the *Macroura*, on the contrary, they are capacious stems, and the inferior of the two sends branches to the two posterior pairs of thoracic extremities.

"The disposition of the first three vessels is the same in the *Stomapoda* as in the preceding species; but the great vessel which represents the heart being extended through the whole length of the body, supplies immediately other arterial branches in pairs, and in number equal to those of the rings.

"The blood returns from the different parts of the body by canals, or rather vacuities, among the tissues (for they have no very evident appropriate parietes), which terminate in the venous sinuses situated close to the branchiæ.

"In the short-tailed *Decapoda* we find no more than a double series of these sinuses included within the cells of the planes above the articulation of the extremities. They communicate with one another, and they appear to have no parieties other than laminæ of cellular membrane, of extreme tenuity, which cover the neighbouring parts. Each of them, nevertheless, receives several venous conduits, and gives origin at its superior and external part to a vessel, which, traversing the walls of the planes at the base of the branchiæ, conducts the blood to the latter organs. This is the external or afferent vessel of the branchiæ.

"We find the same lateral venous sinuses in the *Macroura;* but instead of communicating with one another athwart the thoracic septa, as is the case in the *Brachyura*, they all empty themselves into a great median vessel, which is itself a venous sinus, and occupies the sternal canal. In the *Squilla* this sinus is almost the only vessel which serves as a reservoir to the venous blood.

"The blood, after being arterialised in its passage through the capillaries of the branchiæ, is poured into the efferent vessel which runs along the internal surface of each branchia. It enters the thoracic cells in the same manner as the afferent vessel passed out from them, bends upwardly under the vault of the flanks, and thus takes its course towards the heart. It is to this portion of the canal that we have given the name of branchiocardiac vessel."

The anatomical accuracy of the above description is generally admitted; but the physiological deductions of M. Lund differ from those of Messrs. Audouin and Milne-Edwards. He regards the heart as destined to propel, not only the pure blood from the gills, but also an admixture of venous blood which enters the cavity of the heart by four orifices, seated on its dorso-lateral aspects, and distinct from those in which the branchial veins terminate. The French anatomists have objected that these orifices described by Lund are closed by a membrane; but we find them plainly shown, and provided with the valvular apparatus for preventing a reflux of the blood, in a preparation (No. 898 a.) added by Mr. Owen to the Hunterian Series illustrating the same subject in the Museum of the College of Surgeons. John Hunter had long ago arrived at the same conclusions as to the mixed condition of the blood which is sent from the heart, and in a series of elaborate researches on the circulation in the *Crustacea* and Insects, first discovered the diffused state of the venous blood in extensive and irregular venous sinuses; the general disposition of which, in the lobster, is well displayed in the four beautiful plates (15, 16, 17, and 18) illustrative of John Hunter's account of the circulating system of the lobster, in the 'Catalogue of the Physiological Collection,' vol. ii.

With regard to the circulation in the *Amphipoda*, Mr. Spence Bate has pointed out to us that there appear to be no vessels, and that the fluid circulates between the muscular structure.

The vascular system just described is regarded by most authors as a true sanguiferous system, but Professor Agassiz has stated his reasons for believing that the fluid which circulates is not blood but chyle, and that this system must be regarded as chyliferous. ('Ann. Nat. Hist.,' 1851.)

The respiration of the *Crustacea* is carried on generally by means of branchiæ. We say generally, because there are some forms where no special organs have been detected, and where it is presumed that oxygen is obtained from the water through the medium of the external tegument. But where, as in the great mass of these animals, branchial respiration is present, the variety in form and disposition of the apparatus, and in some cases the complexity of it, are very great. Thus, in the *Branchiopoda* the lamellar form of all the thoracic extremities and the two external appendages corresponding to the palp and flabellum present membranous vesicles, flat in shape, highly vascular and soft, whose office is to facilitate the action of the air upon the blood. In the *Amphipoda* and *Læmodipoda* we begin to perceive a gradual departure from this type. In the *Læmodipoda* the vesicular bodies produced by the flabelliform appendage of a certain number of pairs of the thoracic extremities, only perform the functions of branchiæ; and in the *Isopoda* the locomotive extremities cease to act as respiratory organs, the first five pairs of abdominal extremities being exclusively devoted to those duties. The *Stomapoda*, which in some cases are without determinate respiratory organs, in others present an organisation analogous to that of the Decapodous embryo, and again in the *Squillæ* and *Thysanopoda* exhibit a highly-complicated structure of branchiæ, which, though superior even to the highest type in complexity, still fall short of the perfection manifested in that type, inasmuch as the branchiæ float in the water unprotected by any envelope.

M. Milne-Edwards thus reviews the respiratory apparatus in its state of greatest complexity, commencing with it in the embryo, and following it in its progressive development. It should however be recollected that the larvæ of *Astacus fluviatilis* undergo no metamorphosis, and can hardly be regarded as typical of the *Crustacea* :—

"In the earliest periods of embryotic life of the common *Astacus fluviatilis* we discover no trace of branchiæ; but at a somewhat more advanced stage of the incubation, though still before the formation of the heart, these organs begin to appear. They are at first small lamellar appendices of extreme simplicity, attached above the three pairs of maxillary extremities, and representing the flabelliform portions of these limbs. Soon these lamellar appendages elongate and divide into two halves, one internal, lamellar, and triangular, the other external, small, and cylindrical; lastly, upon the surface of this, striæ are observed to appear, which are the rudiments of the branchial filaments. During this interval the thoracic extremities have become developed, and above their bases other branchiæ have made their appearance, presenting in the beginning the form of tubercles, and subsequently that of stilets, smooth and rounded on their surface, but by-and-by becoming covered with a multitude of small tuberculations, which, by their elongation, are gradually converted into branchial filaments similar to the preceding. During this period of the development of the branchiæ, these organs are applied, like the extremities, to the inferior surface of the embryo; but they subsequently rise against the lateral parts of the thorax, become lodged within a cavity situated under the carapace, and thus are no longer visible externally.

"The cavity destined to protect in this manner the branchial apparatus is neither more nor less than an internal fold of the common tegumentary membrane. It shows itself first under the guise of a narrow groove or furrow, which runs along the lateral parts of the thorax, below the edge of the lateral piece of the carapace. This longitudinal furrow is not long of expanding, and becomes consolidated by its superior edge with the internal surface of the carapace, which, by being prolonged inferiorly, constitutes the external wall of a cavity, the opening of which, situated above the base of the extremities, becomes more and more contracted, and ends by being almost entirely closed. The space in this way circumscribed incloses the branchiæ, and constitutes what is called the respiratory cavity of the Decapod Crustaceans.

"From what has just been said, it would appear that the embryo of *Astacus fluviatilis* presents four principal periods with reference to the state of the respiratory apparatus: 1, that which precedes the appearance of this apparatus; 2, that during which the branchiæ are not distinguishable from the flabelliform appendages of the extremities, or in which it consists of simple lamellar or stiliform processes, which appear as mere processes of other organs especially dedicated to locomotion or mastication; 3, that characterised by the transformation of these extremely simple appendages into organs of a complex structure, entirely distinct from the extremities, but still entirely external; 4, and lastly, that during which the branchiæ sink inwards, and become lodged in a cavity especially adapted for their reception, and provided with a particular apparatus destined to renew the water necessary to the maintenance of respiration.

"If we now turn to the examination of the apparatus of respiration in the different groups in which it exhibits important modifications, we shall, in the series of Crustaceans, encounter permanent states analogous to the various phases through which we have just seen the apparatus passing in the most elevated animals of the class. And in fact the first period which we have particularised above in the embryonic life of the Decapod is exhibited in the permanent condition of some inferior Crustaceans, in which not only are there no special organs for respiration, but in which none of the appendices occur with such modifications of structure as would fit them to become substitutes for the branchiæ, in which, consequently, the process of respiration, that is, the aeration of the blood, appears to take place over the surface of the body at large. The greater number of the Haustellate *Crustacea*, of the *Entomostraca* properly so called, of the *Copepoda*, and even of the *Phyllosomata*, appear to belong to this type of organisation."

The branchial character is so inherent in this class, that it is preserved even in certain species that live on the land. The Land-Crab (*Gecarcinus*), for example, would die if long immersed in water; but this, as well as other land Crustaceans, requires a certain degree of moisture to enable the branchiæ to act, and accordingly they never remove far from damp situations.

Much light has been recently thrown on the anatomy of the nervous system and senses in the *Crustacea*.

The principles derived from the study of the gradual evolution of the nervous system in the common Crawfish are—1. The isolated formation of the nervous centres, independently of one another. The ulterior junction of the organs constitutes the law of centripetal development of M. Serres. 2. A tendency to conjunction by a motion transversely. 3. A second motion in the line of the axis of the body, producing a final concentration of a greater or less number of nervous centres, originally independent of each other.

The first of these conditions is well seen in *Talitrus*. On each side of the mesial line in this genus is a chain of ganglions, conjoined by nervous centres of simple construction, flattened, and somewhat lozenge-like in their outline. Thirteen pairs of these correspond to the thirteen segments of the body, the two nuclei of each pair communicating together in the same way that each pair is connected with its antecedent and succeeding pair, by means of medullary cords in the first case, and longitudinal cords in the second. Each of these pairs in all essentials is a counterpart of the other, the cephalic ganglion, which sends branches to the antennæ and eyes, not excepted. In *Phyllosoma* the tendency to centralisation is more obvious, and in *Cymothoë* the union of the medullary nuclei is accomplished, the approximated chains forming a single longitudinal series from head to tail.

In the types, as might be expected, the centralising system is perfected by the actual conjunction of the nuclei. This subject has been fully treated by Rathke, Audouin, Milne-Edwards, and Newport. Mr. Newport's excellent and instructive paper 'On the Nervous System of the *Sphinx ligustri* of Linnæus' ('Phil. Trans.' part ii., 1834), including beautiful illustrations of the nervous system of the Lobster, and showing its identity in principle with that of the Sphinx, may be consulted with advantage.

The conclusion formed by M. Milne-Edwards in his 'Histoire' is, that "the nervous system of the *Crustacea* consists uniformly of medullary nuclei (ganglions), the normal number of which is the same as that of the members or rings of the body, and that all the modifications encountered, whether at different periods of the incubation or in different species of the series, depend especially on the approximation, more or less complete, of these nuclei (an approximation which takes place from the sides towards the median line, as well as in the longitudinal direction), and to an arrest of development occurring in a variable number of the nuclei."

Mr. Newport appears to have been the first who pointed out the double ganglionic chain in the Lobster, as being composed of two orders of fibres, forming distinct and superposed fasciculi or columns, designated by him columns of sensation and of motion.

The highest degree of nervous centralisation is found in *Maia*, according to M. Milne-Edwards, who lays down the following principles, the result of the experiments made by himself and M. Audouin, and his deep and elaborate investigation of the subject:—

"1. The nervous system is the system which entirely presides over the sensations and motions.

"2. The nervous cords are merely the organs of transmission of the sensations and of volition, and it is in the ganglions that the power of perceiving the former and of producing the latter resides. Every organ separated from its nervous centre speedily loses all motion and sensation.

"3. The whole of the ganglions have analogous properties; the faculty of determining motions and receiving sensations exists in each of these organs; and the action of each is by so much the more independent as its development is more isolated. When the ganglionic chain is nearly uniform through its whole length, it may be divided without the action of the apparatus being destroyed in either portion thus isolated,—always understood, that both are of considerable size, because, when a very small portion only is isolated from the rest of the system, this appears too weak, as it were, to continue its functions, so that sensibility and contractility are alike speedily lost. But where one portion of the ganglionic chain has attained a development very superior to that of the rest, its action becomes essential to the integrity of the functions of the whole.

"It must not be imagined, however, from this that sensibility and the faculty of exciting muscular contractions are ever completely concentrated in the cephalic ganglions, and it seems to us calculated to convey a very inaccurate idea of the nature and functions of these ganglions to speak of them under the name of brain, as the generality of writers have been led to do, seduced by certain inconclusive analogies in point of form and position.

"It is nevertheless to be remarked, that in these animals an obscure tendency to the centralisation of the nervous functions is observable in the anterior portion of the ganglionic chain; because if, in the lobster, for instance, it be divided into two portions, as nearly equal as possible, by severing the cords of communication between the ganglions belonging to the first and second thoracic rings, sensibility, and especially mobility, are much more quickly lost in the posterior than in the anterior half, and this disproportion is by so much the more manifest as the division is performed more posteriorly; still there is a great interval between this first indication and the concentration of the faculties of perception and of will in a single organ—the brain—of which every other portion of the nervous system then becomes a mere dependency." ('Cyclo. of Anat. and Phys.')

The sense of sight is possessed by the whole of the class at some period of their lives, and in the great majority the organ is of a highly complicated structure. The parasitic *Crustacea*, which undergo a kind of metamorphosis, possess eyes in the early stage of their existence, though they are subsequently obliterated; but the great mass of Crustaceans are gifted with the power of distinguishing objects through the medium of light from their birth to their death. The different forms presented by the visual apparatus are as follows:—

Smooth or Simple Eyes.—These consist of a smooth rounded transparent cornea, being a modification of the tegumentary membrane, immediately behind which and in contact with it is the crystalline lens, generally spherical, and behind this last and in contact with it is a mass of gelatine, which performs the function of the vitreous humour, and touches the extremity of the optic nerve. A thick deep-coloured pigment envelops the whole, and lines the inner surface of the eye-globe up to the point at which the transparency of the cornea begins. *Limulus* (Molucca Crab, King-Crab) affords an example of this kind of eye. The simple eyes have never been found to exceed two or three in number.

Intermediate Eyes.—*Nebalia*, *Branchipus*, and *Daphnia* present us with the first modification of a visual structure, intermediate as it were between the simple and the compound eyes. In this organisation the cornea is still undivided externally, but a number of small crystalline lenses and vitreous humours, each in its separate pigmentary sac and terminating in immediate contact with the optic nerve, presents an eye consisting of a conjunction of several stemmata or simple eyes under a common cornea—*Apus* [BINOCULUS], besides its pair of simple eyes, has also a posterior compound pair. The second modification, which is to be found in the Edriophthalmians (*Amphithoë*, for instance), brings us still nearer to the truly compound form with distinct facets. Two transparent laminæ form the cornea in these Crustaceans: the external is smooth and undivided, the internal divided into a variable number of hexagonal facets, each with a distinct cornea, which are superposed upon the conical crystalline lens, which is an ingredient in compound eyes properly so called.

Compound Eyes.—The external and internal membranes, the junction of which forms the cornea, present simultaneously the division into facets, each of which forms anteriorly an ocular compartment. Unlike the facets in the eyes of insects, which are always hexagonal, these present various figures in different *Crustacea*. In *Scyllarus*, *Galathea*, the common Crawfish, &c., for example, they are square: in *Pagurus*, *Squilla*, the Crabs, &c., they are hexagons. The crystalline humour that succeeds them immediately, is, according to M. Milne-Edwards, "of a conical form, and is followed by a vitreous humour having the appearance of a gelatinous filament, adhering by its base to the optic nerve." Each of the columns thus formed is moreover lodged within a pigmentary cell, which likewise covers the bulb of the optic nerve. "But the most remarkable circumstance is, that the large cavity, within which the whole of these parallel columns, every one of which is in itself a perfect eye, are contained, is closed posteriorly by a membrane, which appears to be neither more nor less than the middle tegumentary membrane pierced for the passage of the optic nerve, so that the ocular chamber at large results from the separation at a point of the two external layers of the general envelope." . . . . "The most remarkable modification of facetted eyes consists in the presence of a kind of supplementary lens, of a circular shape, and set within the cornea in front of each proper crystalline lens. These small lenticular bodies exist independently, and are perfectly distinct from the small corneal facets. In some cases they might be mistaken (in the *Idoteæ*, for example, where they may be perceived singly, and with their distinct circular forms), and the incautious observer led to conclude that the corneal facets are merely these lenticular bodies so much enlarged that their hexagonal or square forms result from their agglomeration in a point; but there are *Crustacea*, such as the *Callianassæ*, in which these two elements of the external cornea may be perfectly distinguished, the lenticular body being of insignificant dimensions, and occupying the centre of the corneal facet only. In general however the diameter of the lenticular body is equal to that of the corneal facet itself, so that their edges blend. Further, the lenticular bodies are most commonly evolved in the substance of the cornea; but there are cases in which, under favourable circumstances, they may be detached from it. Although the existence of these different modifications must not be considered as being exclusive, inasmuch as there are certain *Crustacea* which exhibit more than one of them at the same time, for instance, stemmata and compound eyes, the latter only are the species of visual organ encountered in the great majority of cases. Their general number is two; but these are occasionally united, so as to form a single mass, and make the animal appear at first sight as if it had but a single eye. This peculiarity of organisation can even be followed in the *Daphniæ* [BRANCHIOPODA], in the embryo of which the eyes are first seen isolated; with the progress of the development however they are observed gradually to approach each other, and finally to become united. Stemmata are always immoveable and sessile; the compound eyes with smooth corneæ however, although in the majority of cases they present the same disposition, now and then occur moveable: sometimes they are supported by a pedicle, moveable in like manner and provided with special muscles. The eyes with facets present the same modifications, and even supply important characters in classifying these animals: thus in the *Edriophthalmia* the eyes are always immoveable and sessile, whilst in the *Decapoda* and *Stomapoda* they are supported upon moveable stems of very various lengths, and which every consideration leads us to view as limbs or appendages of the first cephalic ring. It sometimes even happens that in these animals, between the outer edge of the carapace and the base of the antennæ, there occurs a furrow or cavity, within which the eyes may be withdrawn or laid flat, so as to be out of the way of injury; this groove or cavity is generally spoken of under the name of the orbit." ('Cycl. of Anat. and Phys.')

Absence of Eyes.—Mr. Westwood has recently made known through the Linnæan Society a form of *Edriophthalmia* inhabiting a deep well, a species in which there is no external appearance of eyes whatever. Mr. Newport has however, with his accustomed accuracy in dissection, pointed out that even in this case a rudimentary visual organ exists underneath the cephalic crust.

In some of the forms (*Maia*, for instance) there is a fringe of hairs on the inner side of the orbit, so placed as to perform the office of a brush in wiping the eye when brought into contact with it.

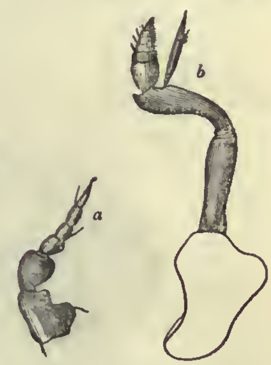
With regard to hearing, a cavity full of fluid, supplied with a nerve fitted for the perception of impulses of sound, forms the basis of the auditory system in the *Crustacea*. This apparatus appears to be assisted by certain organs, elastic membranes, and rigid stems, for instance, organised so as to vibrate under the action of sonorous undulations, or to assist such vibrations. The long rigid stem formed by the antennæ of the second pair is said to assist in this function, and, according to the highly interesting experiments of M. Savart, the addition of such a rigid stem renders certain vibrations appreciable; but in some instances no such stem exists. In many of the forms (*Maia*, for instance) there is an ossiculum auditus.

In the Museum of the College of Surgeons (Gallery, No. 1559 A) is a Hermit Crab (*Pagurus Miles*, Oliv.), prepared by Mr. Owen to show the organ of hearing, which is composed of a simple vestibular cavity situated at the under part of the basal joint of the external antennæ. The cavity is surrounded by a dense crustaceous substance, except at the internal opening, where the auditory filament of the antennal nerve penetrates it, and at the opposite side, where an elliptical opening or fenestra is left, which is closed by the acoustic membrane: the membranes of sound affect this membrane, and are transmitted to the nerve, which is exposed on the left side. (Owen, 'Cat. of Physiolog.,' series, vol. iii. part 1.)

Every lobster-pot that is baited on our coasts affords evidence that the Crustaceans are endued with the sense of smelling, but where the organ is seated is doubtful. M. de Blainville placed it in the antennæ, where it certainly does not reside, according to M. Milne-Edwards, who further states that the opinion of M. Rosenthal, who ascribes the function to a cavity which he discovered at the base of the first pair of antennæ, requires to be supported by direct experiment.

Though the *Crustacea* have no true tongue, their selection of food and the preference exercised by them, show that they are gifted with the sense of taste or a sense analogous to it. The seat of the faculty is most probably that portion of the tegumentary membrane that lines the inside of the mouth and œsophagus.

The more or less calcareous crust with which the *Crustacea* are covered forms a medium not calculated to convey external impressions of any delicacy. "Nevertheless," says M. Milne-Edwards, "in front of the head there are certain special organs which all the observations I have had an opportunity of making upon the organisation of these animals lead me to regard as parts more particularly destined to be the seat of the sense of touch. These organs are the antennæ—those slender filaments possessed of a great degree of flexibility, of motility, and of sensibility. M. de Blainville was led to regard these organs as the seat of the sense of smell; but direct and conclusive experiment has satisfied us that the destruction of the antennæ has no influence whatever on the exercise of the sense of smell: and we are on the same grounds induced to believe them destined to the exercise of the sense of touch of considerable delicacy, unless we would imagine them as the instruments of some quite peculiar sense, the existence of which would be purely hypothetical. The number and disposition of these organs vary extremely. Some of the Crustaceans at the very bottom of the series are wholly without antennæ, or are furnished with them in a merely rudimentary state. Some species have no more than a single pair; the normal number however is two pairs. In speaking of the tegumentary skeleton we have said to which of the rings these appendages belong; we shall only say further here that they may be inserted on the superior or inferior surface of the head according to the respective development of the different pieces of which this segment is composed. They do not differ less widely in their form and composition, and under this double point of view present modifications analogous to those which we have specified as occurring in the extremities."



a, right external antenna of *Thelphusa fluviatilis*; *b*, left antenna of the same. Desmarest.

As a rule the sexual organs are separate in the *Crustacea*, that is, they never co-exist in the same individual, and the reproduction is oviparous. Milne-Edwards has however described a crab in which the organs were male on one side and female on the other. Mr. Spence Bate also informs us that he has in his possession a specimen of *Corystes* in which all the characteristics are female but with male organs. The celebrated hermaphrodite lobster also ('Phil. Trans.,' 1730, p. 290) presented a different sexual organ on each side, and both the male and female portion were complete. In the more perfect *Crustacea* the analogy between the male and female organs is so great as frequently to deceive the observer at first sight.

In the male organs of the Common Crab the testis is grape-like, the cluster consisting of four principal lobes formed of numerous worm-like delicate canals convoluted into pellets. The first portion is placed in the front of the thorax, and terminated in a large coiled-up vessel situated on the side of the stomach; behind, and connected with it, is the deferent vessel, a convoluted canal of some size and of a milky colour. It is twisted about the thorax, and at last penetrates the cell of the last pair of limbs, opening outwardly on the basilar piece, and again passes into the styliform organs, which are true intromittent organs. The intercourse of the sexes only takes place during the time that the female is moulting.

"The female reproductive apparatus of the *Crustacea*," says Milne-Edwards, "in the highest state of complication consists of an ovary, an oviduct, and copulatory pouches. The ovaries in the *Decapoda brachyura* resemble four cylindrical tubes placed longitudinally in the thorax, and divided into two symmetrical pairs, each opening into a distinct oviduct, yet communicating with one another by a transverse canal, and by the intimate union of the two posterior tubes in a portion of their length. The oviducts as well as the ovaries are of a whitish colour; they are short, and become united in their course to a kind of sac, the neck of which extends to the exterior of the animal's body; there is one of these on each side, and they are known by the name of the copulatory pouches. It is into these reservoirs that the male pours the spermatozoa, which are simple round cells, and are applied to the ova as they pass in succession along and out of the oviducts. These, after a course which is never long, terminate at the vulvæ—openings formed in the sternal pieces of the segment which supports the third pair of ambulatory extremities.

"The *Anomoura* and *Macroura* have no copulatory pouches, and their vulvæ are situated on the basilar joint of the ambulatory extremities of the third pair. The mode in which fecundation is accomplished in these genera is consequently much less apparent than in the *Brachyura*. Many writers are of opinion that this operation takes place in the interior of the ovaries, a process that appears by no means feasible on account of the inequality of development of the ova, which is such that the last of them are not in being even long after the first have been expelled.

"The female Crustacean does not abandon her eggs after their extrusion. Those of the Decapods preserve them under their abdomen by means of the abdominal extremities modified in their structure. The *Edriophthalmia*, again, keep them under their thorax by means of the flabelliform appendages of the extremities belonging to the region; whilst the inferior genera, such as the *Entomostraca*, &c., have suspended to the external orifices either horny tubes or a pair of membranous sacs which contain and transport them from place to place. These varieties in the accessory organs of generation are in many cases sufficient to distinguish the sexes; thus, among the *Decapoda brachyura*, the females are known at a glance by their wider abdomen, which is sometimes of such dimensions as to cover the whole sternum."

The following cuts will convey some idea of the relative position of the parts in the carapace.

Common Shore-Crab (*Carcinus mænas*), open.

a, a, a, a, a, stomach; *b, b*, genital organs; *c*, heart; *d, d*, branchiæ; *e, f, f*, liver.

Fresh-Water Cray-Fish (*Astacus fluviatilis*), open.

a, a, a, a, stomach; *b*, genital organs; *c*, heart; *d, d, d, d, d*, liver; *e, e*, branchiæ; *f, f*, muscles of the mandibles.

At one time it was supposed that the young of the *Crustacea* underwent no change after being hatched from the ova, and this was formerly given as a distinction between the Insects and *Crustacea*. We now know however that those anomalous forms of animal life known by the name of *Zoea*, and referred by Bosc and others to the Entomostracous *Crustacea*, are truly the young of the higher forms of *Crustacea* undergoing metamorphosis. [BRANCHIOPODA.] The facts of this process were first made out by Mr. V. Thompson in the year 1823, and subsequently the instances in which it has been observed are so numerous that there can be no doubt that metamorphosis takes place in all the Marine Decapodous *Crustacea*. In the various forms of *Macroura*, the metamorphosis is less decided than in the *Brachyura*; and in the Fresh-Water Cray-Fish (*Astacus fluviatilis*) no change takes place at all. These have led some observers to doubt the correctness of Mr. Thompson's conclusions. One of the last and most important series of investigations conducted on this subject was by Mr. R. Q. Couch, of Penzance, Cornwall, who, dissatisfied with the uncertainty and contradiction of former testimony, resolved to investigate the matter for himself. He observed the metamorphosis to occur in the following genera:—*Cancer*, *Zantho*, *Pilumnus*, *Carcinus*, *Portunus*, *Maia*, *Galathea*, *Homarus*, and *Palinurus*. The details of Mr. Couch's observations were published in the 'Proceedings of the Cornwall Polytechnic Society' for 1843.

Professor Bell says, "Eliminating, therefore, this exceptional case (that of *Astacus fluviatilis*), it will be found that the fact of a metamorphosis has been demonstrated with more or less success in no less than seventeen genera of the Brachyurous order of the *Decapoda*, in which order the phenomenon is most decided and obvious, belonging to the families *Leptopodiadæ*, *Maiadæ*, *Canceridæ*, *Portunidæ*, *Pinnotheridæ*, *Grapsidæ*, *Gecarcinidæ*. In the Anomourous order it has been shown in the genera *Pagurus*, *Porcellana*, and *Galathea*, and amongst the *Macroura* in *Homarus*, *Palinurus*, *Palæmon*, and *Crangon*."

The following is Mr. Couch's account of the changes which take place in the Common Shore-Crab (*Carcinus mænas*). Having procured some specimens of the Crab laden with ripe ova, he says—"These were transferred to captivity, placed in separate basins, and supplied with sea-water, and in about sixteen hours I had the gratification of finding large numbers of the creatures alluded to above swimming about with all the activity of young life. There could be but little doubt that these creatures were the young of the captive crabs. In order however to secure accuracy of result, one of the crabs was removed to another vessel and supplied with filtered water, that all insects might be removed; but in about an hour the same creatures were observed swimming about as before. To render the matter if possible still more certain, some of the ova were opened, and the embryos extracted, but shortly afterwards I had the pleasure of witnessing beneath the microscope the natural bursting and escape of one precisely similar in form to those found so abundantly in the water. Thus then there is no doubt that these grotesque-looking creatures are the young of the *Carcinus mænas;* but how different they are from the adult need hardly be pointed out. When they first escape they rarely exceed half a line in length. The body is ovoid, the dorsal shield large and inflated; on its upper edge and about the middle is a long spine, curved posteriorly, and rather longer than the diameter of the body, though it varies in length in different specimens; it is hollow, and the blood may be seen circulating through it. The upper portion of the body is sap-green and the lower semitransparent. The eyes are large, sessile, and situated in front, and the circumference of the pupil marked with radiating lines. The lower margin of the shield is waved, and at its posterior and lateral margin is a pair of natatory feet. The tail is extended longer than the diameter of the shield, and is composed of five equal annulations besides the terminal one; its extremity is forked, and the external angles long, slender, pointed, and attached to the last annulation by joints. Between the external angles, and on each side of the median line, are three lesser spines, also attached to the last ring by joints. Between the eyes and from near the edge of the shield hangs a long stout and somewhat compressed appendage, which as the animal moves is reflexed posteriorly between the claws. Under each eye there is also another appendage, shorter, and slightly more compressed. The claws are in three pairs; each is composed of three joints, and terminates in four long slender hair-like appendages. These claws are generally bent on the body, but stand in relief from it. If the animal be viewed in front the lower margin of the dorsal shield will be found to be waved into three semicircular festoons, the two external of which are occupied by the eyes, and between which the middle one intervenes; the general direction of the claws will be seen to be at right angles to the body. As the young lies inclosed within the membranes of the egg, the claws are folded on each other, and the tail is flexed on them so far as the margin of the shield; and if long enough is reflected over the front of the shield between the eyes. The dorsal spine is bent backwards, and lies in contact with the dorsal shield; for the young, when it escapes from the egg, is quite soft, but it rapidly hardens and solidifies by the deposition of calcareous matter in what may be called its skin. The progress of this solidification may be very beautifully observed by watching the circulation in the dorsal spine. When the creature has just effected its liberation from the egg, the blood globules may be seen ascending to the apex, but as the consolidation advances the circulation becomes more and more limited in its extent, and is finally confined to the base. These minute creatures, in this early state of their existence, are natatory and wonderfully active. They are continually swimming from one part of the vessel to the other, and when observed free in their native pools, if possible even more active than when in confinement. Their swimming is produced by flexions and extensions of the tail, and by repeated beating motions of their claws; this, together with their grotesque-looking forms, gives them a most extraordinary appearance when under examination. As the shell becomes more solid they get less active, and return to the sand at the bottom of the vessel to cast their shells, and acquire a new form. They are exceedingly delicate, and require great care and attention to convey them through the first stage, for unless the water be supplied very frequently and in great abundance they soon die. The second form of transmutation is equally as remarkable as the first, and quite as distinct from the adult animal. In the species now under consideration this second transformation is marked by the disappearance of the dorsal spine; the shield becomes flatter and more depressed: the anterior portion more horizontal and pointed, the three festoons having disappeared. The eyes, from being sessile, are now elevated on foot-stalks; the infra-orbital appendages become apparently converted into antennæ. The claws undergo an entire revolution; the first pair become stouter than the others, and are armed with a pair of nippers, the others being simple, but the posterior pair are branched near the base, and one of the branches ends in a bushy tuft. The tail is greatly diminished in its relative size and proportions, and is sometimes partially bent under the body, but is more commonly extended. This form is as natatory as the first. They are frequently found congregating around floating seaweed, the buoys and strings of the crab-pot marks, and other floating substances, both near the shore and in deep water. Their general form somewhat resembles a *Galathea*."

Subsequently to this second change a third takes place, in which the animal loses its tail, and becomes more like to the form it assumes in adult age. In the various species different forms are assumed, but they can all be referred to departures from the typical form of the family. On this point the following observations of Mr. Couch are very interesting:—

"So far as my observation has extended, it appears probable that the metamorphosis of the young in their progress to adult growth is not universal in all Crustaceans; but, on the contrary, that the families in which the eyes are always sessile in their adult growth, and which do not exuviate or voluntarily throw off their limbs, are in the habit of producing their young perfectly formed: and an opportunity that has occurred to me of observing the process of early development in the common lobster will tend to establish the existence of a law of nature as applicable not only to it, but probably also to all the genera of this extensive family or class, that is, the Long-Tailed *Crustacea*; which law is, that the greatest extent of metamorphosis is in those genera which are of the highest rank in the series, that is, the Short-Tailed, or Crabs, that even at their birth the Long-Tailed genera, as the Lobster, approach more closely to the ultimate size of the parent; and, what is still more extraordinary than all beside, that so long as the lobster in particular retains the eyes sessile, the progress of development and growth is conformed to what is the perpetual mode of growth of the permanently sessile-eyed races; and it is only when the crust has become fully extended and hardened, and thus the exuviation is rendered necessary, that the eyes become elevated on foot-stalks, and the adult form and habit are completely established."

With regard to the arrangement of the *Crustacea*, almost every writer on this class of animals has embodied his own views in their classification. Among the principal zoologists who have written on the subject, the names of Cuvier, Desmarest, Latreille, and Leach will, with many others, occur to the observer. We select the arrangement of M. Milne-Edwards, because it is founded on anatomical investigation, and on actual experiment made in a great many instances by himself and M. Audouin. He makes the *Crustacea* to consist of two great divisions.

1st. Those which have the mouth furnished with a certain number of organs destined in an especial manner to the prehension or division of the food.

2nd. Those which have the mouth unfurnished with special prehensile or masticatory organs, but surrounded by ambulatory extremities, the bases of which perform the part of jaws. We shall take this second division first, because it contains but one order, namely, the *Xyphosura*. Example, *Limulus*.

But it is to the first division that the great mass of the Crustaceans belong, and these are subdivided into two great groups.

1st. The *Maxillosa*, or *Mandibulata*, which possess a mouth armed with jaws, &c.

2nd. The *Edentata*, or *Haustellata*, whose mouth is prolonged in the shape of a sucker.

I. Maxillosa.

The *Maxillosa* are separated into four great sections:—

1. *Podophthalmia.*

These almost always possess true branchiæ; pedunculated and moveable eyes; feet or extremities vergiform, partly prehensile, partly ambulatory; and a thorax covered by a carapace.

The *Podophthalmia* contain two orders, the *Decapoda* and *Stomapoda*.

1. The *Decapoda*, whose branchiæ are fixed to the sides of the thorax, and are inclosed in special respiratory cavities. The oral apparatus is composed of six pairs of members. There are five pairs of thoracic extremities, which are generally ambulatory. The *Decapoda* are divided into 1st, the *Brachyura* (*Cancer, Portunus, Grapsus, Podophthalmis, Thelphusa, Gecarcinus, Ocypode, Pinnotheres, Maia, Leucosia, Dorype*, &c.); 2nd, the *Anomoura* (*Dromia, Ranina, Pagurus, Hippa, Remipes, Brigus*, &c.); 3rd, the *Macroura* (*Astacus, Scyllarus, Palæmon, Palinurus, Penæus*, &c.).

2. *Stomapoda*, whose branchiæ are external; sometimes rudimentary, or none. Oral apparatus composed in general of three pairs of members. Thoracic extremities prehensile, or for swimming; generally six or eight pairs. (*Mysis, Phyllosoma, Squilla, Thysanopodes, Alima, Cynthia*, &c.).

2. *Edriophthalmia.*

True branchiæ none, but replaced by certain portions of the extremities modified for this in their structure; eyes sessile; thoracic extremities ambulatory, almost always consisting of seven pairs; no carapace. The *Edriophthalmia* contain three orders, namely, the *Amphipoda*, the *Læmodipoda*, and the *Isopoda*.

1. *Amphipoda*.—These have the flabella of the thoracic extremities vesicular, and subserving respiration. The abdomen is very much developed, subserving locomotion, and is furnished with six pairs of limbs, the first three of which differ in form and use from the last three. (*Grammarus, Talitra, Hyperia, Phronima*, &c.)

2. *Læmodipoda*.—Abdomen rudimentary. Flabella of the thoracic extremities vesicular, and subserving respiration. (*Proto, Caprella, Cyanus*, &c.)

3. *Isopoda*.—Abdominal extremities well developed; the first five pairs lamellar, and subserving respiration. Abdomen well developed. (*Idotea, Spheroma, Cymothoa, Iona, Bopyrus*, &c.)

3. *Branchiopoda.*

No true branchiæ, but thoracic extremities lamellar, membranous, and so formed as to be subservient to respiration. The *Branchiopoda* contain two orders, *Phyllopoda* and *Cladocera*.

1. *Phyllopoda*.—No bivalve shell-like covering. Extremities natatory, and in considerable numbers (from 8 to 22). (*Limnadia, Chirocephalus, Nebalia*, &c.)

2. *Cladocera*.—Carapace in form of a bivalve-shell. Thoracic members five pairs. (*Daphnia*, &c.)

4. *Entomostraca.*

No branchiæ nor any modification of organ apparent to supply the place of these. Eyes sessile, and commonly united into a single mass. The *Entomostraca* contain two orders, namely, the *Copepoda* and *Ostrapoda*.

1. *Copepoda*.—Body divided into distinct rings, neither carapace nor valvular envelope. Thoracic and oral members in considerable numbers. (*Cyclops, Pontia*, &c.)

2. *Ostrapoda*.—Body without very evident annular divisions, and entirely inclosed under a large dorsal shield having the form of a bivalve-shell. Extremities in very small number. (*Cypris*, &c.)

II. Edentata.

The *Edentata* contain three orders, namely, the *Araneiformes*, the *Siphonostomata*, and the *Lernæiformes*.

1. *Araneiformes*.—Extremities rod-like, long, adapted for walking. (*Pycnogonon, Nymphon*.)

2. *Siphonostomata*.—Extremities not adapted for walking; partly lamellar, partly prehensile. (*Caligus, Dichelestion, Nicothoa*, &c.)

3. *Lernæiformes*.—Extremities rudimentary, body presenting anormal forms. (*Lernæa*, &c.)

Fossil Crustacea.

Various forms of *Crustacea* have been found throughout the whole series of fossiliferous rocks. Although their shells are not so well calculated to resist decomposition as those of the *Mollusca*, and even the *Echinodermata*, yet a considerable number of species have been recorded, especially of the smaller forms. Bronn, in his list of extinct and recent species of the families of animals, gives the following as the result amongst the *Crustacea*:—

	Extinct.	Recent.
Entomostraca	563	143
Malacostraca	244	541

These numbers are probably higher for the extinct and lower for the recent than the present state of our knowledge would warrant.

One of the most interesting groups of extinct *Crustacea*, are those found in the Silurian Rocks, and which from their most prevalent forms may be called Trilobitic. [Chirocephalus; Trilobites.] The species in this formation are more abundant than at any subsequent period, and present greater departures from the types of existing *Crustacea*.

In the Devonian Rocks the *Crustacea* are represented also by Trilobitic forms, some of which, as *Brontes*, are characteristic and remarkable. This fossil which was at first supposed to be a fish, has been referred by Agassiz to the *Crustacea*. It was not unlike a lobster in shape, but was four feet in length. Its claws were of gigantic size. The shield was sculptured with delicate markings, looking like scales. The tail was continuous, and so large that a lobster of ordinary size might stretch its entire length on it.

The Carboniferous group of Rocks presents us with a considerable number of species of *Crustacea*, but they principally belong to the groups of smaller forms referred to the Entomostracous *Crustacea*. [Entomostraca.] We have however, in certain forms, as in those species which have been referred to *Apus, Asaphus, Daphnia, Cypris*, and *Limulus*, approaches to the forms which exist at the present day. Of the Ostracodous *Crustacea* Professor M'Coy has figured, and has described twenty-two species from the Carboniferous Limestone of Ireland; M. de Koninck six species in Belgium. The *Ostracoda* described in the Carboniferous and Silurian Rocks amount to about thirty-seven species.

The Permian system, embracing the Magnesian Limestone Formation of England, affords the remains of no other Crustacean but those belonging to the *Entomostraca* or *Ostracoda*.

In the Oolitic Rocks the species of *Crustacea* are not numerous, but the forms so closely resemble those more common at the present time as to afford some difficulty in distinguishing them. The specimens discovered in British rocks have all been referred to the genus *Astacus*, of which Professor Tennant gives four species—*A. leptomanus A. mucronatus, A. scabrosus, A. rostratus*. The Lithographic Limestone of

Solenhofen, affords several examples of the *Crustacea* of this formation. It contains species of *Limulus*, and also of a genus *Ergon* allied to the recent genus *Astacus*.

In the Chalk, specimens of *Crustacea* are found representing both the lobster and the crab. The following list of species is given by Tennant in his 'British Fossils:'—*Astacus Leachii, A. longimanus, A. Sussexianus, Orithrya Bechei, Pagurus Faujasii, Scyllarus Mantellii.*

In the Tertiary beds the remains of *Crustacea* are not very numerous, but their forms are many of them identical with those now existing. Many forms remain yet to be discovered, especially among the minute *Entomostraca* [CYTHERE], of which only a few have yet been described.

(Bell, *History of the British Stalk-Eyed Crustacea;* Owen, *Lectures on Comparative Anatomy;* R. Jones, *Outlines of Animal Kingdom; Cyclopædia of Anatomy and Physiology*, article *Crustacea;* Spence Bate, in *Annals of Natural History;* Milne-Edwards, *Histoire Naturelle des Crustacées;* Rathke, *Untersuchungen über die Bildung und Entwickelung des Fluss-Krebses;* J. Soc.; Baird, *History of British Entomostraca*—Ray Soc.; Burmeister, *The Organisation of Trilobites*—Ray Soc.)

CRYOLITE, a species of Mineral, a fluate of soda and alumina. It is of a white colour, or reddish, or yellowish-brown, and its streak is white. It occurs in crystalline masses, but its primary form has not been observed; its cleavage is parallel to the terminal and lateral planes of a rectangular prism. Its specific gravity is from 2·94 to 2·963. It is not so hard as fluor-spar, is translucent, and by immersion in water becomes transparent. It fuses by the blow-pipe into a transparent globule, which becomes opaque on cooling.

It is found at Arksut-fiord, in West Greenland. According to the analysis of Vauquelin it consists of—

Fluoric Acid and Water	47
Soda	32
Alumina	21
	——100

CRYPTOCE'PHALUS (Geoffroy), a genus of Coleopterous Insects of the section *Cyclica* and family *Chrysomelidæ*. It is known by the antennæ being filiform, nearly as long as the body; palpi with the joints nearly of equal thickness; head deeply inserted into the thorax, small and vertical; thorax nearly as broad as the elytra; body short and cylindrical.

Upwards of twenty species of this genus are found in this country. The most abundant species is *Cryptocephalus sericeus*. This little beetle is of a brilliant golden-green colour, and about a quarter of an inch in length; it is found during the month of July in the flowers of the *Hieracium* and similar plants.

Cryptocephalus Lineola is about the same size as the last, and is found on oak-trees, hazels, &c.; it is black and glossy; the elytra are red, and have an oblong dash in the middle, and the suture and outer margin black.

CRYPTOCONCHUS, a name given by some zoologists to those *Chitonidæ* whose shelly plates are entirely hidden by the investing border. [CHITONIDÆ.]

CRYPTODIBRANCHIATA, De Blainville's name for the Cephalopodous *Mollusca*. [CEPHALOPODA.]

CRYPTOGA'MIA, the twenty-fourth class of the Linnæan System of Plants. It includes all those genera the flowers of which are either altogether absent, or formed upon a plan different from that of ordinary plants. Ferns, Mosses, Lichens, *Algæ*, *Fungi*, with their immediate allies, form the class, which is the same as the Acotyledons of Jussieu and the *Cellulares* of De Candolle. It is often employed to distinguish the Flowerless from the Flowering Plants, which are thence called *Phanerogamia*. [LICHENS; LYCOPODIACEÆ; ALGÆ; FUNGI; DIATOMACEÆ; ACROGENS; DESMIDEÆ.]

CRYPTOLITE. [CERIUM.]

CRYPTONYX. [TETRAONIDÆ.]

CRYPTO'PHAGUS (Herbst), a genus of Coleopterous Insects of the family *Engidæ*. They are minute beetles, which are found in *Fungi* and in flowers, and some of the species are common in damp cellars.

The *Cryptophagi* are seldom more than an eighth of an inch in length, generally of a pale brown colour, and more or less pubescent. They have the antennæ rather thick and 11-jointed; the basal joint is thicker than the seven following, and the three apical joints form an elongated knob; the terminal joint is somewhat conical, and the two preceding joints are cup-shaped; the head is nearly triangular, inserted into the thorax as far back as the eyes; the thorax is nearly square, and the lateral margins are more or less denticulated; they usually exhibit an obtuse tooth-like process in the middle; the elytra are elongate; the sides are generally straight and parallel, or nearly so, and the apex is rounded.

About sixteen species have been found in this country. *Cryptophagus bituberculatus* is sometimes abundant in puff-balls, and probably inhabits other *Fungi*.

CRYPTOPROCTA. [VIVERRIDÆ.]

CRYPTORHY'NCHIDES (Schönherr), a family of Coleopterous Insects belonging to the section *Rhynchophora*, the species of which are chiefly distinguished by their possessing a groove in the chest into which the rostrum is received when at rest.

This family contains upwards of twenty genera, of which the genus *Cryptorhynchus* may be considered as the type. The characters of this genus are:—Antennæ 12-jointed, short, funiculus 7-jointed, the first joint rather longer than the rest; club oval or oblong oval; rostrum moderate, rather arched; thorax often broader than long, narrower towards the apex, and furnished with tufts on the anterior part; elytra somewhat ovate, covering the abdomen; scutellum distinct; legs moderate, femora often armed with a spine beneath.

Of this genus upwards of ninety species are known, only one of which inhabits England, *Cryptorhynchus Lapathi*. This beetle is less than half an inch in length, and of a dull brownish-black colour; the thorax is whitish at the sides, and is furnished on the upper part with five black tufts—two on the anterior part near the eyes, and three in a line a little behind these, one in the middle of the thorax, and one on each side; the elytra are brown-white at the base, and white at the apex, and are studded with numerous black tubercles.

C. Lapathi is found on willows, and is sometimes tolerably abundant in osier-beds in the south of England: when touched, like most of its tribe, it contracts its legs and falls to the ground.

CRYPTOSTOMA. [CHISMOBRANCHIATA.]

CRYPTURUS. [TETRAONIDÆ.]

CRYSTALLINE LENS. [EYE.]

CRYSTALLO'GRAPHY, or the doctrine of the relations of crystalline forms, is in strictness an application of solid geometry; but it is practically allied to Mineralogy, and may also be regarded as a subsidiary department of that science.

Minerals occur very generally in the state of crystals, that is, in certain definite and symmetrical forms, and these are regarded as crystals whether they are transparent or opaque.

A solid figure, of the shape of a common die used in games of chance, frequently occurs among minerals, and is then termed a Cube or Cubic Crystal.

If the corners of this cube were to be cut off so as to take away equal portions of the three adjacent edges, a new figure would be produced which is said to be derived from the cube.

If the edges were to be all cut off so as to produce new surfaces, making equal angles with the adjacent sides of the cube, another derived form would result. In these cases the cube would be deemed the primary form, and the derived figures secondary forms of the cube.

Minerals are very generally known by their primary forms; but as these are of different kinds, and as natural crystals are very generally found in secondary forms, from which the primary is to be inferred, a knowledge of the exact relations of the primary and secondary forms is requisite to enable the mineralogist to determine the primary from the secondary, and hence to arrive at a knowledge of the mineral to which any given crystal belongs.

Our subject may therefore be considered under three heads, namely:—

1. Primary Forms.
2. Secondary Forms.
3. The Laws of Derivation, or the mutual relations of the secondary and primary.

We must however premise a few definitions.

What we have called the corners of the cube will be termed its Solid Angles, and so of the corners or points of all other figures.

A solid angle, or edge cut off so as to produce a new surface, or Plane as it is termed, is said to be truncated.

The series of forms resulting from each of the primary forms constitutes a peculiar System of Crystallisation; there are consequently as many different systems as there are different kinds of primary forms.

A Prism is a solid figure, having any number of sides with parallel edges, and its two ends parallel.

A Right Prism is one which stands upright when placed on a table; if it overhangs the base in the direction of an edge or diagonal it is termed oblique, and if an oblique prism is again oblique in the direction of a second edge or diagonal it is doubly oblique. The bases of doubly oblique prisms are usually oblique-angled parallelograms.

The edges of the sides, and the side planes of a prism, are termed lateral, and those of the ends terminal edges and planes.

1. Primary Forms.

These are in some degree arbitrarily assumed, as it appears from the three following figures, showing the relation between the cubes and angular octahedron.

Fig. 1 is a Cube.

Fig. 2, a Cube, with its solid angles truncated.

Fig. 3, an 8-sided figure or octahedron, which is produced when the solid angles are so deeply truncated as to obliterate all the faces of the cube.

Now it is, mathematically speaking, indifferent whether we take the cube or the octahedron as the primary form of all the derived figures of this system of crystallisation; for it may be readily perceived, from an attentive comparison of the following figures, that new planes which might be produced on the octahedron by the truncation of its solid angles would correspond in position with the faces of the

Fig. 1.

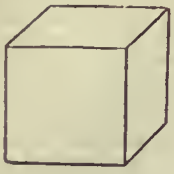


Fig. 2.

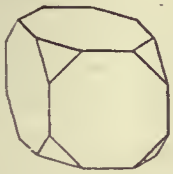

Fig. 3.

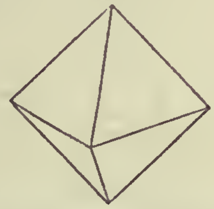

cube, and those which would result from the truncation of its edges would correspond in position with those which would result from the truncation of the edges of the cube. The cube might therefore be regarded as the secondary form of the octahedron, arising from the truncation of its six solid angles. Relations of the same nature subsist among the original and derived figures belonging to each kind of the primary forms except the rhomboid. The reason for preferring the one or the other of these as the primary will be considered when we treat of the relations of the different forms of crystals.

We have, for reasons which we shall then state, assumed the following figures as the primary or fundamental forms of all known crystals.

The Cube, *fig.* 1.

The Square Prism, in which, supposing the base of this prism to be of the same dimensions as a side of a given cube, and this and the cube to be both standing on a table, the upright edges would be longer or shorter than those of the cube.

A Right Rhombic Prism, *fig.* 4.
An Oblique Rhombic Prism, *fig.* 5.
A Double-Oblique Prism, *fig.* 6.
A Rhomboid or Rhombohedron, *fig.* 7.

Fig. 4.

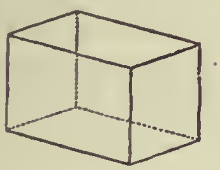

Fig. 5.

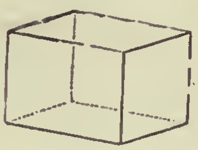

Fig. 6.

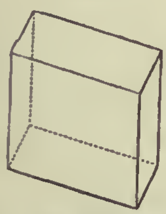

Fig. 7.

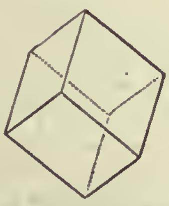


The Cube being bounded by six equal square planes, the minerals which assume this form are not distinguishable by the figure of their crystals; but minerals which occur under the other forms may generally be distinguished as follows:—

Those which can be referred to square prisms, by the different proportions which, in each particular case, the lateral edges bear to the terminal edges; and those which belong to the other prisms and to the rhomboid, by the angles at which their planes intersect each other. The ratios of the edges of square prisms may be determined by known algebraical formulæ from the angular measurement of some of the secondary forms, and the angles at which the planes of the other forms meet, may, in many cases, be ascertained by measurement with an instrument called a Goniometer, but in others they must be deduced mathematically from some of their respective secondary forms.

These six primary forms stand in certain relations to each other, which it may not be useless to point out. If the lateral edges of the cube be supposed to be longer or shorter than the terminal edges, a square prism, as we have already seen, would be produced; if two opposite lateral edges of a square prism could be pressed towards each other, the parallelism being kept, a right rhombic prism would be formed; if this prism could be pressed in the direction of either of the diagonals of its terminal plane, so as to make the figure overhang the base in that direction, an oblique-rhombic prism would be represented; and if again pressed in the direction of the other diagonal, so that it would overhang the base in both directions, a doubly-oblique prism would be formed. If we suppose a cube to be made to stand on one of its solid angles by placing the fingers on an opposite one, and if, while held in this position, the two solid angles could be pressed nearer together or drawn further apart, the altered cube would become a rhomboid.

2. Secondary Forms.

These might be produced, and are most conveniently described, by supposed truncations of the solid angles or edges of any of the preceding forms; but as in nature the most minute crystals appear in the shape of secondary forms, it is to be inferred that these modifications of the primary are occasioned by some natural influence operating upon the first germ of the crystal, and continuing during the period of its increase in size.

Secondary Crystals are sometimes altered from the primary only by single sets of planes replacing some of the solid angles or edges; in other cases both the solid angles and edges are replaced by planes in the same secondary crystal; and in others, several different sets of planes appear replacing the solid angles and edges of the same crystals, and producing very numerous and complicated secondary forms. Thus it occurs that the solid angles of the cube are sometimes replaced by three and sometimes by six symmetrical planes, of which several sets may occur on the same crystal, and perhaps with other planes replacing the edges. Similar changes of figure may also occur on each of the other kinds of the primary forms, thus producing the different systems of crystallisation before referred to.

The number of known secondary forms belonging to each system is already very great; in one mineral, carbonate of lime, they amount to many hundreds; but thousands and tens of thousands more might occur under the operation of only a few of the laws of which we shall afterwards treat.

Among the secondary forms of crystals there are some which differ in their characters from those already described. Let us suppose two diagonal lines to be drawn through opposite angles, and crossing each other on the faces of the cube. It may be observed, by referring to *fig.* 2, that the solid angles at the extremities of all these diagonals are truncated to produce the octahedron; but it sometimes happens that the solid angles at the extremities of only one of those diagonals on one plane, and a transverse diagonal on a parallel plane are truncated, producing a four instead of an eight-sided secondary figure; these are termed *hemi* forms, from their presenting only half the number of planes which might be expected from the symmetry of the primary crystal. These defective figures, as they may be termed, from their wanting the number of faces which might be expected on the crystal, are frequently troublesome to the mineralogist, and occasionally mislead him; but there is another, of a much more capricious deviation from the regularity of the simple forms, which is still more troublesome than the preceding; these are what have been termed Hemitrope and Twin Crystals. In twin crystals the two individuals are united in such a manner that if one of them be made to describe a half-revolution round an axis perpendicular to a plane, which is either a face of one of the crystals or which might be one in virtue of the laws of crystallography, it comes into the position of the other.

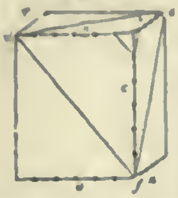
Twin Crystals are produced by the union of two or more crystals according to some regular plan, so that if any number of twin crystals of the same kind of mineral should be found, they would be fashioned in the same manner. Hence these apparently capricious composite figures are subject to definite laws, and are not the results of merely accidental aggregation. There are also two other classes of irregular forms of crystals, one of which, termed by Haüy 'Epigene,' occurs where a crystallised mineral has undergone a chemical change without disintegration or suffering any change of figure; the form in the altered state of the mineral not being proper to the new substance, but remaining that of the original body.

The other class, termed Pseudomorphous, appears as if they had been produced in moulds resulting from the destruction of crystals of other substances which had been inclosed or imbedded in them, and which moulds being filled with some new kind of mineral, the new and intrusive matter assumes the form of the originally inclosed body, and one altogether foreign to its proper shape.

3. The secondary forms of crystals are not derived from the primary by accidental and indefinite truncations of the solid angles and edges, but according to known and definite laws, so that all the possible alterations of figure which any given primary form can undergo, might be determined à priori, if the extreme limits of the relative proportions of the edges considered to be cut off in producing new planes were known. Within well ascertained limits however many thousand of possible secondary forms, belonging to each kind of primary, might be determined with absolute precision.

The laws according to which any secondary planes are produced are termed the laws of those planes. To illustrate the nature of these laws, let *fig.* 8 represent a square prism, whose edges *a b c* are each divided into any equal number of parts, which parts are consequently proportional to the respective edges. Now a new plane, which should cut off one proportion from each of the edges *a b c*, would evidently be parallel to the plane *d e f*, whose edges would coincide with the diagonals of the primary planes. It would carry us beyond the limit to which we must restrict this paper, if we were to enter upon a geometrical consideration of these lines, and we shall therefore confine ourselves to this statement, that if, on any square prism, we find a set of planes truncating its solid angles, and if we assume the edges of these planes to be respectively parallel to the diagonals of the primary planes, the ratio, or comparative lengths of the edges *a* and *c*, may be found, and thus the distinction between prisms of different heights belonging to different minerals may be ascertained. Crystals belonging to the other primary forms may generally be distinguished, as we have already stated, by measurement of the angles at which the planes severally incline to each other. But in order to investigate the laws of their respective secondary planes, we require to know the comparative lengths of the lateral and terminal edges, which may be found by means analogous to those we have just described. The rhomboid however, whose edges, like those of the cube, are all equal, does not require this preliminary investigation, but the laws of new planes may be determined from measurement alone.

Fig. 8.



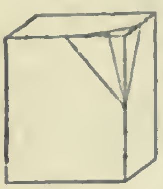
When a plane similar to that shown in *fig.* 8 occurs on one solid angle of a crystal, it generally occurs on all the others, establishing what Haüy has termed the Law of Symmetry. But, as we have before stated in reference to the cube, this law is occasionally deviated from by the production of only one-half the symmetrical number of secondary planes on a square prism. This remark also applies to such other kinds of secondary planes as we now proceed to describe.

Besides the plane shown in *fig.* 8, there are three other kinds affecting the solid angles.

First, such as would cut off one, two, three, or more portions of the edges *a* and *b*, but at the same time some other number from the edge *c*. Thus if one portion be cut from *a* and one from *b*, there will be two, three, four, or some other number cut from *c*; or if three portions were cut from *a* and three from *b*, either one, two, four, five, or some other number would be cut from *c*, so that a numerous series of planes of this nature might occur on each solid anglo.

The second kind of planes are those which would cut off an equal number of parts from *a* and c, but a different number from *b*. But in this case there would be two planes on each solid angle, for if we suppose one plane to cut three parts from *a*, and three from *c*, and two from *b*, a second plane would also be produced, cutting three parts from *b* and c, and two from *a*, producing two planes similar to those in *fig.* 9.

Fig. 9.



Each of the series of planes of the first kind would have an edge parallel to the diagonal *d e*, *fig.* 8; and each of those of the second kind would have edges parallel to the diagonals *d f* and *e f* of the same figure. The planes of the third class also occur in pairs, and are such as would be produced by cutting off dissimilar numbers of parts from the three edges, such as two parts from *a*, three from *b*, and four from *c*, none of the edges of these new planes being parallel to any diagonal.

The secondary planes on the terminal edges may cut off any number of parts from the edges *r* and *b*, and the same, or any other number, from *s* and c. Those on the lateral edges, if they cut unequal portions from *a* and *o*, and *b* and *n*, will be found to occur in pairs. Single planes on the lateral edges are such as would result from cutting *a* and *o*, and *b* and *n*, equally; and the secondary planes on the other primary forms are produced by laws analogous to those we have just described.

The reasons for preferring prisms to octahedrons for the primary forms may be thus briefly stated.

We have already seen that the octahedron derived from the cube might be taken as the fundamental or primary figure of that system of crystallisation. An octahedron derived from the truncation of the upper and lower edges of the square prism, or of its solid angles, by planes which would intersect the terminal planes parallel to their diagonals, might be assumed as the primary form of this system; and octahedrons similarly derived from the other prisms might also be regarded as the primaries of their respective systems. And these figures have accordingly been adopted by Möhs, as the fundamental forms of his system of crystallography. From the greater simplicity however of derivation which results from the assumption of the prisms as primary forms, and the greater mathematical facilities in determining the relations of the derived to the primary, we have been induced to retain them as the fundamental forms of our system. For the relations among these primary and their respective secondary forms are, according to our plan, dependent only upon the proportions of the primary edges required to be cut off to produce given secondary planes. But in taking the octahedrons as primaries, Möhs has founded the relations of these to the secondary figures upon the relative lengths of the axes of the derived figures, according to which view of derivation the lateral planes of the square prism would be denoted as those of an octahedron with an infinitely long axis, and the end planes as those of an octahedron with an infinitely short axis. And for all the various prisms which may occur, octahedrons must first be found, from the infinite prolongation of whose axes the given prisms may be produced. From the complexity of this method it will probably not extend far beyond the school of its highly ingenious author.

The exact relations among primary and secondary forms may be determined mathematically, sometimes from measurement and sometimes from parallelisms between certain edges of the secondary figures: and the mathematical processes may be either those of plane trigonometry, as applied by Haüy; or spherical trigonometry, as used by other authors; or analytical geometry, as applied by Professor Whewell in a paper in the 'Phil. Trans.' for 1825; or by referring the planes of the crystal to the surface of a sphere and denoting their positions stereographically, as shown in a paper by Professor Miller, of Cambridge, in the 'Lond. and Edinb. Phil. Mag.' of Feb. 1835.

Crystallisation and the circumstances under which it takes place form an interesting subject of inquiry, not only in respect of the variety of figures under which crystals present themselves, but in relation to much more comprehensive geological investigations into the formation of the early crystalline rocks and the various embedded crystallised minerals, and into the manner in which the numerous crystalline bodies found in the metallic and other veins have been produced.

From the great length of time during which these natural processes must have been in action, the slowness with which they probably have proceeded, and the hidden recesses in which they have taken place, the progress of natural crystallisation can scarcely be said to have been ever observed; for the production of saline crystals at the bottom of certain lakes, and even that of iron pyrites, which are said to have been observed in a progressive state of formation, cannot be regarded as belonging to the class of phenomena we are contemplating.

Not having therefore the operation of nature open to our inspection, our only sources of information relative to the formation of crystals are those afforded by the processes of artificial crystallisation; and here until very recently our experiments were circumscribed and our views bounded by a very few modes of operation: that of the deposit of crystals from solution in some fluid; their production while gradually cooling from a state of fusion; and their volatilisation by heat or otherwise. Latterly however, by the aid of that universal agent, electricity, new methods of producing crystals have been pursued: much of the darkness in which the subject had been previously involved has been dispelled, and there can now be little doubt that the phenomena of crystallisation are influenced in a greater or less degree by electric influence.

The crystallisation of salts from solution in fluids generally takes place when the solutions are sufficiently evaporated, but the degree of evaporation is very different for different substances. Some salts begin to crystallise at the surface very soon after evaporation commences, and others (for example, sugar) must be evaporated to the consistence of a thick syrup before any crystals will be formed. Hot fluids will generally dissolve more matter than cold ones, and crystals are frequently produced during the cooling of the hot solution. Some soluble substances however cannot be brought to crystallise under any circumstances hitherto tried; but on the solvent evaporating a thick pasty matter is left, which by further evaporation becomes a hard solid mass. Camphor affords an instance of the formation of crystals by volatilisation. The sides of a bottle containing this body may frequently be observed incrusted with brilliant crystals.

The slags of furnaces will frequently be found to contain crystallised matter; and the common rolls of sulphur when broken will frequently present small cavities lined with thin needle-like crystals.

(Austed, *Elementary Geology; Dana, Manual of Mineralogy.*)

CTENACA'NTHUS, a genus of Fossil Placoid Fishes, from the Mountain Limestone and Old Red-Sandstone. (Agassiz.)

CTENODA'CTYLA (Dejean), a genus of Coleopterous Insects belonging to the section *Geodephaga* and sub-section *Truncatipennes*. It has the following characters:—Body but slightly elongated, flattened; thorax longer than broad, truncated posteriorly; terminal joint of the palpi almost oval; three basal joints of the tarsi dilated, nearly triangular or heart-shaped; claws denticulated beneath.

Dejean, in his 'Catalogue des Coléoptères,' only enumerates three species of this genus, all of which are from Guyana. There are however other species known.

C. Chevrolatii is less than half an inch in length, of a blue-black colour above, and brown beneath; the thorax is red, and the legs and antennæ are yellowish-red.

CTENODA'CTYLUS, a genus of Rodent Animals of the family *Arvicolidæ*, established by Dr. J. E. Gray.

Each foot has four toes only, and an obsolete clawless wart in place of the thumb; claws small and falculated; toes pectinated internally, with small bony appendages. Tail very short and hairy.

Dental formula:—Incisors, $\frac{2}{2}$; Molars, $\frac{3-3}{3-3}$. (Gray.)

Dr. Gray is of opinion that this sub-genus appears to be most nearly allied to the Lemmings (*Lemmus*), with which it agrees in teeth and form, but differs from them in only having four free toes on each of the feet and a very obscure clawless wart in place of the thumb, and in the claws of all the feet being short and incurved, those of the hinder ones being covered with a tuft of rigid hair, more especially to be distinguished in the two inner toes, each of which also has a double, small, deeply pectinated, bony plate on its inner side. The tail is very short, scarcely longer than the fur of the back, covered with long bristly hair. The cutting teeth incurved, the lower rounded in front, the upper concavely truncated. The upper grinders are probably like the lower, which are laminar and with a 2-lobed crown, the anterior lobe being transverse, narrow, round on the outer, and narrow and sharp on the inner side; the hinder lobed, larger, and rounded, the lobe of the two anterior ones being rather wider than long, and that of the last as long as it is wide. (Gray.)

C. Massonii, Masson's Comb-Rat. The fur is soft and silky; upper parts fulvous brown; the hair very thin, pale lead-coloured at the base, pale fulvous at the end, with very short blackish tips, especially upon the head; chin, throat, inner side of limbs, and beneath, whitish, with the same lead-coloured base to the hairs. Head rather small, and densely hairy; muzzle very small, black; mouth rather small; cutting teeth exposed, rounded and smooth in front, white; the whiskers very long, twice as long as the head, rigid, black, with two or three slender long bristles over the eyebrows; eyes moderate, rather nearer the ears than the end of the nose; the ears rounded, externally covered with dense short fur like the body, internally rather naked, black, with a distinct helix. Limbs short; the feet covered with shortish rather adpressed hair; the fore feet short; the toes free, the two middle ones nearly equal, the inner rather shorter, and the outer shortest of all; the claws short, subequal, incurved, black, not so long as the hinder ones; the hinder feet large with naked soles; toes free, the three inner equal, the outer rather the shortest, the two inner toes with two series of four or five bony laminæ placed side by side, forming a comb-like process, and covered with some very stiff bristly incurved hair; the tail very short, cylindrical, ending in a parcel of rather rigid black-tipped hairs. Size and shape about that of a half-grown guinea-pig. Length (stuffed specimen) from nose to base of tail 9 inches; of the tail 1 inch (the longest bristle extends beyond the tip); of the hind feet, $1\frac{1}{8}$ inch; of the ears, $\frac{3}{12}$ of an inch. (Gray.) Locality, Cape of Good Hope.

"I am not aware," says Dr. Gray, speaking of the comb-like appendage, "of the same kind of process being found on the toes of any of the *Mammalia*. It most nearly resembles the pectinated edge of the claws of the middle toes of the feet of the Goatsuckers and Herons: it may probably be used for the same purpose to clear their coats of intruding insects, and this idea is strengthened by the fact of the two living animals in the collection of the Zoological Society, said to come from Barbary, continually scratching themselves with their hind claws. Some of the Lemmings, to which these animals are most nearly allied, are peculiar for having a very curious conformation in the claw of the index finger of the hand."

Dr. J. E. Gray refers to two specimens in the British Museum, one of which is marked in the hand-writing of his late uncle, Dr. E. W. Gray. "C. B. Spei Masson, 1744, appears to be a variation of No. 1," which last Dr. Gray thinks is probably the other specimen in the British Museum, which is rather larger.

The species is named after Mr. Francis Masson, who was one of his Majesty's gardeners, and published a paper in 'Phil. Trans.,' lxvi. (1775), giving an account of three journeys from Cape Town to the southern parts of Africa, undertaken for the discovery of new plants towards the improvement of the Royal Botanical Gardens at Kew.

The description of this curious animal is taken from Dr. Gray's 'Spicilegia Zoologica,' where there is a figure of the species.

CTE'NODUS, a genus of Fossil Fishes, from the Coal Formation of Yorkshire and Lancashire, and the Limestone of Burdie-House. (Agassiz.)

CTENOID FISHES, a great division of Fishes, thus named by Agassiz, from the pectinated appearance of the retral edges of the scales, which are of a horny substance, not bony nor enamelled. Abundant in the actual creation, they are rare as fossils in all but the more recent strata.

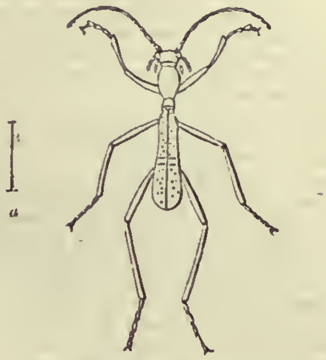
CTENO'LEPIS, a genus of Fossil Fishes, from the Oolite of Stonesfield. (Agassiz.)

CTENOMYS, a genus of Rodent Animals. [MURIDÆ.]

CTENO'STOMA (Klug), a genus of Coleopterous Insects of the section *Geodephaga* and family *Cicindelidæ*. The species have the following distinguishing characters:—The basal joints of the anterior tarsi dilated in the male sex, the third with an obliquely elongated portion on the inner side; body narrow and long; thorax long, somewhat globular in the middle, and suddenly constricted towards the base and apex; antennæ setaceous; palpi long and distinct; mentum furnished with a tooth-like process in the anterior and emarginated part.

Ctenostoma macilentum (Klug), is about half an inch in length, and of a brassy-black colour; the elytra are distinctly punctured, and have a transverse yellowish fascia in the middle; the legs are yellowish.

This species is from Buenos Ayres. Eight or nine other species are known, all of which inhabit South America: several are from Brazil.



Ctenostoma macilentum.
a, denotes the natural length.

Under this head may be noticed three other genera which are closely allied to the one just described—*Therates*, *Tricondyla*, and *Colliurus*.

The species of these three genera are at once distinguished from those of *Ctenostoma* by their having no tooth-like process in the emargination of the mentum. The principal characters of the genus *Therates* (Latreille) are as follows:—Tarsi nearly the same in both sexes, the third joint shorter than the two basal joints, and notched at the extremity; fourth joint very short and heart-shaped; internal maxillary-palpi very small, and consisting of one joint only.

The species of this genus are of an intermediate form between *Ctenostoma* and *Cicindela*: they are shorter and broader in proportion than those of the former, and hence approach the latter; but the thorax is of that same globular form (though short) as observed in *Ctenostoma*.

Only four or five species are known, and these are from Java and Guinea: their colouring is very brilliant.

Therates labiata is of a brilliant blue colour, with violet reflections; the elytra are nearly double the width of the thorax; the labrum, femora, and abdomen, are of a reddish-yellow colour.

The species of the genus *Tricondyla* (Latreille) very much resemble, in form and general appearance, those of *Ctenostoma*; but they may be distinguished by their having the joints of the tarsi nearly equal in length, the three basal joints of the anterior tarsi of the males dilated, the third being prolonged obliquely on the inner side, and the palpi being less conspicuous from their comparatively smaller size.

Of this genus three species are known: they inhabit the islands north of Australia.

The technical characters of the genus *Colliurus* are:—fourth joint of all the tarsi prolonged on the inner side in both sexes; thorax elongate, nearly cylindrical, and constricted near the base and apex; body elongate, nearly cylindrical, broader towards the posterior part; antennæ short, slightly thickened towards the apex.

All the species of this genus as yet discovered (which amount to only four or five) are found in the southern parts of Asia, and in the islands north of Australia.

Colliurus emarginata (Dejean), is about an inch in length, and of a dull blue colour; the elytra are coarsely punctured, and truncated at their apex; the legs are black, with the exception of the thighs, which are red.

CUBAN, a native Sulphuret of Copper and Iron.

CUBE-ORE, a native hydrous Arsenate of the Peroxide of Iron. It crystallises in cubes, and is found in the mines of Cornwall, France and Saxony. [PHARMACOSIDERITE.]

CUBE-SPAR, a name by which *Anhydrite* is known. [ANHYDRITE.]

CUBEBA. [PIPER.]

CUBICITE. [ANALCIME.]

CUBOIDES. [ACALEPHÆ.]

CUCKOO. [CUCULIDÆ.]

CUCKOO-FLOWER. [CARDAMINE.]

CUCKOO-PINT. [AROIDEÆ.]

CUCUBALUS, a genus of Jelly-Fishes. [ACALEPHÆ.]

CUCU'BALUS, a genus of Plants belonging to the natural order *Caryophyllaceæ*. It has a 5-toothed naked calyx; 5-clawed petals; 10 stamens; 3 styles; capsule a globose 1-celled berry; reniform seeds. There is but one species of this genus, *C. baccifer*, the Berry-Bearing Campion. It differs but little from the species of *Silene* except in its berried capsule, which is black. It is a native of Europe, and has been found wild in Great Britain. It has been undoubtedly introduced, but is scarcely naturalised. (Babington, *Manual.*)

CUCULÆA. [POLYODONTA.]

CUCU'LIDÆ, the *Cuckoo-Tribe*, or Cuckoos, a family of Scansorial Birds, placed by Cuvier and Lesson next to the Wrynecks, *Yunx*, and by Mr. Vigors in the aberrant group of his *Scansores*, between the *Certhiadæ* and the *Rhamphastidæ*.

The *Cuculidæ* are placed by Mr. Swainson also between the *Certhiadæ* and *Ramphastidæ*, and these three families constitute what he terms his third and aberrant circle of the *Scansores*. The following is his definition of the family character:—Feet not strictly scansorial, very short, nostrils naked, tail-covers remarkably long; and he separates the group into the following sub-families: *Cuculinæ*, *Coccyzinæ*, *Saurotherinæ*, *Opisthocominæ*, *Indicatorinæ*. Of the first sub-family *Cuculus*, Linn., is the type; of the second *Coccyzus*, Vieill.; of the third *Saurothera*, Vieill.; of the fourth *Opisthocomus*, Hoff.; and of the fifth *Indicator*, Sparrm.

The following account of this family by Mr. Swainson bears the stamp of actual observation. "So faintly is the scansorial structure indicated in these birds that but for their natural habits, joined to the position of their toes, we should not suspect they were so intimately connected with the more typical groups of the tribe as they undoubtedly are. They neither use their bill for climbing, like the parrots, or for making holes in trees, like the woodpeckers, neither can they mount the perpendicular stems, like the *Certhiadæ*, or Creepers; and yet they decidedly climb, although in a manner peculiar to themselves. Having frequently seen different species of the Brazilian cuckoos (forming part of the genus *Coccyzus*) in their native forests, I may safely affirm that they climb in all other directions than that of the perpendicular. Their flight is so feeble, from the extreme shortness of their wings, that it is evidently performed with difficulty, and it is never exercised but to convey them from one tree to another, and these flights in the thickly-wooded tracts of tropical America are of course very short: they alight upon the highest boughs, and immediately begin to explore the horizontal and slanting ramifications with the greatest assiduity, threading the most tangled mazes and leaving none unexamined. All soft insects inhabiting such situations lying in their route become their prey, and the quantities that are thus destroyed must be very great. In passing from one bough to another they simply hop, without using their wings, and their motions are so quick, that an unpractised observer, even if placed immediately beneath the tree, would soon lose sight of the bird. The Brazilian hunters give to their cuckoos the general name of Cat's-Tail; nor is the epithet inappropriate, for their long hanging tails, no less than their mode of climbing the branches, give them some distant resemblance to that quadruped. I have no doubt that the great length of tail possessed by nearly all the cuckoos is given to them as a sort of balance, just as a rope-dancer, with such an instrument in his hands, preserves his footing when otherwise he would assuredly fall. Remote therefore as the cuckoos unquestionably are from the typical *Scansores*, we yet find the functions of the tail contributing to that office, although in a very different mode to that which it performs among the woodpeckers, the parrots, and the creepers. The structure of the feet, as before observed, is the only circumstance which would lead an ornithologist to place these birds among the climbers, supposing he was entirely unacquainted with their natural history properly so called, or with their close affinity to the more perfect *Scansores*. The toes indeed are placed in pairs; that is, two directed forward and two apparently backward; but a closer inspection will show that the latter are not strictly posterior, and that they differ so very materially from those of the *Picidæ* (the pre-eminently typical family of the climbers), as clearly to indicate a different use. The organisation of the external posterior toe of all the woodpeckers, parrots, and toucans, renders it incapable of being brought forward, even in the slightest degree; whereas in the cuckoos this toe can be made to form a right angle with that which is next it in front, from which circumstance it has been termed versatile; this term however is not strictly correct, inasmuch as the toe cannot be brought more than half way forward, although it can be placed entirely backward. Now this form, which is obviously the least developed state of the scansorial structure, accords exactly with the rank of the family, which is that of the most aberrant group in the circle, and farthest removed from the type. The cuckoos in fact are half-perching half-climbing birds, not only in their feet, but, as we have seen, in their manners. No one, from seeing them alive, would suppose they were truly scansorial birds; and yet it is highly probable that this singular power of varying the position of one of their toes gives them that quickness of motion and firmness of holding which accompanies the habit just mentioned.

"There is another circumstance in the history of this family of birds, which, with one solitary exception, is altogether peculiar, as they contain the only parasitic birds yet known. This term indeed has been applied, I think improperly, to other genera, which, like the frigate pelicans, the jagers, and some of the eagles, rob other birds of their food; but this is a mere act of thieving, for all these feathered robbers can and do habitually depend just as much upon their own industry in procuring food. But with the typical cuckoos the case is far different, for, by depositing their eggs in the nests of other birds, to whom they leave the care of hatching their young and feeding them afterwards, they become as truly parasitic as any of the *Acari* or *Pediculi*; they fasten themselves, as it were, on the living animal, whose animal heat brings their young into life, whose food they alone live upon, and whose death would cause theirs during the period of infancy. Such only is a parasitic animal, and such only, among birds, belong to the typical cuckoos and their representative, the *Molothrus pecoris*." [MOLOTHRUS.]

Warm and temperate climates are the chosen haunts of the Cuckoos. The European species—there are but two—never show themselves in our quarter of the globe, except in the warm weather, quitting it upon the first approaches of a colder temperature. "So congenial is warmth to their nature," says Mr. Swainson in the memoirs last quoted, "that even the mild temperature of an Italian winter is not sufficient to retard their return to the sultry groves of Northern Africa. There is a fact regarding their structure which appears connected with this susceptibility of cold, and which I believe has not hitherto been noticed. All the cuckoos, both of the old and the new world, which I have had the opportunity of dissecting, are remarkable for the thinness and delicacy of their skins, so much so indeed as to render their preservation in an entire state extremely difficult to inexperienced hands. Every one who has skinned the common British species must doubtless have observed this. On the other hand, as if to compensate for the delicacy of the cuticle, the feathers, more especially upon the back and rump, are unusually thick-set and compact."

Tropical countries, and those which approach the equator, afford the greatest number of species.

The food of the Cuckoos, as might be expected from this geographical distribution, consists principally of soft fruits and soft insects, especially the latter, and more particularly when they are in the larva state.

Cuculinæ include the genuine Cuckoos. This sub-family has the following characters:—Bill wider at the base than it is high, rather suddenly contracted behind the nostrils and becoming compressed; upper mandible slightly sinuous at the tip, so as to assume the form of the dentirostal notch. Wings considerably long, nearly reaching to two-thirds the length of the tail, and so far pointed as to diminish rapidly in length beyond the fourth quill. Feet remarkably short; tarsus thickly clothed with feathers for nearly half its length, not longer than the hallux or true hind toe. Upper cover-feathers of the tail thick-set, narrow, generally pointed, and comparatively elongated, and in rigidity only comparable to those of the *Ceblepyrinæ*, the corresponding type in the *Laniadæ*.

"Popular interest," adds Mr. Swainson, "has been so much confined to the parasitic habits of the cuckoo, that upon many other points of its economy we are still in comparative ignorance. Hence it is that we cannot trace, so fully as could be wished, the influence which the structure just described exercises upon the habits and manners of such birds as possess it. We know however that all the genuine cuckoos fly with strength and rapidity. Most of them, in fact, are migratory birds. . . . . The form of the nostrils in the typical cuckoos is very peculiar, and I believe that future observations will shew this structure to be intimately connected with their parasitic habits. The nests of those species in which the cuckoo deposits its eggs, we all know, are built in the thickest and most central part of trees and bushes, to discover which, superior powers of smell have been given to the toucans (which feed upon the eggs or young), and, in a less degree, are probably conferred upon the cuckoos, to facilitate their search after a foster-parent for their young. How far this idea may be correct future observations will determine. Certain however it is, that this peculiar-shaped nostril is restricted to such cuckoos as are parasitic, for the whole of the *Coccyzinæ* have the aperture of a lengthened oval shape, or in the form of a slit, and all we know of these birds sanctions the idea that they are not parasitic. The shortness of the feet, in the typical cuckoos, is another important distinction, and leads to the belief that these members are much less used than those of the *Coccyzinæ*, whose habits we have already mentioned when alluding to the cuckoos of South America, all of which are excluded from the group now under consideration."

Cuculus.—Bill broad at the base, compressed beyond, the upper mandible obsoletely notched; nostrils circular, with a tumid margin; wings long, pointed, the third quill longest, the second and fourth of equal length; feet slender, very short, tarsi feathered posteriorly almost to the toes; rump and upper tail-covers long, thick-set, and rigid. Inhabits the Old World. Parasitic.

C. canorus, the Cuckoo. It is the Κόκκυξ of the Greeks; *Cuculus* and *Coccyx* of the Romans; Cucculo, Cucco, Cuco, Cucho, Cuccu, of the Italians; Cocuo, Coucou, Coqu, of the French; Kukuk and Kuckuck of the Germans; Gjok of the 'Fauna Suecica;' Gjoeg of the Danes; Gouk of the Norwegians; Cog of the Welsh; Gowk and Cuckoo of the British.

Length about 14 inches, weight about four ounces and a half. Bill black, yellowish at the base of the upper mandible; inside of mouth red. Irides yellow. Head, and whole upper part of the bird, dark ash-colour. Throat, under side of the neck, and upper part of breast, pale ash, the latter sometimes inclining to rufous brown; lower part of breast and belly white, with transverse undulating black lines. Quills dusky, inner webs barred with white oval spots. Tail-feathers ten, of unequal length; two middle ones black, dashed with ash and tipped with white, the rest black, with white spots on each side of the shaft. The lateral feathers in some have white spots only on the interior webs, but all are tipped with white. Female, rather less than male, and differing from him generally in the neck and breast being of a tawnyish brown, barred with dusky, and the coverts of the wings marked with light ferruginous spots. Tail-feathers and quills much like those of the male, but the edges of the spots incline to reddish-brown. Legs in both sexes short and yellow. Outer tail-feather and first quill remarkably short.

Cuckoo (*Cuculus canorus*), male.

The young is so distinct in its plumage from the adult that it has been described as a distinct species (*C. rufus*, Bris). It is supposed not to throw off its nestling feathers till the second year's moulting, for it is stated in Montagu's 'Dictionary' (last edit.), that in three specimens killed the same season (two males and a female), the thirteenth and three succeeding quill-feathers, and the three greater coverts impending them, are barred with brown and ferruginous. In the first year the irides are grayish; the whole upper plumage is a mixture of dusky black and ferruginous, in transverse bars, except the forehead and a patch on the back of the head, which in this specimen described in Montagu was white, and the tips of the scapulars pale; the feathers of the whole under parts sullied white, with distant transverse bars of dusky black. In general each feather is barred twice or thrice. The sides of the neck and breast are tinged with rufous; lateral tail-feathers and inner webs of the quills more or less barred with white. Tail coverts, which, as well as the feathers on the rump, are unusually long, dashed with cinereous and slightly tipped with white.

The Common Cuckoo arrives in this country early in spring. In White's 'Naturalist's Calendar,' the Cuckoo is noted as first heard April 7-26, and in Markwick's, April 15, May 3; last heard June 28. By the 1st of July it has almost always taken its departure, but it is sometimes later. Mr. Swainson, in his 'Memoir on the Cuculidæ,' says, "The common species comes to us every spring, from northern Africa or Asia Minor, and returns in autumn. This we know from personal observation; for vast numbers arrive in the spring in Sicily and Naples, in company with the bee-eaters, orioles, hoopoes, and other migratory birds; but after remaining a short time, they appear to direct their flight northward, from whence they return in August and September." Speaking of the food, the same author observes, "The English cuckoo, no doubt, searches for its food among foliage, but its nature is so shy that we have never been fortunate enough to witness its mode of feeding." Montagu however, one of the best authorities we can cite, says, that "its principal food consists of caterpillars, so that it not only possesses the general cast of colours, and much of the structure of its prototypes, the *Ceblepyrinæ*, but actually feeds on the same description of insects." The Editor of the 'Magazine of Zoology and Botany' adds, "In an open and muirland district where the cuckoo is very common, we have always found, during May and June, that their stomachs were filled with the remains of caterpillars which fed on the various plants frequent in such localities. Among them those of the *Lasiocampæ* formed a great proportion, and hairy species seem to be preferred." White, in his 'History of Selborne,' thus writes: "In July I saw several cuckoos skimming over a large pond; and found, after some observation, that they were feeding on the *Libellulæ*, or Dragon-Flies; some of which they caught as they settled on the weeds, and some as they were on the wing." The following narrative from the last edition of Montagu's 'Dictionary' will throw some light on this part of the subject: "A young cuckoo, brought to Colonel Montagu in the month of July, just as it could fly, was, by great care, kept alive till the fourteenth of December. It had, during that time, two or three attacks of dysentery, from which it recovered by having chalk and ginger given to it; and during the time it lived no change was observed to have taken place in its plumage. For two months after this bird was caught, it never attempted to feed itself by picking; and even to the last moment seemed to prefer being fed by the hand of its mistress rather than have the trouble of picking up its food, of which it was extremely choice. Nothing appeared to be acceptable as a substitute for insects except raw beef. Flies it would eagerly devour; but its most delicious morsel was any species of hairy caterpillars; these it seized with avidity, shook them to death, and softened by passing several times through the bill, till they were perfectly pliant, when it would swallow whole the largest of the caterpillars of the egger or drinker moths. Of strangers it was extremely fearful, fluttering in its cage to avoid their attentions; but it would quietly suffer itself to be handled and caressed by a young lady who had been its kind benefactress, appearing to like the warmth of her hand to its feet."

It is the habit of the Cuckoo in depositing her egg in the nest of another bird that has made it so much an object of curiosity. Many strange stories were formerly rife on this custom, which can hardly be called abandonment, as the nest of a bird that feeds its young with insects is always selected. Among others, the hedge-sparrow, the reed-sparrow, the tit-lark, the water-wagtail, the yellow-hammer, &c., have been recorded as the birds to whom the egg has been committed, but the first seems to be most frequently chosen. White saw one hatched in the nest of the tit-lark. The nests of the green-bird, the linnet, the white-throat, and even of the wren have been mentioned as the places of deposit. Dr. Jenner's celebrated paper in the 'Philosophical Transactions' threw great light on this subject, and many other observers have corroborated in general that author's remarks. Some indeed, and among them Dr. Fleming, have declared that in some cases the Cuckoo constructs its own nest, but there can be little doubt that there is no foundation for this assertion, and as little that the nests and young supposed to be those of the Cuckoo on such occasions were those of the goatsucker. Whether the bird actually deposits the egg from her body while sitting on the nest has been doubted; and if the case of the deposit of one in a wren's nest be a fact, it is almost conclusive that she does not so deposit it in all cases, for the aperture of the wren's nest is in the side, and not more than big enough to admit the wren. Another observer has recorded the following facts:—"Previous to the above-mentioned publication (Dr. Jenner's) I had taken much pains towards investigating the several phenomena I had noticed in this bird, and was so fortunate as to have ocular proof of the fact, related by Dr. Jenner, of a young cuckoo turning out of a hedge-sparrow's nest a young swallow I had put in for the purpose of experiment. It is needless to recite all the circumstances attending this extraordinary bird, as that gentleman has so amply explained it; I shall therefore only add, that I first saw it when a few days old, in the hedge-sparrow's nest, in a garden close to a cottage, the owner of which assured me the hedge-sparrow had four eggs, when the cuckoo dropped in a fifth; that on the morning the young cuckoo was hatched, two young hedge-sparrows were also excluded; and that, on his return from work in the evening, nothing was left in the nest but the cuckoo. At five or six days old, I took it to my house, when I frequently saw it throw out the young swallow for four or five days after. This singular action was performed by insinuating itself under the swallow, and with its rump forcing it out of the nest with a sort of jerk. Sometimes indeed it failed, after much struggling, by reason of the strength of the swallow, which was nearly full feathered; but, after a small respite from the seeming fatigue, it renewed its efforts, and seemed continually restless till it succeeded. At the end of the fifth day this disposition ceased, and it suffered the swallow to remain in the nest unmolested." This wonderful instinct is absolutely necessary for the self-preservation of the young Cuckoo, which, if it did not dispose of all other claimants on the affection of the parents, must perish for want, and, as it is, the poor little birds to whose lot it falls to supply the demands of their craving and gigantic nestling, have a weary time of it. Indeed there are well recorded instances of their being assisted by others of their own species, and by other insectivorous birds.

The Romans considered the Cuckoo excellent eating. Pliny (lib. x. c. 9) says that no bird can be compared to it for sweetness of flesh.

C. glandarius, the Great Spotted Cuckoo, is a native of Senegal and North Africa. It has been observed on the continent of Europe, and a specimen is recorded by Mr. R. Ball as having been taken in Ireland.

Oxylophus (Sw.)—Bill slender, considerably compressed nearly its whole length; upper mandible entire; nostrils ovately round; head crested; wings moderate, pointed, shorter than the tail-covers, the fourth quill longest; tarsi moderate, naked; upper tail-covers long but not rigid. The species inhabit the Old World; and are parasitic.

O. Levaillantii.—Head crested, the feathers pointed; plumage above, black glossed with green; band at the base of the quills, end of the tail, and under parts of the body, white; throat striped with black. Wings long but rounded, fifth quill longest. Total length, 15 inches. Mr. Swainson, whose description we have given, says that, unlike the true Cuckoos, these birds rear and provide for their young in the ordinary manner. Locality, Senegal and the western coast of Africa.

Oxylophus Levaillantii.

Erythrophrys (Sw.)—Bill as in *Oxylophus;* head not crested; nostrils oval; wings lengthened, pointed, extending beyond the tail-covers, the third quill longest, the second much shorter than the fourth; tarsi moderate, naked. They inhabit the New World, and rear their own young.

E. Americanus (*Cuculus Carolinensis*, Wilson).—The male has the bill as long as the head, compressed, slightly arched, acute, scarcely more robust than in many *Sylviæ;* upper mandible carinated above, its margins acute and entire; lower mandible carinated beneath, acute. Nostrils basal, lateral, linear-elliptical, half-closed by a membrane. Feet short, tarsus scutellate before and behind; toes two before, separated; two behind, one of which is versatile, the sole flat; claws slender, compressed, arched. Plumage blended, slightly glossed. Wings long, the first quill short, the third longest, the primaries tapering. Tail long, graduated, of ten feathers, which are rather

Coucou (*Erythrophrys Americanus*).

narrow and rounded. Upper mandible brownish black, yellow on the margin towards the base; under mandible yellow. Iris hazel. Feet grayish-blue. The general colour of the upper parts, including the wing-coverts and two middle tail-feathers, is light greenish-brown, deeper anteriorly. Primary quills with the inner webs brownish-orange. Tail-feathers, excepting the two middle ones, black, the next two entirely black, the rest broadly tipped with white, the outermost white on the outer web. The under parts are grayish-white. Length, 12½ inches; extent of wings, 16 inches; bill along the ridge, 1 inch; along the gap, one inch and a third. The female differs very little from the male in colouring. (Audubon.)

The author whose specific description we have given above, thus graphically describes the habits of the Yellow-Billed Cuckoo (*Cuculus Carolinensis* of Wilson, *Coccyzus Americanus* of the Prince of Canino, *Cuculus Americanus* of Linnæus, and Carolina Cookoo of Latham. "The flight of the bird is rapid, silent, and horizontal, as it moves from one tree to another, or across a field or river, and is generally continued amongst the branches of the trees in our woods. When making its way among the branches, it occasionally inclines the body to either side, so as alternately to show its whole upper or under parts. During its southward migration it flies high in the air, and in such loose flocks that the birds might seem to follow each other, instead of their keeping company together. On the other hand, early in March, the greater number enter our southern boundaries singly, the males arriving first, and the females a few weeks after. They do not fly in a continued line, but in a broad front, as, while travelling with great rapidity in a steam-boat, so as to include a range of a hundred miles in one day, I have observed this cuckoo crossing the Mississippi at many different points on the same day. At this season they resort to the deepest shades of the forests, and intimate their presence by the frequent repetition of their dull and unmusical notes, which are not unlike those of the young bull-frog. These notes may be represented by the word 'cow, cow,' repeated eight or ten times with increasing rapidity. In fact, from the resemblance of its notes to that word, this Cuckoo is named Cow-Bird in nearly every part of the Union. The Dutch farmers of Pennsylvania know it better by the name of Rain-Crow, and in Louisiana the French settlers call it Coucou. It robs smaller birds of their eggs, which it sucks on all occasions, and is cowardly and shy, without being vigilant. On this latter account it often falls a prey to several species of Hawks, of which the Pigeon-Hawk (*Falco columbarius*) may be considered as its most dangerous enemy. It prefers the southern states for its residence, and when very mild winters occur in Louisiana some individuals remain there, not finding it necessary to go farther south. This bird is not abundant anywhere, and yet is found very far north. I have met with it in all the low grounds and damp places in Massachusetts, along the line of Upper Canada, pretty high on the Mississippi and Arkansas, and in every state between these boundary-lines. Its appearance in the state of New York seldom takes place before the beginning of May, and at Green Bay not until the middle of that month. A pair here and there seem to appropriate certain tracts to themselves, where they rear their young in peace and plenty. They feed on insects, such as caterpillars and butterflies, as well as on berries of many kinds, evincing a special predilection for the mulberry. In autumn they eat many grapes, and I have seen them supporting themselves by a momentary motion of their wings opposite a bunch, as if selecting the ripest, when they would seize it and return to a branch, repeating their visits in this manner until satiated. They now and then descend to the ground to pick up a wood-snail or a beetle. They are extremely awkward at walking, and move in an ambling manner, or leap along sidewise, for which the shortness of their legs is ample excuse. They are seldom seen perched conspicuously on a twig, but on the contrary are generally to be found amongst the thickest boughs and foliage, where they emit their notes until late in autumn, at which time they discontinue them. The nest is simple, flat, composed of a few dry sticks and grass, formed much like that of the common dove, and like it fastened to a horizontal branch, often within the reach of man, who seldom disturbs it. It makes no particular selection as to situation or the nature of the tree, but settles anywhere indiscriminately. The eggs are four or five, of a rather elongated oval form, and bright green colour. They rear only one brood in a season, unless the eggs are removed or destroyed. The young are principally fed with insects during the first weeks. Towards autumn they become very fat, and are fit for being eaten, although few persons, excepting the Creoles of Louisiana, shoot them for the table." ('Ornithological Biography,' vol. i. p. 18.)

Chalcites, Less.—Bill and general structure as in *Cuculus*. Plumage metallic green; upper mandible entire; nostrils circular; wings pointed, the third quill longest, the second much longer than the fourth; tarsi very short, almost entirely plumed; rump and upper tail-covers soft. Inhabits the tropics of the Old World. Parasitic.

C. auratus; Cuculus auratus of authors (Swainson). Of this genus Mr. Swainson says, "I feel much more scrupulous in adopting the genus *Chalcites*, than in proposing that of *Erythrophrys*. The beautiful little shining cuckoos, indeed, which have thus been detached, have altogether the appearance of belonging to a different type from those of the genus *Cuculus;* and this idea is strengthened, when we find that there are already four or five species, all distinguished at first sight by their diminutive size and their beautiful golden-green plumage. On the other hand, their actual structure is so completely that of an European group, that I must beg to be understood as being by no means satisfied on the propriety of the separation. For the present however I shall adopt this genus, conceiving that these splendid little birds may probably constitute the tenuirostral type of the *Cuculinæ*, in which case they will be analogous to the humming-birds, and nearly all those genera whose plumage is ornamented with metallic colours. The attempt that has been made to define the group by its bill, nostrils, &c., as distinct from the cuckoos, is singularly unsuccessful; while those light shades of difference really existing between *Chalcites* and *Cuculus* have been completely overlooked. *Chalcites*, in fact, has the bill, nostrils, feet, and wings of *Cuculus*, with this difference only, that the tip of the upper mandible is without the slightest indication of a notch; the second and third quills are longer than the fourth, and the feathers of the rump and upper tail-covers, instead of being thick-set and rigid, are of the same degree of density and softness as in ordinary birds. We have seen that, however dissimilar in their appearance the foregoing groups of the *Cuculinæ* may be, yet that the variation of their external structure is but slight. This consideration has much weight with me in the temporary adoption of M. Lesson's genus *Chalcites*, for we have just seen an example in *Erythrophrys*, where there is an equally slight variation in external form, yet a most important one in economy and internal organisation." ('Mag. of Zool. and Bot.')

Chalcites auratus.

Eudynamys, Horsf. and Vig.—Bill strong, thick, the under mandible not curved, and angulated beneath; upper mandible entire; wings pointed, the fourth quill longest; tarsi much shorter than the longest toe; the upper part plumed; rump and tail-covers soft. Inhabits the Old World.

Mr. Vigors and Dr. Horsfield, who established this genus in their description of the Australian birds in the collection of the Linnæan Society ('Linn. Trans.,' vol. xv. p. 303), observe that the true Cuckoos, or that portion of the family of *Cuculidæ* which constitutes the genus *Cuculus* of authors, is distinguished from the remaining groups of the family by the comparative weakness of the bill, in which the nares are small and rounded, and situated on an elevated membrane; by the wings being strongly acuminated, the primary quill-feathers considerably exceeding the secondary in length; and by the feebleness of the legs and toes, the former of which are plumed beneath the knee, and are generally covered by the feathers. *Eudynamys*, they state, deviates from these characters, which may be considered typical in the family, by the greater strength of all these members. The bill is powerful, the under mandible more particularly, which is marked by a strong ascending gonys. The nostrils are wide and oval, and covered only on the upper part by a membrane. The tarsi and feet are particularly strong; the former are much compressed on the external side, exhibiting by this conformation a nearly flattened surface in front. In many of these particulars the group agrees very nearly with the neighbouring genera, *Centropus*, Ill., and *Phœnicophaus*, Vieill., which have equally been separated from the typical species of the family. But it may at once be distinguished from *Centropus* by the absence of the lengthened nail to the hallux; and it will be seen equally to differ from *Phœnicophaus* in its stronger, shorter, and less arcuated bill, in the wings being longer, and the tail rounded, not graduated. The compressed formation of the sides of the tarsi in *Eudynamys* is also wanting in *Phœnicophaus*.

The species are widely distributed over the East.

E. Orientalis; Cuculus Orientalis, Linn.; Coucou des Indes Orientales, 'Enl.'; Eastern Black Cuckoo, Lath.

The plumage of the male is black with metallic lustre. Bill yellow. The female is shining greenish-brown above, spotted with white; tail-feathers banded with white; whitish beneath, transversely undulated with greenish-brown. The synonyms of the female are *Cuculus Mindanensis*, Linn.; Coucou Tacheté de Mindanao, 'Enl.' 277.; Mindanao Cuckoo, Lath. (Vigors and Horsfield.)

Eastern Black Cuckoo (*Eudynamys Orientalis*).

"These birds, which now generally are considered the sexes of one species, appear to be but accidental visitors in the colony. At least Mr. Caley informs us that he never met with more than two individuals of the male and one of the female. The male specimen in the society's collection seems to be a young bird changing to the adult plumage. It has several pale ferruginous feathers in the lower parts of the body, and it has a single ferruginous feather streaked with black among the secondary quill-feathers of the right wing, which forms a striking contrast with the deep black of the rest. The corresponding feather on the left wing was lost, as Mr. Caley tells us, by the shot striking the wing. This bird had berries of *Cassytha* in its stomach. The native name of the male is Cowhat, of the female, Bellingiug." (Vigors and Horsfield.)

"All the cuckoos I have yet seen," says Mr. Swainson in his 'Memoirs on the Cuculidæ,' "with more or less pointed wings, and circular nostrils, and whose habits are parasitic, will arrange themselves under one or other of the foregoing genera. Nor are there wanting considerations, drawn from their analogical resemblances in other groups, which render it highly probable that they serve to indicate a circular group. *Erythrophrys*, as the rasorial type, resembles the rufous-winged scansorial creeper; and as it is by this group that the parasitic cuckoos lead immediately to those which build nests, so we have the external characters of *Oxylophus* joined to the economy of *Coccyzus*. *Chalcites*, again, as representing the humming-birds, may be viewed as the tenuirostral type; while *Eudynamys*, with its large bill, and black glossy plumage, will become the representative of the toucans, and of the fissirostral type. It may be questioned, indeed, whether *Cuculus* or *Oxylophus* follows *Eudynamys*; but I incline to the series in which they are here placed, from the obvious affinity of *Erythrophrys* to *Oxylophus*." ('Mag. of Zool. and Bot.')

The family *Indicatorinæ* includes the Honey-Guides. There appears to be but one genus, *Indicator* (Le Vaillant), which is thus characterised:—Bill straight, Finch-like, the base triangular, the sides compressed. Culmen and gonys equally inclined towards the tip; gonys angulated. Wings lengthened, pointed. Tail moderate, rounded. Feet short. Middle toe much longer than the tarsus.

Mr. Swainson is of opinion that the nearest approach to the Creepers yet known is made by the African Honey-Guides, whose bill is not unlike *Orthonyx*; and he adds that these birds are said to climb in a more perpendicular manner than any others of this family; the same zoologist has pointed out the affinity of *Indicator* to *Buphaga*.

The species are not numerous. The stories told of these birds indicating the nests of bees and guiding men to them by their motions and cries, from the time of Sparrman downwards, appear to be perfectly authentic, though some great travellers affected to disbelieve them. Mr. Swainson censures Bruce and Le Vaillant for their scepticism on this subject, and quotes Mr. Barrow to prove the universality of agreement on this point in the country itself. He farther says, "If more evidence was wanting than this and other similar confirmations of Dr. Sparrman's statement, it will be found in the following note by M. Wiedmann, attached by a label to the specimen from which the subsequent description was taken:—"So soon as this bird sees a man in the woods, where a bees' nest is in the neighbourhood, he flies before the man, and cries 'shirt! shirt! shirt!'" Mr. Swainson then proceeds to describe his *Indicator leucotis* (*I. albirostris*, Temm.). ('Birds of Western Africa;' 'Naturalist's Library;' 'Ornithology,' vol. viii.)

Mr. Steedman, in his 'Wanderings and Adventures in South Africa' (1835), says, "The little honey-sucker, or *Indicator*, kept fluttering before us with its cry of 'cherr, cherr,' as if inviting us to follow. It is frequently known to conduct travellers to a nest of honey deposited in the hollow of a tree. I have however heard many instances mentioned of its stopping short of the hive, and hovering over a spot where a lion or tiger has been reposing, justly establishing its character as an *Indicator*. Mr. Van der Nes informed me that he was once induced to follow it in expectation of discovering honey; and on pushing through the thick brushwood that enveloped the trunk of a tree over which the *Indicator* was hovering, he suddenly came upon a leopard: at the same instant the animal made a spring in a contrary direction, and much to his gratification disappeared without attempting to do him any injury, being evidently as much alarmed at the intrusion as the Veld cornet had been at so unexpected an encounter."

The species of this family are natives of Africa.

The other sub-families belonging to the *Cuculidæ* are, according to Mr. Swainson, *Coccyzinæ*, and *Crotophaginæ*, and *Leptostominæ*.

The *Coccyzinæ*, or Hooked-Billed Cuckoos, are characterised as having the wings short and rounded, the nostrils linear, the bill curved, the margins of the upper mandible dilated, the tarsus naked and lengthened, and the tail very long and concealed.

The genera comprised by Mr. Swainson under this sub-family are the following:—

Serisomus.—Bill short and strong, the gonys thick, ascending, and angulated; the culmen thickened and arched; the tarsus and middle toe equal, the lateral toes unequal, and the claws short. Example, *Serisomus cristatus*. (Sw.) The species are found in Africa. (Sw.)

Zanclostomus.—Bill much compressed throughout, gonys curved downwards, culmen and upper mandible greatly curved, and the basal margin considerably dilated; wings, tail, and feet, as in the last genus, but the lateral fore toes nearly equal. Found in the tropics of the Old World (Sw.). Example, *Zanclostomus Javanicus*, *Phœnicophaus Javanicus* (Horsf.). Java.

Coccyzus (Vieillot).—Bill moderate, thickened at the base, compressed; gonys straight; basal margin of the upper mandible not curved outwards, and scarcely dilated; tarsus and middle toe of equal length; lateral toes unequal. Natives of America only. This genus haunts the branches of lofty trees, from which it collects the insects which form its food.

C. Americanus is described by Yarrell as an occasional visiter in Great Britain. He records four captures of this bird.

Mr. Swainson places the Coucals of India and Africa under the new sub-genus *Leptourus*.

Ptiloleptus.—Wings very long; bill intermediate in form between *Coccyzus* and *Centropus*; nostrils long and linear; feathers of the head and neck slender and rigid; tarsus and middle toe equal, lateral toes unequal, all the claws curved and of equal size; tail-feathers eight. Habits terrestrial. The species inhabit South America. Example, *Ptiloleptus cristatus*. (Sw.)

Centropus (Illiger).—Bill strong; tarsus and middle toe equal; anterior claws slender, slightly curved; hinder claw very long and nearly straight. Native of Africa. Example, *C. Senegalensis*. Mr. Salt, in his 'Travels,' notices this bird as common in the mountainous districts (Abyssinia), generally sitting in the thick caper and thorny bushes, whence it is difficult to drive it.

The *Crotophaginæ*, or Horn-Bill Cuckoos, consist of the following genera:—

Crotophaga. [CROTOPHAGA.]

Dasylophus.—Bill rather large and compressed throughout; gonys angulated; culmen convex, gradually arched; frontal feathers incumbent and concealing the nostrils; feathers before the eye erect, forming a double crest. (Sw.) Example, *D. superciliosus*. (Sw.)

Phœnicophaus (Vieillot).—Bill large, very thick, smooth, resembling that of a toucan in miniature; face naked; nostrils basal, oval, close to the gape, placed in a groove of the bill, and defended by stiff erect bristles. (Sw.) Example, *P. viridis*.

The *Crotophaginæ* are found in Africa and America.

The *Leptostominæ*, or Long-Billed Cuckoos, consist of the following genera:—

Saurothera (Vieillot).—Bill lengthened, longer than the head, and straight, except towards the tip; the culmen convex, the gonys straight, the upper mandible with its margins finely crenated; orbits naked; wings moderate, second and third quills longest; feet short. Example, *S. velata*.

Anadænus.—General structure of *Saurothera*; but the upper mandible is only notched at the tip, the margins are entire; wings much rounded, the first four quills graduated. (Sw.) Native of India. Example, *A. rufescens*.

Leptostoma.—Bill very long and entire; wings very short and rounded; tail long and cuneated; tarsus much longer than the toes. Example, *L. longicauda*.

Mr. Swainson considers *Leptostoma* to be the grallatorial type of the *Cuculidæ*. *Centropus* he also considers to be a grallatorial type.

The *Leptostominæ* are found in India and America.

CUCULINÆ. [CUCULIDÆ.]

CUCULLUS. [ACALEPHÆ.]

CUCUMBER, the name of the fruit of *Cucumis sativus*. [CUCUMIS.] For its culture and varieties see CUCUMBER, in ARTS AND SC. DIV.

CUCUMBER, SPIRTING. [MOMORDICA.]

CU'CUMIS, a genus of Plants belonging to the natural order *Cucurbitaceæ*, comprehending the Melon, the Cucumber, and some sorts of Gourd. It is distinguished from the neighbouring genera by its three thick split stigmas, and by the seeds having a thin margin. The fruit is in all cases pulpy internally, many-seeded, and divided into three or six cells when young. The following are the principal species:—

C. Melo, the Melon. The native country of this valuable plant is unknown. Linnæus says Tartary, but his authority is not given, and in all probability is erroneous; De Candolle says Asia; Roxburgh only knew it in a cultivated state in tropical India; and Professor Royle seems unacquainted with any wild station for it in the Himalaya regions. Cashmere is the most likely to be the country whence it sprang; for it seems to be the mother of many of our other cultivated fruits, and has from time immemorial been famous for the excellence and abundance of its melons, which form a staple article of the food of the inhabitants. For the varieties and cultivation of this fruit see MELON, in ARTS AND SC. DIV.; we only here observe that all the melons known in Europe belong to the present species, unless it be the Winter Melon and its varieties, and that kind possibly originates from the following species:—

C. utilissimus, an annual, native of the higher cultivated lands of India, but generally found in a cultivated state. "The stems exactly as in *C. sativus*, but not quite so extensive. Tendrils simple, leaves broad-cordate, generally more or less 5-lobed; lobes rounded, toothletted; above pretty smooth, below scabrous, the largest generally about six inches each way. Floral leaves of the female flowers sessile, and very small. Male flowers axillary, peduncled, crowded, but opening in succession. Female flowers axillary, peduncled, solitary, both sorts yellow, about an inch or an inch and a half in diameter. Fruit fleshy, generally a very perfect oval; when young, downy and clouded with lighter and darker green; when ripe perfectly smooth, variegated with deeper and lighter yellow; from 4 to 6 inches long, and from 3 to 4 inches in diameter. This appears to me to be by far the most useful species of *Cucumis* that I know. When little more than one-half grown the fruits are oblong and a little downy; in this state they are pickled; when ripe they are about as large as an ostrich's egg, smooth and yellow; when cut they have much the flavour of the melon, and will keep for several months if carefully gathered without being bruised and hung up; they are also in this state eaten raw, and much used in curries by the natives. The seeds, like those of other cucurbitaceous fruits, contain much farinaceous matter blended with a large portion of mild oil. The natives dry and grind them into a meal, which they employ as an article of diet; they also express a mild oil from them, which they use in food and to burn in their lamps. Experience as well as analogy proves these seeds to be highly nourishing, and well deserving of a more extensive culture than is bestowed on them at present. The powder of the toasted seeds mixed with sugar is said to be a powerful diuretic, and serviceable in promoting the passage of sand or gravel. The cultivation of this species is chiefly confined to the Guntoor Circar, where the seeds form a considerable branch of commerce; they are mixed with those of *Holcus Sorghum*, or some other of the large culmiferous tribe, and sown together; these plants run on the surface of the earth, and help to shade them from the sun, so that they mutually help each other. The fruit keeps well for several months if carefully gathered and suspended." (Roxburgh, 'Flora Indica.')

C. sativus, the Cucumber, has rough stems bearing tendrils; leaves cordate, obscurely 5-lobed, petiolate, the terminal lobe the largest; flowers on short peduncles, usually 3, of a yellow colour; the fruit is long, somewhat triquetrous, smooth or prickly, usually shining. When very young the Cucumber is known by the name of Gerkin. Tartary is assigned to this species as its native country, but upon authority equally questionable with that for the Melon. No modern traveller seems to have found it wild. [CUCUMBER, in ARTS AND SC. DIV.]

C. Colocynthis, the Colocynth Gourd. This plant furnishes the drug Colocynth, so well known for its purgative properties. It is found wild in the Grecian Archipelago, Egypt, and the north-eastern parts of Africa generally. Burckhardt saw it covering large tracts in Nubia, and Roxburgh speaks of it as common on the coast of Coromandel. It is doubtful however whether the plant of the latter botanist is not rather *C. Pseudo-Colocynthis*. This species grows like a cucumber, but has cordate-ovate many-cut and lobed leaves, white beneath with hairs. Its fruit is small, round, deep yellow, smooth, hard externally, with an intensely bitter pulp. The gourds are gathered in autumn, when they are beginning to turn yellow; they are then peeled and dried rapidly in stoves. [COLOCYNTH, in ARTS AND SC. DIV.]

C. Citrullus, the Water-Melon. Its deeply-lobed and gashed leaves, and its round fruit, with a spotted rind and a cold watery pink or white flesh, in which lie a number of black seeds, sufficiently mark this species, which is most extensively cultivated all over India and the tropics of Africa and America, and generally in hot countries, but which is of no value in the north of Europe, where high flavour is required more than cooling properties. This plant serves both for food, drink, and physic to the Egyptians. It is eaten in abundance during the season, which is from May to July. It is the only medicine the common people use in ardent fevers: it is gathered when ripe or almost decaying; the juice is expressed, and mixed with sugar and rose-water. It is generally considered to be the Melon of the Jews mentioned in many parts of the Bible.

The other species are of little moment compared with the preceding; many are eatable, but they are in all respects inferior in quality and size. *C. Dudaim* is sometimes grown under the name of Queen Anne's Pocket Melon, but it is a mere curiosity.

CUCUMITES, a genus of Fossil Plants, from Sheppey. (Bowerbank.)

CUCURBITA, a genus of Plants belonging to the natural order *Cucurbitaceæ*. It has monœcious flowers; a campanulate yellow corolla, the petals joined together and to the calyx. In the male flowers the calyx is hemispherically campanulate. The stamens 5, in three bundles, or joined at the apex; anthers abruptly curved both at the base and the apex, the rest straight and parallel. In the female flowers the calyx is obovate clavate, narrowed towards the top or campanulate, and always circumcised under the limb after flowering; the anthers usually sterile; stigmas 3, thickish, and 2-lobed; fruit 3-5-celled; seeds ovate, compressed, with hardly tumid margins.

C. maxima, the Common Large Gourd, has cordate leaves, very rugged hispid petioles; the tube of the calyx obovate, ending in a short neck; fruit globose, somewhat depressed, yellow, red, or green. The native country of this common plant, as well as that of its many varieties, is unknown.

C. Melopepo, Squash Gourd, has cordate obtuse leaves, somewhat 5-lobed; denticulated tendrils, usually transformed into very imperfect leaves; the calyx hemispherically campanulate, short, having the throat much dilated; the fruit depressed; carpels irregular, rising beyond the throat of the calyx; the flesh dry, spongy, and white. The fruit is flattened at both ends. It is of great use in long voyages, for it can be kept for several months in a fresh state, and is commonly made into pies like the pumpkin, or boiled and eaten with meat instead of turnips or potatoes.

C. Pepo, Pumpkin, has cordate obtuse leaves, somewhat 5-lobed, denticulated, the calyx ending in a neck beneath the limb; fruit roundish or oblong, and smooth. It is a native of the Levant. This is the Melon or Millon of the early horticulturists, the true melon being formerly distinguished by the name of Musk-Melon. Though often grown in gardens for curiosity, it is cultivated in many country villages in England on dunghills, with the shoots trained a great length on the grass. When the fruit is ripe a hole is often cut in the side, the seeds taken out, and the space filled with apples, sugar, and spice; the whole being baked is then eaten with butter. On the Continent the fruit is a good deal used in soups, and also stewed or fried in oil and butter. Pumpkin pie is also very common in many parts of the world. There are various receipts given in cookery-books for dressing this fruit so as to render it a palatable and wholesome article of diet.

C. aurantia, the Orange-Gourd, is rather more tender than the other species. Its native country is unknown. It has hitherto only been cultivated for curiosity. When trained spirally round a pole or against a wall, and loaded with yellow fruit, it is very ornamental.

C. ovifera, Egg-Bearing Gourd, or Vegetable Marrow, has cordate angular leaves, 5-lobed, denticulated, pubescent; the calyx obovate, ending in a short neck, and cut round after flowering to the neck. It is a native of Astrakhan. The herb and flowers are very like those of *C. Pepo*, but less scabrous. This fruit is useful for culinary purposes in every stage of its growth. When young it is good fried with butter; when larger, or about half grown, it is excellent either plain boiled or stewed with a rich sauce; in either case it should be cut in slices. The flesh has a peculiar tenderness or softness, from which circumstance it received its name; and this property remains till it is almost fully grown, when it is used for pies.

C. Lagenaria, Common Bottle-Gourd (*Lagenaria vulgaris* of Seringe), is a musky-scented plant clothed with soft pubescence; the stems climbing; tendrils 3-4-cleft; leaves cordate, nearly entire; the flowers monœcious, stellate, spreading much in fascicles; the fruit is pubescent, but when mature quite smooth; the flesh white and edible. It is a native within the tropics. The fruit is shaped like a bottle; when ripe of a pale yellow colour; some nearly six feet long, with a roundish bottom and a neck; the rind becomes hard, and when dried is capable of containing water. It is then of a pale bay colour. It is very important that these bottles should be well and repeatedly washed out, so as to remove all traces of a bitter principle in which they abound, which is poisonous. It is said that a sailor was poisoned some years since by drinking beer out of one of these bottles which had been improperly prepared. Professor Royle also mentions, upon good authority, that cases of poisoning have occurred from eating the bitter pulp of this plant, in which the symptoms were those of cholera.

There are about nineteen species of this genus: they are propagated from seeds.

CUCURBITA'CEÆ, *Cucurbits*, the Cucumber Tribe, a natural order of Plants. It consists of climbing or trailing species with unisexual flowers, scabrous stems and leaves, a lobed foliage, and a more or less pulpy fruit with parietal placentæ. Nearly all the species climb by means of tendrils. The greater part consists of annuals, either wholly, or in so far as their stems at least. The petals are deeply veined, and usually either yellow, white, or green.

The order abounds in useful or remarkable plants, comprehending as it does the Melon, Gourd, Cucumber, Colocynth, Bryony, and all the many species approaching those types. Professor Royle, in his valuable 'Illustrations,' remarks that "they are chiefly remarkable for the power of adapting themselves to the different situations where they may be grown. Thus we hear of their affording large and juicy fruit in the midst of the Indian Desert, where water is 300 feet from the surface (Elphinstone); and they are equally grown in the dry season on the sandy islands of Indian rivers; but excess of moisture does not appear to be injurious, as the great majority are successfully cultivated in the rainy season; and Mr. Moorcroft describes an extensive cultivation of Melons and Cucumbers on the beds of weeds which float on the lakes of Cashmere; they are similarly cultivated in Persia and in China. ('Hort. Trans.,' 2nd ser., vol. i. p. 468, and Staunton's 'Embassy.') Being chiefly annuals which a few months suffice to bring to perfection, we find them succeeding in the summer temperature of northern climates, and thus extending from the line to 55° or 60° of northern latitude, and southwards to the Cape of Good Hope. Some of the species may be seen in the most arid places; others in the densest jungles. Planted at the foot of a tree, they emulate the vine in ascending its branches; and near a hut they soon cover its thatch with a coating of green. They form a principal portion of the culture of Indian gardens: the farmer even rears them in the neighbourhood of his wells."

The affinities of this order are with *Datiscaceæ* and *Begoniaceæ*. There are 56 genera and above 270 species.

Momordica Balsamina.

1, a sterile flower; 2, a fertile flower; 3, a section of a seed; 4, the embryo.

Two principles especially deserve attention in this order; the one saccharine and nutritious, the other bitter, acrid, and purgative; and the qualities of the products of the species vary according to the preponderance of the one or the other. In the Melon, the Gourd, and their allies, the first exists almost exclusively, and hence the edible nature of their fruit; but even here its well-known laxative quality sufficiently attests the presence of the bitter principle in some degree. In the Colocynth, the Bottle-Gourd, various species of Luffa, Bryony, and others, the bitter principle is found in a state of concentration, and hence the active and even dangerous qualities of those plants, from which the Cucumber itself is not exempt: only its bitterness is destroyed by the peculiar cultivation of that plant. The seeds of some kinds yield oil; and those of *Cucumis Momordica* are said to be ground into a kind of meal. [CUCUMIS; CUCURBITA; BRYONIA; MOMORDICA.]

CUDDEN. [MERLANGUS.]

CUDWEED. [FILAGO.]

CULEX. [CULICIDÆ.]

CULICIDES (Latreille), a family of Dipterous Insects of the section *Nemocera*. It has the following characters:—Proboscis long and slender, projecting forwards, usually straight, terminated by two little lip-like appendages; sucker composed of six slender bristle-like members; palpi 5-jointed, generally elongated; antennæ filiform, covered with hairs—in the male sex resembling little plumes; eyes contiguous; no ocelli; wings inclined, lying close to the body when at rest, and having one marginal and two sub-marginal cells.

The *Culicides*, according to Latreille, constitutes the first family of Dipterous Insects, and is the same group as that designated by Linnæus *Culex*. It is divided into three genera, distinguished principally by the following characters:—

Anopheles (Meigen.)—Palpi equal in length to the proboscis in both sexes.

Culex.—Palpi of the males longer than the proboscis, and in the females very short.

Ædes.—Palpi shorter than the proboscis in both sexes.

We are but too well acquainted with the torment inflicted by the insects of this tribe, which are known in this country by the name of Gnats; are called in France Cousins; and in America Mosquitoes.

The pain and irritation are caused by their piercing the skin to feed upon the blood (by means of the little bristles forming part of the proboscis), and injecting at the same time a poisonous fluid. It is said the females alone are the persecutors.

The humming noise accompanying their flight is produced by the vibration of their wings. Gnats seldom appear during the day-time, except in thick woods, and they always abound most in damp situations, a circumstance owing to the habits of their larvæ, which reside in stagnant waters.

The female Gnat deposits her eggs (which amount to 200 or 300 in a year) one by one: and as they are deposited they are joined together, and form a little raft, which floats on the surface of the water. The eggs are hatched in about three days' time, and produce little greenish larvæ, which have a distinct head and lengthened body, composed of numerous segments. The head is furnished with two ciliated organs, which are in constant motion. This motion appears to be for the purpose of creating a current, by which means minute animalculæ, or other substances which may constitute the food of the animal, are drawn into the mouth. Two other appendages, furnished with tufts of hair, appear to co-operate with the former for this purpose.

The breathing apparatus of the larva consists of a tube, terminated by radiating setæ situated at the apex of the body; through this tube the air is conveyed to the tracheæ, and for this purpose it is brought to the surface of the water, so that the animal is then in an inverted position. There is another apparatus also, situated at the tail of the animal, opposed to the breathing apparatus, which serves as a fin, and enables the larva to swim and dive with considerable velocity.

These larvæ are full grown in about fifteen days' time; they next assume the pupa state; the animal then appears to have a rounded form, owing to the apex of the body being recurved. It still inhabits the water and is active; the position of its breathing apparatus is however altered, it being now situated on the anterior part of the body, and consists of two little tubes, which, as before, are applied to the surface of the water for the reception of air. When about to assume the imago state, the skin which covered the pupa being loosened from the animal within, and the space between the two being occupied with air, it floats upon the surface of the water; the Gnat breaks through the upper part, and stands on the skin it has quitted, and which now serves as a little boat, upon which it floats until it has attained strength to fly.

Culex pipiens (Linn.), the Common Gnat, is less than a quarter of an inch in length; the palpi and antennæ are brown; the thorax is of a yellowish brown, with two darker lines; the abdomen is of a pale gray colour; the legs are brown, and the base of the thighs yellowish.

The insect which is so troublesome in the West Indies, the Mosquito (*Culex Mosquito*), is not quite so large as the Common Gnat. Its proboscis is black; the palpi are spotted with white; the head and thorax are spotted with silvery white, and the latter has a curved band of the same hue. The edges of the segments of the body are also of a silver-like colour.

CULM, the stem or straw of grasses.

CULTIROSTRES, a name given by Cuvier and others to a family of Birds, consisting of those species which were united under the genus *Ardea* by Linnæus, and whose bill is large, long, and strong, and most frequently pointed also, such as Cranes, Herons, Storks, &c. [ARDEA.]

CUMBRIAN ROCKS. Professor Sedgwick has given this term to the lowest series of Slaty Rocks which appear in the ranges of Skiddaw and Grasmore Fell in Cumberland. They lie below the green slaty rocks of Scawfell and the Old Man, which the same writer regards as coeval with the strata of Snowdon, and ranks under the title of Cambrian. [CAMBRIAN ROCKS.]

The succession of rocks, as pointed out by Professor Sedgwick in the Cumberland hills, is as follows:—

1. Skiddaw Slate, usually without fossils, but containing *Graptolites* in one locality.

2. Couiston Limestone, abounding in fossils.

3. Coniston Flagstone and Grit.

These rocks find their representatives in those called Cambrian in North Wales. These latter rocks are included by Sir Roderick Murchison in his 'Silurian System.' As the nomenclature of these rocks is still a disputed question, we subjoin the account of them published by Mr. Jukes, in his work on 'Physical Geology.'

"Cambrian or Cumbrian Rocks.—The word 'rocks' is used here instead of 'system,' or 'formation,' because we cannot yet precisely tell the value of the Cambrian division. Cambrian means the rocks of Wales; Cumbrian those of Cumberland and Westmoreland. In Wales these rocks consist of certain thick sandstones, gritstones, and conglomerates, with interstratified beds of green or green and purple slates. It is in the uppermost of the slate beds of this Cambrian group that the great Penrhyn and Llanberris slate quarries are opened. They contain no fossils. These rocks are found to have a thickness of upwards of 20,000 feet in some places in North Wales; but as the base of them is never exposed we know not how much greater thickness they may possess, nor what is below them. One portion of this division has been provisionally called the 'Barmouth and Harlech Sandstone Group.' Their upper boundary is a purely arbitrary line along the top of a certain set of beds drawn by the officers of the Geological Survey of Great Britain, under the direction of Sir H. T. De la Beche, C.B.; their reason for drawing it being simply that no fossils have as yet been found below that line, whereas fossils are pretty abundant in many places above it. It must not be forgotten that Professor Sedgwick (of whose peculiar department we are now speaking, he being the one geologist who has single-handed done far the most to unravel the structure of these older rocks) dissents from this placing of the boundary of the Cambrian Rocks; and himself places it much higher, so as to include the beds we shall subsequently speak of, as Lower Silurian, dividing his system into Upper and Lower Cambrian. There can be no doubt that if we neglect the fossils, and look only to the physical structure and position of the rocks of Wales, Professor Sedgwick is right. There can be no reason for drawing the boundary where it has been drawn, and along no other geological horizon in North Wales, except the fact that fossils have been found in all the rocks above that line of division, and in none of those below. Whether they may not hereafter be found is another question. If we go to Cumberland, Professor Sedgwick there describes the Cambrian, or, as he there calls them, Cumbrian Rocks, as likewise consisting of upper and lower, and gives the following abstract of them:—

		Feet.
Cumbrian, Upper	Coniston Flagstone	1500
	Coniston Limestone	300
	Slates and Porphyry	10,000
Cumbrian, Lower	Skiddaw Slate	6000

He describes these however as all fossiliferous, which, by the rule lately mentioned, would exclude them from being considered as Cambrian at all, more especially as the fossils of the upper beds are such as palæontologists seem agreed to consider of Silurian age. It is highly probable that the Skiddaw Slates are of the same age as the Barmouth and Harlech Sandstone Group of North Wales, which likewise contains the best roofing-slates of that country. In that case, according to the classification adopted by the Geological Survey, the Skiddaw slates would be considered Cambrian, and all above them as Silurian. The reader will see from these statements that this part of the classification of the stratified rocks is far from being settled. There is however no dispute about the things themselves; the rocks are all known, and their order completely ascertained; the uncertainty is merely as to the name by which certain portions of them shall be called." [WALES, GEOLOGY OF, in GEOG. DIV.]

CUMINGIA. [CONCHACEA.]

CUMINUM, a genus of Plants belonging to the natural order *Umbelliferæ*. It has 5 calyx teeth, which are lanceolate, setaceous, unequal, and permanent. The petals are oblong, emarginate, erect, spreading, with an inflexed lobe. The fruit is contracted at the side. The ridges of half-fruits wingless; the primary filiform, minutely muricated, the laterals forming a border, the secondary more prominent and aculeated; the channels under the secondary ridges with one vitta in each. The species are annuals, with multifid leaves, having setaceous divisions. The flowers are pink or white.

CUMMINGTONITE, an American Mineral belonging to the Hornblende series. It is fibrous, of an ash-gray colour, with a slight silky lustre. It is found at Cummington and Plainfield, in Massachusetts. (Dana, *Mineralogy*.)

CUNITA, a genus of Plants belonging to the natural order *Labiatæ*. It has a 13-nerved calyx, ovate, tubular, equal, 5-toothed, the throat villous inside. The corolla having the tube equalling the calyx, naked inside, and the limb bilabiate; the upper lip erect, flattish, usually emarginate; lower lip spreading, trifid, with nearly equal entire lobes, the middle lobe rather the largest and emarginate. The stamens 2, erect, exserted, without any rudiments of the upper two; filaments glabrous, toothless; anthers 2-celled, cells parallel, or at length divaricate. The style shortly bifid at the apex; the lobes nearly equal, subulate, minutely stigmatiferous at top; the achenia dry and smooth. The flowers small, white, or purplish. The species are herbs, shrubs, or undershrubs.

C. Mariana, native of Canada to Carolina, on dry mountains, is a branched herb with short glabrous branches, but pubescent at the nodes. The corolla is about twice as long as the calyx, and is pubescent inside, and of a red colour. It is employed medicinally, where it grows, in slight colds and fevers, with a view to excite perspiration.

C. microcephala is also used medicinally in coughs and colds, in Brazil, where it grows. It has a procumbent stem, with scarcely pubescent branches; the leaves petiolate, oblong or obovate, obtuse, quite entire, or subsinuately serrated, narrowed at the base, glabrous, and flat. The corolla is white; the throat villous inside.

There are several species of this genus, none of which are of any known use except those above mentioned.

CUNNINGHAMIA, a genus of Plants belonging to the natural order *Coniferæ*. *C. Sinensis* is an evergreen Chinese tree, formerly called *Pinus lanceolata*. It has narrow oval lanceolate stiff pungent leaves, which, when the plant is old enough, collect into cones, after the manner of an *Araucaria*. The plant will live near London in the open air, with a little protection in winter.

CUNONIA'CEÆ, *Cunoniads*, a small natural order of Polypetalous Apocarpous Exogens, allied to *Saxifragaceæ*, with which they were formerly united. They are trees or shrubs, inhabiting Southern Africa, South America, and very sparingly the East Indies. In most respects their flowers are constructed like those of *Saxifragaceæ*, but the styles are more consolidated, and they have a dense spiked or racemose inflorescence instead of a few loosely-arranged blossoms. The leaves are opposite, and furnished with interpetiolar stipules, and being pinnated, in most cases give the plants a peculiar aspect. Little is known of their properties, except that their bark is sometimes very astringent, and used for tanning purposes. There are 22 genera and 100 species.

C. Weinmannia rubescens.

1, a perfect flower; 2, an ovary; 3, a transverse section of the same; 4, a ripe fruit.

CUPRESSINITES, a genus of Fossil Plants from Sheppey, containing 13 species. (Bowerbank.)

CUPRESSOCRINITES, a genus of *Crinoïdea*. (Goldfuss.)

CUPRESSUS, a genus of Plants belonging to the natural order *Coniferæ*, distinguished from the firs and pines by its leaves being mere scales, its cones formed of a small number of peltate woody bracts, and the seeds very small, angular, and several to each bract. Botanists mention several species, but of these three only are suited to the climate of Great Britain.

C. sempervirens, the Common Upright Cypress, is a native of the warmer parts of Europe, but has long since been transferred to gardens for the sake of its deep evergreen branches and leaves, and the gloomy air it imparts to the situations which it occupies. Its timber is of great durability: it is probable that Gopher-Wood, which some have referred to the cypress, was rather the timber of *Thuja articulata*. It is not much cultivated in England, the climate being too damp and cold for it in summer; otherwise it is sufficiently capable of resisting the cold of winter. Its formal mode of growth moreover is not to the taste of the people of this country. The cypress was anciently, as well as at present, in south-eastern Europe, chosen as a memorial of the dead; and they are still the principal ornaments of cemeteries in Greece and all over the Ottoman empire.

C. horizontalis, the Spreading Cypress, is a far handsomer species, partaking in all the excellent qualities of the last, being more hardy, and becoming a beautiful object with its graceful spreading branches, loaded, as they usually are, with large round cones. Miller has rightly pointed out the difference between this and the last, but it is nevertheless exceedingly uncommon in the collections of this country. The Spreading Cypress of the nurseries is nothing but a very slight variety of *C. sempervirens*.

C. Lusitanica, the Cedar of Goa, differs from the two preceding in its much freer mode of growth, and in its leaves having a singularly glaucous colour. It is said to be of Indian origin, but has long since been naturalised in Portugal, where about Cintra it acquires a large size. In England it will only succeed well in the warm parts of the southern coast.

CUPULE, a kind of cup or involucre surrounding certain kinds of fruit, and composed of bracts more or less grown together. In the oak the cup of the acorn is the cupule; in the hazel-nut it is the husk; in the beech and chestnut the prickly shell; and in the hornbeam the lobed bract.

CUPULIFERÆ. [CORYLACEÆ.]

CUPULITES. [ACALEPHÆ.]

CURASSOW. [CRACIDÆ.]

CURCU'LIO, a genus of Insects founded by Linnæus for such Tetramerous *Coleoptera* as have club-shaped antennæ inserted on a prolonged rostrum. In the twelfth edition of the 'Systema Naturæ,' 95 species are enumerated. The progress of entomology has converted the genus, as defined by its founder, into a family including several thousand species, though the original name is retained for a few South American beetles, of which *Curculio splendidus* is the type. The popular name for these insects, whatever may be their scientific designation, is the Weevil. The Weevils are favourites with the entomologist on account of the sigularity and often beauty of their forms and colours. The splendid Diamond Beetle, the wing-cases of which furnish such gorgeous microscopic objects, is a member of the tribe. Many of them are adorned with the most vivid metallic lustre, and some in intensity and brightness of hue emulate gems, and have been used for purposes of ornament. The family includes very numerous genera and species, and they are distributed widely over the world.

The Weevils are interesting in another point of view. Many of them are dangerous enemies to the agriculturist, destroying grain, fruit, flowers, leaves, and stems, and from their numbers often perpetrating serious mischief. Their natural history therefore has been made an object of special researches, in the hope of counteracting their ravages. We shall here give some account of the noxious species.

1. Weevils attacking the nutritive organs of plants.—*Rhynchites Betuleti* is a little blue or green beetle, glossed with metallic lustre, which attacks the vine and the pear-tree. It is four lines in length, one-third of which is occupied by its snout. Short spines on the thorax distinguish the male from the female. It attacks the leaves of the plants mentioned, in order to construct its habitation of them, and with a view to their furnishing food for its offspring. It rolls up the leaves and deposits its eggs in the rolls, where they are hatched, the nest afterwards supplying the larvæ with food. As the maggot grows, the rolled leaf and its stalk dry up, and at length fall to the ground on the first high wind, by which time the maggot is fully grown and ready to leave its house, to bury itself in the ground and wait for the spring, when it is to appear in a new garb as a Weevil.

The process by which the roll is made is thus described by Köllar: "When the female has selected a suitable leaf, she cuts the petiole with her rostrum almost half through, so that it hangs down, and is more conveniently placed for future proceedings. She then begins to roll the leaf together, generally alone, but sometimes assisted by the male. While this operation is going forward, she also lays her eggs, that is, she pierces the roll, lays an egg in the opening, and pushes it in with her rostrum, in such a manner that it remains on the inner side of the leaf. When she has introduced five or six eggs in this manner, between the different folds, she rolls the remaining part of the leaf entirely together, so that it is impossible to discover, from the outward appearance, in what manner the eggs were deposited." This beetle is extremely injurious to vineyards by defoliating the vine, after which the grapes will not ripen, and the prospect of a vintage is destroyed. The rolled-up leaves containing its young should be carefully collected and destroyed before the worms have time to arrive at maturity. Its operations are often erroneously ascribed to *R. Bacchus*. *Otiorhynchus sulcatus* is another beetle which is injurious to the vine by gnawing off the young shoots. It also attacks the roots of succulent plants.

Nemoicus oblongus is a little Weevil only two lines long, with a very short beak, a black head, body, and thorax; and reddish antennæ, feet, and wing-cases. It attacks the young leaves of young fruit-trees, above all those of the peach, and is both a glutton and an epicure; for while it devours most voraciously, it selects only the delicate portions of the leaf, the cellular parenchyma, leaving the midrib and petiole untouched. It appears very early in spring, and after pairing the female deposits her eggs in the ground, the grub feeding on the roots of various plants until the following spring. When these insects are on the trees, they must be gathered with the hand.

There is a very small species of *Rhynchites*, the *R. Alliariæ*, scarcely a line and a half in length, and of a steel-blue or green colour, which, by injuring the shoots of young trees and fine grafts, is a source of great annoyance to the planter, sometimes perpetrating great ravages in nurseries, without distinction as to the kind of trees. The following interesting account of the operations of this insect is extracted from Köllar:—

"When the shoot of the tree or graft is about a span long, the female selects one that suits her, and it does not signify to what kind of fruit-tree it may belong. As soon as she has reached the most suitable part of the shoot, she marks the place first by a prick or by a small cut, where she intends to cut off the bud or shoot. She then recedes about a line upwards, and begins (with her head turned downwards), on the side which is not next the tree, to bore with her proboscis, until she reaches the middle of the shoot. With it she also widens the chamber, and prepares it for her offspring. She then places herself over the entrance, and lays an egg, which is pushed in by the proboscis and conveyed to the proper place. This operation lasts an hour. Immediately after the female returns to the former place, to cut off the shoot, moving it from one side to the other with her proboscis, until she has cut it a certain depth. She then gives some decided thrusts, which she continues, without fatigue, till the shoot only hangs by the under part. When she observes this, she gets up on the point of the twig, to make it fall over by her own weight. It not unfrequently happens that it falls immediately, the shoot having been previously so cut as to remain attached to the stem only by the bark. If the beetle however finds that the pierced shoot does not fall, she turns back to labour again at the same place, and cuts still deeper through the branch; and if she is not able to divide it, she gets up once more to the further extremity, by which means she generally succeeds in bringing the separated branch to the ground. When this labour is over, she feeds upon a leaf, scraping off the epidermis, which serves her as food." This operation is repeated day after day for the same purpose until the middle of June, at the rate of two eggs a day, the insect reposing under a bent leaf at night. Her work is interrupted by bad weather. When the egg is hatched, usually in eight days, the grub eats the pith of the shoot which falls off, upon which it leaves its habitation, and buries itself in the earth, where it makes a subterraneous vault for its winter residence. When the spring comes, it appears as a Weevil to pursue the avocations above described. The beetle is timid, and drops from the leaf when approached, so that, when we proceed to gather them, which should be done in order to destroy them (besides collecting and destroying all fallen and injured shoots where their eggs may be), we must approach with caution to gain our object.

There are two species of Weevil which attack the wood of the pine-tree, namely, the *Hylobius Abietis* and *Pissodes notatus*; the first is the larger species, and usually precedes the latter in its attacks. When the one is plentiful, the other is also abundant, and vice versâ; the cause of this correspondence in numbers being, that they usually only attack such trees as are sickly, but when the supply of sickly trees fails, they are apt to have recourse to the more healthy plants, and thus may destroy valuable plantations. They apparently attack sickly trees in preference, since in such the motion of the sap is sluggish, and there is not so much resin exuded as to oppose and impede their operations. The larger insect attacks both bark and buds, and dangerously wounds such ramifications of the roots as are near the surface of the ground. The wound is an ugly bean-shaped scar. The second species chiefly confines its attacks to the bark and sickly cones. The wounds it makes resemble pin-holes, and are often extremely numerous. On account of their caution and timidity, both these insects, although numerous when present, are very difficult to find. The best preventive of their ravages is to root up and burn such young trees in the plantation as are sickly.

There is a species of *Calandra*, the *C. Palmarum*, which in South America attacks the pith of the palm-tree. Its larva is called by the colonists Ver Palmiste, and is esteemed a delicacy.

In the third volume of the 'Journal of the Royal Agricultural Society of England,' Mr. Curtis has given an account of two little Weevils, *Ceutorhynchus assimilis* and *C. contractus*, which injure turnip crops by puncturing the leaves of the young turnips, sometimes causing as much damage as the Turnip-Fly (*Haltica Nemorum*). They should be collected from the turnip-flowers left for seed, by shaking the stalks over a bag-net or cloth, and sweeping the insects into a pail of lime and water. The insects should afterwards be destroyed by boiling, as the hardness of their horny coat renders it no easy matter to destroy them otherwise.

2. Weevils attacking the reproductive organs of plants.—There is a little brown Weevil which often destroys our prospects of a plentiful supply of apples. As soon as the spring comes it goes forth to seek the apple-tree, and when the blossom-buds appear, and are full of sap, it deposits its eggs in them, so that the grubs are hatched in the first warm weather, and immediately proceed to destroy the generative organs of the plant, eating up the innermost first. It is called *Anthonomus Pomorum*. The affected flowers swell out, and form a sort of cup, within which, when we open them, we find the larva in the form of a small white maggot with a black head. The beetle selects the finest apple-blossoms to be the cradles of its offspring. It bores a hole in them with its proboscis, making a canal even to the parts of fructification; then laying its eggs at the entrance it turns round and pushes them in with its snout as far as it can. This operation it repeats as long as it has eggs to lay, walking from blossom to blossom, choosing the finest and calmest days for its labours. Nothing but gathering the beetles and destroying the affected flowers can arrest their progress in the orchard, and by doing so we may diminish their number, though, it is to be feared, hopes of their extirpation are vain.

There is another Weevil of the same genus, the *A. Pyri*, very similar in appearance, which destroys both blossom and leaf-buds of the pear, and which, when not too numerous, may even increase the crop by preventing an overweight of fruit. The ascent of both these beetles up the trunks of the trees may be impeded by circles of paper covered with tar.

The fruit of the plum is destroyed by a Weevil called *Rhynchites cupreus*, which sometimes also makes use of the soft spring shoots of plum and apricot trees. The female beetle attacks the plums when they are about the size of almonds. She has two objects in view: first, to deposit her egg in the pulp; and second, to sever the fruit from the tree in order that the larva may bury itself in the earth preparatory to its final metamorphosis. The first purpose she effects by cutting the epidermis with her proboscis, raising it, boring a hole in which her egg is to be laid, and after that has taken place covering it carefully over with the raised skin so as to prevent the access of water. Before she sets about this, she half cuts through the peduncles; and when the egg-laying operation is completed she severs the stalk entirely; the joint operations occupy from two to three hours. It takes the grub five or six weeks to devour the pulp of the plum. If left undisturbed, the beetle never leaves the tree until it has pierced and thrown down every plum it can find. The only remedy or preventive to its destructive industry is to gather and destroy the affected plums. Similar ravages are committed on the apple by another species of *Rhynchites*, *R. Bacchus*, the hue of which is beautiful purple and gold.

In the first volume of the 'Transactions of the Entomological Society,' Mr. W. Christy has made known a Weevil, the *Calandra Tamarindi*, which destroys tamarind stones. There are sometimes thirty or forty of these Weevils in a single stone. He was led to seek for them from finding that the stones of tamarinds sometimes crumbled to pieces in the mouth. In such cases the albumen was perforated in every direction, and the cavities filled with a brownish powder. Those in which he first found the insect exhibited no trace of puncture in the epidermis. It would be curious to ascertain in what manner the parent insect deposits her eggs. If she attacks the fruit in an advanced state she must have to make her way through the external shell, the internal acid pulp, and the leathery envelope of the inside, before arriving at the stone itself.

A more destructive species of *Calandra* is the Corn-Weevil, *C. granaria*. In this case the maggot also is found in the centre of grains without trace of an aperture. The insect probably lays the egg in the blossom. It is often very abundant in old granaries. The bread made from the affected flour is supposed sometimes to be unwholesome. Perfect ventilation and a constant shifting of the grain are the best remedies. Mr. Mills states ('Ent. Trans.' vol. i.) that a heat of 110° Fahrenheit did not prevent the development of the insect, whilst from 130° to 140° killed them.

The *Bruchus granarius* attacks peas and beans, selecting the finest seeds in which to deposit her eggs. The bean- and pea-fields in Kent suffer sometimes severely from this beetle. It is a little black punctured species, gray beneath, with legs of the same colour. *B. Pisi*, a larger species, common in peas from Germany and Russia, is in North America at times such a pest, that in some States, towards the beginning of the last century, the cultivation of peas was abandoned in consequence of its ravages.

The family of *Curculionidæ*, as at present constructed, has been made the subject of special research on the Continent by M. Schönherr, and in England by Mr. Walton. The former entomologist has published a work entitled 'Genera et Species Curculionidum.'

CU'RCUMA, a genus of Plants belonging to the natural order *Zingiberaceæ.* It has the tube of the corolla gradually enlarged upwards; the limb 2-lipped, each lip 3-parted; the single filament broad; the anther incumbent, with two spurs at the base; the style capillary; the capsule 3-celled; the seeds numerous, arillate. The species are stemless plants with tuberous roots; the flowers are of a dull yellow colour, surrounded by bracteolæ.

C. Zerumbet, Zedoary, has lateral spikes, the tubers palmate, pale straw-coloured; the leaves from 4 to 6 together, with a long somewhat winged petiole, with a dark purple cloud running down the centre; the flowers shorter than the bracteolæ; the embryo truncate, nearly as long as the seed, the upper half lodged in the vitellus, the lower half in the perisperm. This plant is the *Zedoaria longa* of the shops, and has the same property as the following species. It is a native of the East Indies and Java.

C. Zedoaria, Broad-Leaved Turmeric, has the spikes lateral; biennial tubers, which are yellow internally; the leaves petioled broad-lanceolate, entire, underneath covered with soft sericeous down. This is the *Zedoaria rotunda* of the shops. Fée has confounded this plant with *Kæmpferia rotunda,* which has no sensible properties resembling the plant in question. The tubers of this plant are aromatic, and are used by the Hindoos not only as a stimulating condiment and a medicine, but as a perfume. Its sensible properties are very like those of ginger, but not so powerful. It is employed in the East in cases of disease, as colic, cramp, torpor, &c., where stimulants are indicated. The Zedoary is used under the same circumstances. The roots of both these plants are imported into Europe, but are not used extensively. *C. Zedoaria* is a native of Bengal, China, and various other parts of Asia, and of the Asiatic Islands.

C. rubescens has lateral spikes, the tubers pearl-coloured inside; the leaves bifarious. broad-lanceolate, cuspidate, smooth, strongly marked with parallel veins, of a uniform dark green with the nerves or ribs red, 12 to 24 inches long, 5 or 6 inches broad; the scapes invested with several dark reddish sheaths. It is a native of Bengal. All the parts of the plant have a pleasant aromatic smell when the plant is bruised. The pendulous tubers of this and several other species of *Curcuma* yield starch, and are employed by the natives for preparing arrow-root. In Travancore it forms the principal diet of the natives.

C. Amada, Mango-Ginger, has few-flowered central spikes; the tubers horizontal, palmate, of a deep orange colour inside; the leaves radical, bifarious, petioled above their sheaths, lanceolate cuspidate, smooth on both sides, from 6 to 18 inches long by 3 to 6 inches broad. This plant is a native of Bengal, and is called by the Bengalees Amada. It is called Mango-Ginger because the fresh root has the smell of a mango. It is used for the same purposes as ginger.

C. leucorhiza grows in the forests of Bahar, where it is called Tikor. It has remarkably long tubers, often a foot in length, of a pale yellow inside, and they produce an excellent arrow-root.

C. angustifolia, with stalked narrow lanceolate leaves, is a native of the forests of India from the banks of the Lona to Nagpore. Its tubers, which are found at the end of fleshy fibres which meet together forming a crown, yield an excellent arrow-root, which is that met with in the markets of Benares.

C. longa, the common Turmeric, is cultivated all over India, and is used as a condiment and for dyeing. The root is divided into several fleshy fingers, of an oblong form, and as thick as the thumb. The leaves spring at once from the crown of the root, have a lanceolate figure, sheathe each other at the base, are about a foot long, and produce from their centre a short thick leafy spike, in the axil of whose bracts are seated the inconspicuous pale cream-coloured flowers. Dr. Roxburgh gives the following account of the manner in which the plant is cultivated: "The ground must be rich, friable, and so high as not to be drowned in the rainy seasons, such as the Bengalees about Calcutta call Danga. It is often planted on land where sugar-cane grew the preceding year, and is deemed a meliorating crop. The soil must be well ploughed and cleared of weeds, &c. It is then raised in April and May, according as the rains begin to fall, into ridges, nine or ten inches high, and eighteen or twenty broad, with intervening trenches, nine or ten inches broad. The cuttings or sets, namely, small portions of the fresh root, are planted on the tops of the ridges, at about eighteen inches or two feet asunder. One acre requires about nine hundred such sets, and yields in December and January about two thousand pounds weight of the fresh root." [TURMERIC, in ARTS AND SC. DIV.]

CURLEW. [SCOLOPACIDÆ.]

CURRANT. [RIBES.]

CURRUCA, a genus of Insessorial Birds belonging to the tribe *Dentirostres* and family *Sylviadæ.* It includes, according to Yarrell, the following British species:—

Curruca atricapilla, the Black-Cap Warbler.

C. hortensis, the Garden-Warbler.

C. cinerea, the Common White-Throat.

C. sylviella, the Lesser White-Throat. [BLACK-CAP; SYLVIADÆ; WHITE-THROAT.]

CURSORIUS. [CHARADRIADÆ.]

CUSCUTA'CEÆ, *Dodders,* the Dodder Tribe, a small natural order of Monopetalous Exogens, cut off from *Convolvulaceæ* because of their imbricate corolla, which does not fall off after flowering, their seeds with a spiral acotyledonous embryo, and their leafless parasitical habit. There are but two genera of this order, *Cuscuta* and *Lepidanche.* About 50 species have been described.

Cuscuta, Dodder, is a genus met with in most temperate climates, the species fixing themselves on the branches of woody or other plants, twisting round them, striking a number of minute suckers down upon their bark, and thus attracting from the system of the plants and from the air the sustenance necessary to their own support. Hence they are true parasites, although they do not actually, like mistletoe, plunge their roots into the wood and incorporate themselves with the tissue.

Cuscuta Epithymum, twining round Lucerne.

1, a perfect flower; 2, a corolla cut open; 3, an ovary with its calyx; 4, the embryo.

The following are the species of *Cuscuta* found in Great Britain:—

C. Europæa, Common Dodder, a white or reddish-looking annual, which flings its thread-shaped arms like a cluster of living threads round the branches of heath, furze, &c., on commons and dry wastes. It has no leaves, except tiny scales that stand in their room; and it bears small clusters of white bell-shaped blossoms, each of which has five scales at the base of its tube. The fruit is a little membranous capsule, opening transversely like a soap-box, and dropping four seeds upon the soil. There is a common prejudice that these seeds actually strike root into the plant; but that this is a popular error is sufficiently shown by the following observations translated from De Candolle: "The seed of dodder differs from that of other *Convolvulaceæ* by the absence of cotyledons, as the dodder itself differs from them by the absence of leaves; the latter are either entirely absent, or are reduced to almost imperceptible scales. The germination of the dodder is effected, like that of plants in general, in the earth, and without requiring the presence of other vegetables. The embryo, deprived of its cotyledons, is nourished, in its first development, at the expense of the central albumen which it envelops. The slender and simple radicle descends into the earth; and the plumule, equally simple and cylindrical, rises like a thread: if it finds no other living plant near it, it dies; if it finds one, it surrounds the stem, and from the points of contact proceed hollow tubercles or suckers which plant themselves in the bark, and suck the juice which has been elaborated by the plant attacked; then the root becomes obliterated and dies, and the plant lives from that time forward by its suckers only. Whilst it was not a parasite, it rose vertically; as soon as it became one, it was no longer tempted to direct itself either vertically, or towards the light. Its shoots dart from one plant to the other, and thus are conveyed to new victims when the old ones are exhausted. Often the seeds germinate before they quit the capsules, and the new plant immediately becomes a parasite; this is particularly observed in the *Cuscuta monogyna,* which attacks the vines in Languedoc.

"The dodders, called by the French cultivators Teigne, Rache, Perruque, &c., are very dangerous to the fields of leguminous plants which they attack, and upon which they multiply themselves with singular rapidity. They destroy the plants either by depriving them of their nourishment, or by strangling them in their folds. It is difficult to guard against them on account of the rapidity of their vegetation, the facility with which they pass from one plant to another, the abundance of their seeds, and the double power which they possess of germinating either in the earth or in the capsule. M. Vaucher cleared his artificial fields from dodder pretty well by perpetually breaking and dividing their stalks with a rake. The means which appear to me really efficacious are immediately to mow all the portions of artificial meadow where dodder has been seen to develop itself, and to do it before it can have produced seed. If it appear in fields of flax, the plants attacked must be cut down, or rooted up; and if it appear among vines, the branches must be cut before the seed is matured. If these precautions have been neglected, and a portion of the land should be infested with these seeds, the crop which has been attacked must be replaced by crops of corn or of grasses. Thus time is given to the seeds of dodder which have been concealed in the soil, to develop themselves, when they may perish without doing any harm, since the soil finds itself covered with plants which cannot nourish them. As to the seeds of leguminous plants which may be infested by a mixture with those of the dodder, the best means to get rid of them is to sift them in a tolerably fine sieve, so that the seeds of the dodder, which are very small, may pass through, leaving those of the trefoil or of the lucerne. In this operation the seed must be shaken rather violently, so as to break the capsules of the dodder, and to force their seeds out."

C. Epilinum, Flax Dodder, has clusters of bracteated sessile flowers, the tube of the corolla ventricose; scales adpressed, fimbriated, distant below, with rounded spaces; the calyx with fleshy segments, deltoid below, nearly as long as the tube of the corolla. This species is parasitical on flax, and very injurious to the crop.

C. Epithymum, Lesser Dodder, has clusters of bracteated sessile flowers; tube of the corolla cylindrical; the scales converging, as long as the tube of the corolla, fimbriated, and rounded at the end, approximate below, with narrow acute spaces; the calyx bell-shaped, shorter than the tube of the corolla. It is parasitical on small shrubby plants.

C. Trifolii, Clover-Dodder, has the scales converging, half as long as the tube of the corolla, fimbriated and rounded at the end, distant below, with rounded spaces; the calyx narrowed below about as long as the tube of the corolla. It is parasitical on clover.

(Babington, *Manual of British Botany.*)

CUSHAT. [COLUMBIDÆ.]

CUSPARIA. [GALIPÆA.]

CUSTARD-APPLE. [ANONACEÆ.]

CUTICLE. [EPIDERMIS.]

CUTTLE-FISH. [SEPIADÆ.]

CYANITE. [KYANITE.]

CYA'THEA, a genus of Plants belonging to the natural order of Ferns. The sori are globose, situated upon a vein or veinlet, or in the axil of a fork of the vein; the receptacle elevated, globose, or columnar; the involucre globose, inferior, membranaceous, or somewhat horny, at first entire and covering the whole sorus, afterwards bursting from the top with a nearly circular opening, becoming cup-shaped, more or less entire, or laciniated, or lobed; the veins pinnate, simple, or forked, free. (Hooker.) The species are arborescent, and the trunks are often beautifully marked with the scars of the fallen fronds. The fronds are simple or pinnate, or decompoundly pinnate. The stipe is frequently aculeated. The species of this extensive genus of Ferns are found most highly developed in tropical climates. They give a peculiar feature to the vegetation of many districts of South America, and specimens have been brought from the forests of Brazil, the mountains of Mexico and Peru, from the islands of the Eastern, Western, and Southern Oceans, and from the south of Africa and the interior of India and China. Sir William Hooker, in the 'Species Filicum,' enumerates about forty different species. They are difficult to determine when brought to this country. "They have," says Sir William Hooker, "arborescent trunks whose appearance, and even external form, are only known to travellers who have the privilege of seeing them in their native soils. The fronds, gigantic in most cases, and large in all, seldom reach us in an entire state. We are but little acquainted with the stipes, whether it be unarmed or aculeated, or with any other character which may afford marks of distinction. The shape or outline of the entire frond we have rarely the means of ascertaining: nor do we know what is the exact nature of its composition, nor the value to be put upon the more or less downy or scaly covering of the pinnæ, or the greater or less breadth of the pinnæ, or pinnules, or segments, or the more or less deeply serrated margins. Hence, too, their synonymy becomes inextricable; and without the opportunity of examining authentic specimens of authors, their species in many instances must be looked upon as doubtful. The difficulty is increased by the older authors not considering the nature of the fructification nor the venation, so that in few herbaria do we find the most common, and, we presume, the original species, the one upon which the genus appears to have been mainly founded, *Cyathea arborea*, correctly named."

The following is the definition of the typical species:—

C. arborea, Common Tree-Fern, unarmed, or with few distant short prickles on the main rachis and stipes which are frequently downy; fronds bipinnate; pinnules lanceolate, elongate, much acuminated, deeply pinnatifid, glabrous, or with the rachis and costa hairy, paler beneath; involucre coriaceous, cup-shaped in age, a little contracted upwards, opening with a beautifully even margin. It is a native of Jamaica, Hispaniola, Martinique, St. Vincent, probably the West India Islands generally, and Brazil.

In Hooker's 'Species Filicum' the members of this genus are distributed according to the districts in which they grow. Twenty-one species are natives of the West Indies, Mexico, and South America. Two only are found in South Africa. Eleven are natives of Eastern India and islands, the Pacific Islands, and New Zealand.

Few of these Ferns are used by man, and although very elegant are seldom cultivated. One of them, *C. medullaris*, a native of New Zealand, produces a starchy matter, which is used by the natives as food, and called Mamaga. The starch is found in the roots, and these are baked and eaten as food.

(Hooker, *Species Filicum;* Burnett, *Outlines of Botany.*)

CYATHOCRINI'TES, a genus of Fossil *Crinoidea*, confined to the Palæozoic Strata. [ENCRINITES.]

CYATHOPHY'LLUM, a genus of *Madrephyllicea*, which occurs fossil in Palæozoic Strata, especially in the calcareous beds of the Silurian and Carboniferous Rocks. In the works of Goldfuss, Murchison, and Phillips, many species are recorded from the Eifel, Salop, Devon, Yorkshire, &c. [MADREPHYLLICEA.]

CY'BIUM, a genus of Fossil Fishes, from the London Clay of Sheppey. (Agassiz.)

CYCADA'CEÆ, *Cycads*, the Cycas Tribe, one of the natural orders of Gymnospermous Plants. It is essentially characterised by its trunk growing in a cylindrical unbranched manner, in consequence of the development of one terminal bud only, and by its diœcious flowers, of which the males at least grow in cones composed of peltate scales. In one genus, *Zamia*, the female flowers also are disposed in the same manner; in the other, *Cycas*, they are placed upon the toothings of abortive leaves, occupying the centre of the terminal bud. The leaves of these plants are pinnated, and have a certain resemblance to those both of ferns and palms; their wood is arranged both in concentric circles, which in *Cycas* are numerous, and in a confused manner among the central pith; so that a Cycadaceous stem partakes in structure of the peculiarities of both Exogens and Endogens. In the manner in which their leaves unrol, and in their terminal single bud, *Cycadaceæ* resemble Ferns, with which they may moreover be compared on account of their fruit proceeding from leaves; with *Coniferæ* they accord in the cone-like arrangement of their parts of fructification and their naked ovules; and with Palms in the secretion of a large quantity of fæcula in their stem, in their mode of growth, and in the

Cycas circinalis.

1, a male cone; 2, a female spike; 3, a section of a ripe fruit.

arrangement of a part of their woody system. *Cycadaceæ* therefore, belonging as they do to Gymnosperms, possess nearly equal affinity with Palms, or Endogens, and Tree-Ferns, or Acrogens. The species are natives of the tropics and temperate parts of America and Asia. They are found at the Cape of Good Hope and Madagascar, but not in equinoctial Africa. One species, *Macrozamia spiralis*, inhabits the west coast of Australia. Undoubted fossil remains of these plants in the Lias, Wealden, and other formations of England, attest the fact of their once having formed a part of the vegetation of Great Britain. All the species contain starch, and from many it is seperated and employed as an article of diet. The epeciee of *Encephalartos* are called Kaffir-Bread. The seeds of *Dion edule* yield etarch in Mexico. The same substance, under the name of Sago, is obtained from epecies of *Zamia* in the Bahamas and other West India Islands; in Japan from *Cycas revoluta;* and in the Moluccas the *Cycas circinalis* yielde a coarse kind of flour. Thie species also yielde a transperent gum. The order contains about fifty epeciee.

A fine collection of Cycadaceous Plants existe in the Royal Gardens at Kew. A unique collection of these plante has elso been recently made hy the Rev. J. Yetes of Lauderdale House, Highgate.

(Lindley, *Vegetable Kingdom.*)

CYCADEOIDEA. The fossil stems proved by Dr. R. Brown to be of the Cycadeoue family, which occur in the Iele of Portland, were thus named by Dr. Buckland. Brongniart called them *Mantellia*, and they are ranked by Presl as *Zamites.*

CYCADI'TES. Fossil remaine of Plants allied to the natural gronp of the *Cycadaceœ* are thus nemed by various authors, but the species are now usually ranked under *Pterophyllum, Zamites, Otopteris*, &c.

CYCLADIDÆ, a family of Lamellibranchiate *Mollusca*. It is a group of Fresh-Water Mollusks, whose shells resemble thoee of *Kellia* or of *Astarte*, but whose eoft parts present etructures conspicuously distinguishing them from the tribes to which either of those genera belongs.

The shells are more or less tumid, equilateral or inequilateral, thin, as in our British forms, or thick, ae in the foreign *Cyrenœ;* emooth or concentrically striated and furrowed, and covered with an epiderinis. The hinge is furnished with cardinal and lateral teeth, and the ligament is external. The animale have plain-edged mantles opcn in front, eiphonal tnbes produced, and either partially separated or completely united to their unfringed extremities, and a large linguiform foot. They live buricd in the mud of slow etreame, lakee, ponds, ditchee, and eprings. Our native species are all ovoviviparous. They hreed readily in confinement, and often exhibit considerable activity, ascending the sides of the vessel in which they are placed. (Forbes and Hanley.) This family contains two British genera, *Cyclas* and *Pisidium.*

Cyclas has the shell equivalve, thin, euborbicular, more or lcss inflated, elightly inequilateral, closed, smooth, or concentrically etriated; cardinal teeth, ono in the right and two in the left valve; lateral teeth devcloped; ligament external.

C. rivicola has the shell oval, glohose, etriated; umbones ohtuse; dorsal area with a emall lunular impression; ligameut manifest.

The ordinery length of the finer epecimene is 10½ lines, and its hreadth about two-thirds of an inch.

The tnbee of the animal are tinged with rose or tawny, and when fully protruded are nearly equal, the branchial, if either, being longest.

The foot is large, white, and linguiform; the mantle white; the labial palpe long, triangular, and strongly striated. It is sluggish in its hahits.

Forbee and Hanley give the following localities:—The most prolific is the river Thames; it is found likewise in the New River (Baily); tho Trent (Jcnyns); the Lea (S. H.); the canals about Leamington, in Warwickshire (Thompson); etreams in Yorkshire (Bean). In a pond at Enville, Staffordshire, a young specimen (Jeffreys). It has uot been takeu either in Scotland or Ireland. Ou the Continent it occurs in Germany, France, and Belgium; and as a fossil is found in the Pleistocene Fresh-Water Beds of the eouth of England.

C. cornea, Linn. Shell euborbicular, almoet emooth; umbonee obtuse; ligament inconspicuous. There is a snbglobose variety (apparently the *Stagnicola* of Mr. Sheppard), which is flettened towarde the ventral margin, and has the pellucid aud ewollen umbonee peculiarly prominent. The dimensions of the larger typical form are six linee and a quarter in length, and five linee in hreadth; of the variety five lines and a half in length, and four and three-quarters in breadth.

The animal is white, its suh-elongated siphonal tubes tinted with pale flesh-colour. Mr. Jenyne ohservee that the superior tube is subconic, with a small aperture, the inferior cylindric and truncate, with a wider aperture.

This very common epecies ie a general inhabitant of rivers, ponds, and ditches throughout the country. It appears to thrive equally well both in running and in stagnant water. (Jenyns.)

It is also generally dietributed throughout Europe, and occurs fossil in fresh-water strata of the Pleiocene age in the valley of the Thames.

C. caliculata has the ehell more or less rhombic; umboncs narrow, more or leee prominent, capped.

Thie species ie apparently less infreqnent in the north than in the more southern parts of England. Mr. Alder has found it near Newcastle; Mr. Bean at Scarborough (where it is not scarce); Mr. Thompson at Lichfield; and Captain Brown records the vicinity of Manchester and the lakes of Westmoreland for its localitiee. Montagu met with it in Devonshire and Wiltshire; Mr. Jenyns at Bookham Common in Surrey, and more sparingly in Cambridgeshire; and Mr. H. Strickland at Hornsea in Yorkshire. Mr. Jeffreys has taken it in the Clumber Lake, Nottinghamshire, and in the neighbourhood of Bristol. In Ireland it is also rare. "On the Continent it occurs in Sweden, Germany, Belgium, France, and Italy. The *C. partumeia* of Say, in despite of the ventricoeity of the adult, is very closely allied, especially in outliue, to this species, and may be regarded as its transatlantic representative." (Forbes and Hanley.)

Pisidium has the ehell equivalve, thin, usually tumid, sub-oval, inequilateral, smooth or concentrically striated; hinge with one tooth in the right and usually two in the left valve; also lateral teeth; ligament external, inserted at the ehorter side.

The epeciee are very small bivalves, living iu similar localitiee with *Cyclas*, and not uucommon even in draine through meadows.

P. pusillum. Shell rouuded, oval, not greatly inequilateral, uot distinctly striated; valvee not ewollen, always a little compressed below; umbones usually broad, and but little projecting. This is by far the commoneet of the smaller *Pisidia* in thie country. It is found abundantly iu pouds and ditches. It inhabite generally northern and central Europe.

P. pulchellum. Shell small, striated (not grooved); umhones simple and without appendages. There are many varietiee of this shell. It has a great tendency to assume a multiplicity of forms. The average eize is a line and a helf long, and a line and a quarter broad. It is very common in many parts of Great Britain.

The other Britieh species of this geuue are—*P. Henslowianum, P. nitidum, P. cinereum* and *P. obtusale.*

CYCLA'MEN, a geuus of Plauts bolonging to the natural order *Primulaceœ*. It has a hell-shaped helf 5-cleft calyx; the corolla with a short bell-shaped tube, and 5-partite reflexed limb; 5 stamens ineerted at the bottom, on the tnbe of the corolla, iucluded; the capeule many-seeded, opening with 5 teeth. Tho spocies are herbaceous humble plants with very handeome flowers.

C. hederifolium has cordate angular crenate leaves, and the throat of the corolla with 5 teeth. The root consiets of a large depreseed tuber; the flowers are nearly white, seated upon long flower-stalke, which roll up after blossoming, and bury the germen. Thie plant has been fouud in Great Britain, at Sandhurst, aud near Cranbrook in Keut. It ie rare, and difficult of cultivation. Its flowers exhale a pleasant fragrauce.

C. Europœum, Common Cyclamen, has the leaves orbicular, cordate, crenate, or toothed, the segments of the corolla lanceolate. Thie species is found in the eouth of Europe. It has been recorded as a native of Great Britain, but, if fouud, has probably been an escape from gardens. It ie often confounded with the former speciee. This plant is abundant in Sicily, where the wild boars prefer it to auy other kind of food. Hence it is called Sow-Bread. It has been used medicinally; it acts upon the syetem as a cathartic, and was formerly esteemod emmenagogue. The acrid principle of the root has been separated under the name of Arthanatiue.

Several other epecies have heen described. Most of them are hardy plants, and may be grown on an open border. They are peculiarly adapted for pots aud for chamber decoration in spring. Ouo of the peculiaritiee of the genue ie, that the flowers are seated on a twisted pedicel, which, when the flowers fade, turn round eud round till they bury the capsule which they bear in the earth. In this position the seeds ripen and germinate, and produce other plants.

(Loudon, *Encyclopœdia of Plants;* Babington, *Manual of Botany;* Burnett, *Outlines of Botany;* Koch, *Flora Germanica.*)

CYCLANTHACEÆ, a group of Plants belonging to the class of Endogens, separated by some writere from the *Pandanaceœ*. It embraces the genera *Carludovica, Nipa, Cyclanthus*, and *Weltinia*. For an account of the order soe PANDANACEÆ.

CYCLA'RTHRUS, a genus of Fossil Fishes, from the Lias of Lymo Regis. (Agassiz.)

CYCLAS. [VENERIDÆ.]

CY'CLICA, a family of Coleopteroue Iusects. According to Latreille, this group forms a sub-section of the section *Tetramera.*

The family *Cyclica* contains the Linnæan genera *Hispa, Cassida*, and *Chrysomela*, the epeciee of which may be distiuguished by the following charactere:—Tarsi 4-jointed, furnished beneath with a velvet-like substance; the penultimate joint bilohed; autennæ of moderate length, generally filiform, or increasing in thickness towards the apex; body usually of a rounded or oval form, the thorax being at the base of the same width as the elytra.

These insects are ueually of brilliaut metallic colouring: various shades of green appear to predominate. Their larvæ have a eoft body, and are furniehed with six legs, attached two to eech of the first three eegments, or those next the head. They feed upon the leaves of plants.

To this group belong the following families:—*Cassidiadœ, Chrysomelidœ*, and *Galerucidœ*. The principal genera belouging to the family *Cassidiadœ* are *Alurnus, Hispa, Chalepus*, and *Cassida*. To these genera we shall at present confine our remarke.

The genus *Cassida* has the following characters:—Body oval or rounded, depressed; thorax generally eomewhat eemicircular, with the anterior portion produced so as to conceal the head; mandiblee with three notchee on the inuer edge; external lobe of the maxilla as long as the inner one.

The *Cassidæ* are usually of a somewhat flattened form, and are remarkable for their having the external margins of the elytra projecting beyond the body; the outer margins of the thorax are also produced, and conceal the head. Those parts which extend beyond the animal itself are generally semitransparent and flattened, whilst the parts which immediately cover the insect are more or less convex. When the insect is at rest, the legs, which are rather short and compressed, are retracted, and the external margins of the elytra and thorax are applied closely to the plant on which it lives. The larvæ of the *Cassidæ* are of a depressed form, and usually armed on the upper parts with numerous little spines; these are longest on the sides of the body and at the tail. The use of these little spines appears to be for the purpose of holding the excrement of the animal, which is always deposited upon its back, and probably serves as a means of defence, by concealing it from its enemies.

C. viridis, an insect not uncommon in this country, is about a quarter of an inch in length, and of a bright green colour above; the body beneath is black. This species lives both in the larva and imago states upon thistles.

Mr. Stephens, in his 'Catalogue of British Insects,' enumerates nineteen species of this genus.

The insects belonging to the other three genera of the *Cassidiadæ* have the body of a more elongated form than those just described, and the head is exposed, the margins of the thorax and elytra not being produced. They are all included in the genus *Hispa* of Linnæus.

CYCLOBRANCHIATA, an order in De Blainville's arrangement of the *Mollusca*. It includes those animals mostly referred to the Cuvierian order *Nudibranchiata*. [NUDIBRANCHIATA.]

CYCLOID FISHES. One great division of Fishes is thus termed by Agassiz, from the concentric striation apparent in their scales, of which the substance is horny, not bony nor enamelled. They are rare as fossils in all except the more recent strata, but abound at the present day. [FISHES.]

CYCLOLITES, a genus of *Madrephylliæa*, including single-celled species. [MADREPHYLLIÆA.]

CYCLOPOMA, a genus of Fossil Fishes, from Sheppey. (Agassiz.)

CYCLOPS. [BRANCHIOPODA.]

CYCLOPTERIS, a genus of Fossil Ferns (Brongniart), remarkable for the size and orbicular or oval shape of the leafits. To the species from the Coal-Measures (*C. orbicularis*, *C. obliqua*, &c.) this remark applies better than to those (*C. Beanii*, *C. dilatata*, &c.) from the Oolites, which are really of a different genus. [COAL-PLANTS.]

CYCLOPTERUS. [DISCOBOLI.]

CYCLOSIS. The regular movements of the contents observed in the interior of the cells of many plants have obtained this name, to distinguish them from other movements to which the vegetable cell is subject.

The fluid contents of the cells exhibit two kinds of movement, one in which there is observable in each cell a single current ascending on the one side and descending on the other, and another in which minute currents, with numerous anastomosing branches present themselves. The fluids which move vary in colour, transparency, and consistency, and carry with them whatever grains or globules of starch, protein, oil, chlorophyle, or other matters that may be loose in the interior of the cell.

The existence of these curious currents was first made known by Bonaventura Corti in 1772, who observed them in the sap of certain species of *Characeæ* and in *Caulinia fragilis*. Fontana about the same time confirmed these discoveries. They however excited no attention, and the facts seem to have been rediscovered by Treviranus in Germany in 1807, and Amici in Italy in 1819, and still later by Varley in England.

The number of plants in which these movements are observed is very numerous, and every day is adding to their number. It is not under all circumstances that the currents are developed. They are less active, and sometimes not at all seen, when the cell is very young or very old. When young the currents are not established, when old they cease. In some instances preparation of the plant is necessary. In some of the forms of *Chara* the bark external to the cells must be removed. In *Vallisneria spiralis* it is seen best when the leaf is cut in two. Heat also increases these movements, so that plants which fail at first to exhibit them, will do so after remaining a little time in a warm room. The persistence of this motion is very curious in some of the plants which exhibit it. Thus in *Vallisneria* it will continue in the leaf several months after it has been separated from its parent plant, and although the leaf exhibits the yellowness of decay. ('Microscopical Journal,' p. 55, vol. ii.)

Mr. Lawson of Edinburgh gives the following list of plants in which he has observed this movement of the cell-contents:—

Charæ and *Nitellæ*.
Sagittaria sagittifolia.
Stratiotes aloides.
Vallisneria spiralis.
Zannichellia palustris.
Hydrocharis morsus-ranæ.
Potamogeton.
Equisetum.
Anacharis Alsinastrum.
Loasæ (in stinging hairs).
Urticæ (in stinging hairs).
Tradescantia virginica (in hairs of filaments).
Campanula medium (hairs of corolla).
Marchantia (*polymorpha*?) (radical hairs).
Mosses.
Ceratophyllum.
Podostemaceæ.
Lemna.
Lichens.
Algæ.
Fungi.

These movements are best seen in the plants in which they were first discovered—in *Nitella*, *Hydrocharis*, and *Vallisneria*. Each of these has its peculiarities, and may be taken as examples of the rest. In *Nitella* the moving stream is very considerable, so that only a narrow streak remains at comparative rest between the ascending and descending currents. The stream is strong and rapid, and carries along with it starch granules of considerable size. Its course is not exactly parallel to the axis of the stem, but forms a small angle with it. In two contiguous cells, the currents flowing on the partition between them run in opposite directions; consequently, throughout the whole plant, the ascending streams are on one side, and in fact owing to their oblique direction form a spiral: this is the case also with the descending streams. If the cell be carefully tied across, the current is in a short time re-established in each sub-division. If the cell be cut through, the fluid escapes only on one side, the remainder of the fluid making the entire circuit of the cell before it comes to its turn to escape.

Mr. Lawson gives the following account of the movement in the new Water-Weed which has just appeared in this country, and is called by Mr. Babington *Anacharis Alsinastrum*. [UDORA; HYDROCHARIDACEÆ.] "The leaf of the *Anacharis* is composed of cells of an oblong form, but in some parts of the leaf becoming much elongated. At the margin of the leaf (which is toothed, each tooth consisting of a single somewhat triangular cell) the tissue consists of a single layer of cells, the latter being more elongated in form than those towards the centre of the leaf. In these marginal cells, the green granules (chlorophyle) which they contain may be readily seen in rotation, thus indicating the currents of cell-sap. The phenomenon is best seen however in those cells (very much elongated) which form the midrib of the leaf. Granules are seen scattered about in the cells; a few in the centre of each cell are fixed. But there will be observed another set of spherules, forming a continuous line around the margin of each cell; these are in rapid motion, flowing along one side of the cell, generally with great regularity, till they arrive at the end, where they cross over and return by the other side, thus forming a continuous rotation in the cell. Although the granules generally move on in this way without interruption closely following each other, still a casual interruption occasionally takes place, and crowding ensues; this is most frequent at the ends of the cells—at the 'crossing.' But the granules are gifted with even a greater share of politeness than is usually to be found at a London crossing; for when a crowding takes place, there is never seen an obstreperous granule trying to gain the precedence of his fellows to get over first."

The movements of the minute anastomosing currents are more difficult to observe than those above described. They do not occur alone in water-plants, but have been principally observed in the *Phanerogamia*. In the anastomosing currents the movement is always observed to and from the cytoblast of the cell, which is invariably present. The fluid is of a mucous (proteinaceous) nature, and mixed with minute opaque granules. The currents cover the internal surface of the cell-wall, or traverse the cavity of the cells from one wall to the other, without mingling with the rest of the cell-fluid, which for the most part is as clear as water. On this subject Schleiden says, "Up to the present time (1849) I have found this peculiar form of circulation in numerous cryptogamous plants, for instance, in *Achlya prolifera*, *Spriogyra*, and other *Hyphomycetes* and *Confervæ*; in almost all the forms of hair in the *Phanerogamia* that I have as yet examined, for instance, in the *Solanum tuberosum*; in many spores, such as of *Equisetum arvense*, and pollen granules, for instance of *Ænothera grandiflora* in the immature state; in almost all immature endosperm-cells, as in *Nuphar luteum*, and especially in such as are subsequently re-absorbed, as in *Ceratophyllum demersum*; in almost all stigma-papillæ, as in *Tulipa Gesneriana*; in the loose cells of juicy fruits in the young state, as in *Prunus domestica*; in the pulp which is formed by the placental cords, as in *Mammillaria*; less frequently in the loose juicy parenchyma of many plants in the young state, as in *Tradescantia rosea*. I believe it exists however in all vegetable-cells as long as the cytoblast retains its vitality. As instances admitting of verification, I would mention the fruit of *Symphoricarpos racemosus* (Snowberry) or of a *Mammillaria*."

In these instances each cell is isolated and filled with an entirely colourless fluid. At one part of the wall can be seen the cytoblast presenting a well-marked nucleolar corpuscle. The cytoblast is always surrounded by a narrow areola of a yellowish mucous fluid, thickly crowded with minute opaque granules, and from it proceed currents of various width and depth. The currents can be seen passing to or from the cytoblast. In their conrse they exhibit various anastomosing branches. Many of the streams are so minute that, under the highest magnifying power, they exhibit the appearance of a line without any breadth, merely rendered to a slight extent irregular by the individual granules.

The cause of these movements in the interior of the cells of plants has been the subject of much discussion. Although not observed in every instance, there appears to be reason for the inference that they are universally preseut, and that they are but the result of the living processes going on in the cell, and perhaps the mode by which nutrition is effected. "After the most careful research," says Schleiden, "with the best instruments, I have been unable to perceive a trace of the presence of vibratile cilia as a cause of the motion." And indeed if cilia had been discovered, the inquiry would then assume the form of the cause of movement in cilia. If this question be answered we get at an ultimate fact applicable alike to movements in granules, cilia, cytoblasts, or cells. One fact presents itself in all these cases, which seems worthy of every consideration, and that is the presence of some form of proteinaceous matter. In the fluid which circulates in the vegetable cell some form of protein is always present. The cytoblast or nucleus, and the primordial utricle in all cells are composed of protein. Cilia take their origin in all cases in a proteinaceous basis, and their movements appear to be but the result of an irritability, which in every case finds its origin in a proteinaceous compound. [Cells; Histology; Tissues, Vegetable.]

(Schleiden, *Principles of Scientific Botany*, translated by Lankester; *Microscopical Journal*, vols. i. and ii.; Huxley, *On the Identity of Structure of Plants and Animals*, Proc. Roy. Inst., 1853; Varley, *Transactions of Microscopical Society*.)

CYCLOSTOMA. [Helicidæ.]

CYDIPPE. [Acalephæ; Beroe.]

CYDO'NIA, a genus of Plants belonging to the natural order *Pomaceæ*.

C. vulgaris, Quince, a small tree with dark smooth branches. Leaves ovate, obtuse at the base, quite entire, cottony on the under side. Flowers large, solitary, with a cottony calyx and bright pink petals. The fruit a turbinate or roundish angular pome, covered with a thin cottony down, extremely austere, but having a peculiar fragrance.

There are two varieties—Apple-Quince and Pear-Quince. The seeds are the parts used in medicine, on account of the mucilage which they yield. The seeds are more numerous in the small hard than in the large fleshy fruits. They generally occur in large irregularly-shaped masses, as they easily adhere to each other, owing to the mucus which invests them. When moistened in the mouth or in water, they give out a large quantity of mucilage, which is white, and not coagulable by boracic acid. One part of these seeds will render 40 to 50 parts of water so mucilaginous that it will possess the thickness of a syrup. They should be set to digest in cold water, otherwise the mucilage acquires the odour of hydrocyanic acid. Indeed the actual presence of, or tendency to form, hydrocyanic acid, may be demonstrated by distillation. (Stockmann.) Many seeds yield a yellow-coloured mucilage. If allowed to remain in a fluid state the solution soon spoils, but by careful evaporation the mucilage may be brought to a dry state; or, as proposed by Zier, the mucilage may be precipitated from its watery solution by alcohol. Ten ounces of seeds yield two ounces of dried mucilage, two grains of which, with distilled water, produce one ounce of mucilage of proper consistence for use. In whatever way obtained, the mucilage possesses demulcent qualities, and may be employed either internally or as a lotion, which is especially applicable to the faces of those who suffer from the cold winds of winter and spring.

CYGNINÆ, a sub-family of Web-Footed Birds, belonging to the family *Anatidæ*, order *Anseres* of Linnæus, including the Swans.

Mr. Swainson makes the genus *Cygnus* the first of his sub-family *Anserinæ*, with the following character:—Size large. Base of the bill tumid, fleshy, and naked. Neck remarkably long. Feet short. Hinder toe simple. ('Classification of Birds.')

The Prince of Canino, in his 'Birds of Europe and North America,' arranges the *Anseres* as his fifth order of birds. The *Anatidæ* stand as the first order of the *Anseres*, and comprise the sub-families *Cygninæ*, *Anserinæ*, *Anatinæ*, *Fuligulinæ*, and *Merginæ*. The *Cygninæ* consist of the single genus *Cygnus*, of which the Prince records *C. Olor*, *C. immutabilis*, *C. musicus*, and *C. Bewickii* as European species, and *C. Americanus* and *C. Buccinator* as American species. The *Cygninæ* in the Prince's method are immediately followed by the *Anserinæ*.

Only two true Swans are recorded by Linnæus, and those as varieties of *Anas Cygnus*, namely, variety α, *C. ferus*, and variety β, *C. mansuetus*. Since his time the researches of zoologists have added considerably to the catalogue.

The peculiarities of organisation in this sub-family deserving of notice are—the great length of the neck, consisting of 23 vertebræ, and the cavity in the sternum for the reception of a considerable portion of the trachea.

The generic character of *Cygnus* is as follows:—Beak of equal breadth throughout its length; higher than wide at the base; depressed at the point; both mandibles furnished along the sides with transverse serrated lamellæ. Nostrils oblong, lateral, near the middle of the beak. Neck slender and very long. Legs short, the hind toe small and free. (Yarrell.)

C. ferus (Ray). Male.—Pure white, with occasionally a buff tinge on the top of the head. Bill black, and depressed anteriorly, quadrangular at the base, and yellow, which tint extends forward along each lateral margin of the upper mandible beyond the aperture of the nostrils, which are black; bare space between the base of that mandible and the eye also yellow, which colours the back part of the lower mandible. Iris brown. Feet black. Length, with neck stretched, about 5 feet; across expanded wings, about 8 feet. Female.—Similar to the male, but smaller, and the neck more slender. Young.—Those that we have seen, when about a week old, have been covered with a gray down above and a whitish down below, with flesh-coloured feet, or rather of a dusky flesh-colour; the bill flesh-coloured, and rather dusky above anteriorly. Mr. Yarrell states that at ten weeks old the bill is dull flesh-colour, the tip and lateral margins black; the head, neck, and all the upper surface of the body, pale ash-brown; the under surface before the legs of a paler brown; the portion behind the legs dull white; the legs, like the bill, of a dusky flesh-colour. This description was taken from young birds in the Garden of the Zoological Society, London, in the middle of August. In the middle of October the same zoologist found the bill black at the end, with a reddish-orange band across the nostrils, and the base and lore pale greenish-white; the general colour pale grayish-brown; a few of the smaller wing-coverts white, mixed with others of a pale buffy-brown, and the legs black. He also observes that the young Hoopers bred in 1839 had almost all their brown feathers at the autumnal moult of 1840, and that before their second winter was passed they were entirely white. ('British Birds.')

This is the *C. musicus* of Bechstein, and, as there are now more than one wild species well defined, the Prince of Canino and others adopt that specific name instead of the original *C. ferus*; but the propriety of this may be doubted. It is the Cygne Sauvage of the French; Cigno and Cigno Salvatico of the Italians; Singschwan and Nordöstliche Singschwan of the Germans; Vild Svane of the Danes; Hooper, Elk, and Whistling Swan, of the British; and Alarch Gwylt of the Welsh.

Head of Hooper (*Cygnus ferus*).

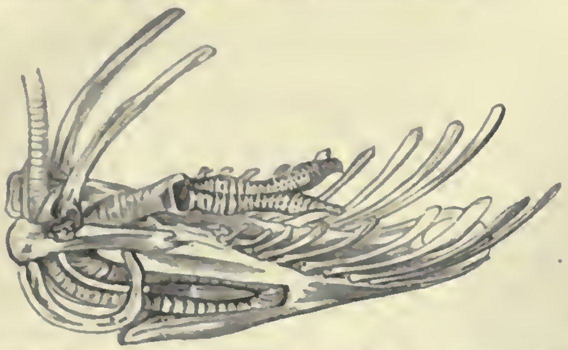
This bird is found in the northern regions of Europe and Asia, residing in summer within the arctic circle, Iceland, and Scandinavia. Winter visiter to the British Islands (where however it has been known to breed in the Shetland and Orkney Islands and in Sutherlandshire), Holland, France, Provence, and Italy, and, according to Mr. Bennett, going as far south as Barbary and Egypt. Eastward it extends as far as Japan. This species is in all probability the Swan so celebrated by the ancient poets for its dying song.

The note of this Wild Swan resembles the word 'hoop' uttered several times successively. They fly in a wedge-like figure, uttering this note as they proceed, and when heard from above it is not unmusical. The apparatus for producing these sounds was known to Aldrovandi, Sir Thomas Browne, Willughby, Ray, Latham, and others. Mr. Yarrell, who has paid so much attention to the tracheæ of birds, has thus well described it:—

"The cylindrical tube of the trachea or windpipe passes down the whole length of the long neck of the bird in the usual manner, but descends between the two branches of the forked bone called the merry-thought, to a level with the keel of the breast-bone or sternum. The keel of the breast-bone is double, and receives between its two plates or sides the tube of the trachea, which, after traversing nearly the whole length of the keel, turns suddenly upon itself, passing forwards, upwards, and again backwards till it ends in the vertical bone of divarication from whence the two long branchial tubes go off, one to each lobe of the lungs. The depth of the insertion is not so considerable in females or young males."

The Hooper, like the rest of the Swans, feeds on aquatic plants and insects, can keep the head under water for some time, but never dives. The large nest is constructed on the ground with flags, rushes, leaves, and marshy plants. The eggs, six or seven in number, are whitish, tinged with yellowish-green. Length of egg, 4 inches; breadth, 2¾ inches.

This species breeds in captivity, and may frequently be seen on ornamental pieces of water in a half-domesticated state.



Sternum of Hooper with a portion of one side of the keel removed to show the convoluted tube within. Yarrell.

C. Bewickii. Independent of external characters, the anatomical distinctions pointed out by Mr. Yarrell, who first proposed to separate the species under the name here given, clearly point out the difference between it and the Hooper. "The principal and most obvious difference," says Mr. Yarrell, "is in the trachea. The tube of the windpipe is of equal diameter throughout, and, descending in front of the neck, enters the keel of the sternum, which is hollow, as in the Hooper, traversing the whole length. Having arrived at the end of the keel, the tube, then gradually inclining upwards and outwards, passes into a cavity in the sternum destined to receive it, caused by a separation of the parallel horizontal plates of bone forming the posterior flattened portion of the breast-bone, and producing a convex protuberance on the inner surface. The tube also changing its direction from vertical to horizontal, and reaching within half an inch of the posterior edge, is reflected back after making a considerable curve, till it once more reaches the keel, again traversing which, in a line immediately over the first portion of the tube, it passes out under the arch of the merrythought, where, turning upwards, and afterwards backwards, it enters the body of the bird, to be attached to the lungs in the usual manner. This is the state of development in the oldest bird I have yet met with. The degree next in order, or younger, differs in having the horizontal loop of the trachea confined to one side only of the cavity in the sternum, both sides of which cavity are at this time formed, but the loop of the tube is not yet sufficiently elongated to occupy the whole space; and the third in order, from a still younger bird, possesses only the vertical insertion of the fold of the trachea." Mr. Yarrell adds however, that in this last case the cavity in the posterior part of the sternum already exists to a considerable extent.

Bewick's Swan is much smaller than the Hooper, the whole length being from 3 feet 10 inches to 4 feet 2 inches.

Head of Bewick's Swan (*Cygnus Bewickii*).

"Young birds," says Mr. Yarrell, "as they appear here in the plumage of their first winter, are grayish-brown. At their second winter, when they have acquired the white plumage, the irides are orange; the head and breast strongly marked with rusty red; base of the beak lemon-yellow; when older, some continue to exhibit a tinge of rust-colour on the head after that on the breast has passed off. The adult bird is of a pure unsullied white; the base of the beak orange-yellow; the irides dark; the legs, toes, and membranes black."

The anterior part of the bill is black, and, in the males, orange-yellow at the base, which is of a lemon-colour in the females.

It is found in the north of Europe and America certainly, and of Asia probably. It breeds within the arctic circle, and in Iceland in May, according to Temminck, who says that it has been found on the maritime coasts of Picardy. It is an occasional visiter to the British Islands, especially in severe winters.

The nest, according to Captain Lyon, is constructed of moss-peat, is nearly 6 feet long, 4¾ feet wide, and 2 feet high on the outside, with the cavity a foot and a half in diameter. The eggs, six or seven in number, are of a yellowish-brown, according to Temminck; brownish-white slightly clouded with a darker tint, according to Lyon. The call-note of this species is said to be a low-toned whistle, according to Mr. Sinclaire, but this was in confinement. Mr. Blackwall describes their calls in their wild flights as loud, and says that a flock of twenty-nine of them were very clamorous.

C. immutabilis (Yarrell), the Polish Swan, is another wild species, and its cygnets, unlike those of the other white swans, are pure white. It has been kept in captivity. Mr. Yarrell states that Lord Derby purchased a pair of these swans, and sent them to Knowsley. The female died. The male paired with a Mute Swan (*C. Olor*), and a brood was the result; but the hybrids, though old enough, neither paired among themselves nor with any of the Mute Swans on the same water.

Head of Polish Swan (*Cygnus immutabilis*).

The following is Mr. Yarrell's description of the Polish Swan:—

"In the adult bird the beak is reddish-orange; the nail, lateral margins, nostrils, and base of the upper mandible, black; the tubercle, even in an old male, of small size; the irides brown; the head, neck, and the whole of the plumage, pure white; legs, toes, and intervening membranes, slate-gray. From the point of the beak to the end of the tail, 57 inches. From the carpal joint to the end of the second quill-feather, which is the longest in the wing, 21½ inches; tarsus 4 inches; middle toe and nail, 5¾ inches. Its food and habits closely resemble those of the mute swan. The organ of voice appears, from one that I examined, to be like that of the mute swan; but Mr. Pelerin has found considerable differences in various parts of the head: the description and measurements were given in a paper published in the 'Magazine of Natural History' for 1839, p. 178."

Mr. Yarrell then extracts Mr. Pelerin's comparative measurements of the crania of adult Mute and Polish Swans, and states that he has verified all his observations.

C. Olor (Genus *Olor*, Wagl.). Our Mute half-domesticated Swan is too well known to require description. The trachea has none of the complicated structure of that of the Hooper, and is even more simple than that of the Black Swan. The large tubercle, or berry, as the swanherds term it, at the base of the bill, at once distinguishes this graceful species from its congeners.

Head of Mute Swan (*Cygnus Olor*).

It is the Cygne of the French; Cigno and Cigno Reale of the Italians; Schwan and Höcker Schwan of the Germans; Tam Svane of the Danes; Tame Swan or Mute Swan of the English; and Alarch of the Welch.

This elegant bird is said to exist in a wild state in Russia and Siberia. The Prince of Canino, in his 'Specchio Comparativo,' speaks of it as occurring in the neighbourhood of Rome ("raro avventizio d'inverno"); and, in his 'Birds of Europe and North America,' he gives north-eastern Europe as the locality. The Polish

Swan above noticed should not be forgotten in assigning these northern localities to our Tame Swan, and very probably was not by the skilful ornithologists who have noted these localities. Temminck says, "Habite en état sauvage les grandes mers de l'intérieur, surtout vers les contrées orientales de l'Europe."

In the Thames, at present, the greatest number of swans belongs to the Queen, and the companies of vintners and dyers own the next largest proportion; but the birds are far less numerous than they used to be. The swan-marks are made upon the upper mandible with a knife or other sharp instrument. The swan-hopping or upping, that is, the catching and taking up the swans to mark the cygnets, and renew that on the old birds if obliterated, in the presence of the royal swanherd's man, is still continued by the companies above mentioned. Below is the royal swan-mark used in the three last reigns and the present, from the cut given by Mr. Yarrell, in whose interesting 'British Birds' much curious information on this subject, together with no less than sixteen swan-marks, will be found.

Royal Swan-mark. Yarrell.

Sir John Richardson ('Fauna Boreali-Americana') records only two American swans, *C. Buccinator* and *C. Bewickii*. The Prince of Canino, in his 'Specchio Comparativo,' gave one, *Anas Cygnus* (meaning, apparently, the Hooper). Nuttall notices three:—1st, the Wild or Whistling Swan, *C. ferus* of Ray; 2nd, the Trumpeter Swan, *C. Buccinator*; and 3rd, *C. Bewickii*. The Prince, in his 'Birds of Europe and America,' records two species, *C. Americanus*, Sharpl. (*C. musicus*, Bonap.), and *C. Buccinator*; but he does not record *C. Bewickii* as an American species. Nuttall declares that in the winter of 1810 he saw two individuals of *C. ferus* (*C. musicus*, Bechst. and Bonap.) in a state of domestication near St. Louis (Missouri), which were obtained, with several others at the same time, in consequence of the extreme cold. The Prince of Canino evidently considers his *C. musicus*, which he gives as a synonym of *C. Americanus*, a different species from *C. Bewickii*, which last stands opposite to *C. Americanus* in the European column.

C. Buccinator. According to Sir John Richardson, it is the most common swan in the Fur Countries, and to which the bulk of the swan-skins imported by the Hudson's Bay Company belong.

Colour white, the forehead alone tinged with reddish-orange; bill, cere, and legs, entirely black. Bill nearly resembling that of *C. ferus* in form, though longer and rather more depressed. Wings: third quill the longest. Tail consisting of 24 feathers. A specimen in the Zoological Museum has the crown and cheeks bright chestnut. Total length 70 inches. (Richardson.)

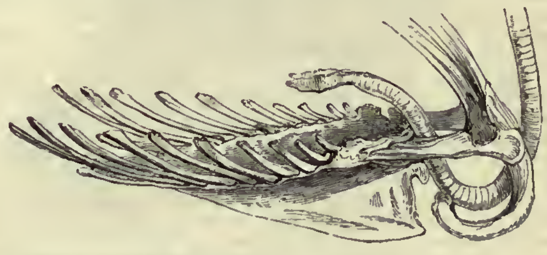
It breeds as far south as the 61st degree of latitude, but principally within the arctic circle, and in its migrations it generally precedes the geese. Sir John Richardson observes that *C. Bewickii* makes its appearance amongst the latest of the migratory birds; while *C. Buccinator* is the earliest, with the exception of the eagles. He states that a fold of its windpipe enters a protuberance on the dorsal or interior aspect of the sternum at its upper part, which is wanting both in *C. ferus* and *C. Bewickii*; in other respects, he adds, the windpipe is distributed through the sternum nearly as in the latter of these species. In the 'Supplement' to Sir Edward Parry's 'First Voyage,' *Anas Cygnus*, Wild Swan, with references which leave no doubt that the Hooper was meant, is noted as breeding on the North Georgian Islands; but *C. Bewickii* had not then been distinguished.

C. atratus (Genus *Chenopis*, Wagl.), the Black Swan. This bird, the *Anas Plutonia* of Shaw, has now become so common in our menageries, where it breeds freely, as not to justify the occupation of space with more than a cut of its head, and of the course of its trachea, which is not unlike that of the Mute Swan.

Head of Black Swan (*Cygnus atratus*).

It is all black, except the primary, and a few of the secondary quills, which are white. Bill bright red above, and sometimes with a slight turbercle at the base, which the female wants. The anterior part of the upper mandible is crossed by a whitish band, and the under one is grayish-white. Legs and feet dull ash-colour. Size less than that of the Mute Swan and Hooper. Irides red. Young, when about a fortnight old, covered with dusky-gray down above, lighter beneath; bill, eyes, and feet, dusky-black.

Mr. Yarrell observes that the structure of the trachea is intermediate between that of the Hooper and the common Mute Swan. "It quits the neck at the bottom, and descends to the centre circular portion of the furcula, to which bone it is firmly bound by a tough membrane: the remaining portion then rises over the front of the breast-bone between the clavicles, and passes backwards to the lungs, the last portion of the tube immediately preceding the bone of divarication being flattened horizontally. The form of the trachea in our common swan, in which it follows the neck without deviation, being remembered, and Dr. Latham's figure of the wild swan referred to, it will be observed that the black swan exhibits an interesting link between the two." ('Linn. Trans.' vol. xv.)



Sternum and trachea of Black Swan (*Cygnus atratus*). Yarrell.

It is found in Van Diemen's Land, New South Wales, and the west coast of Australia.

In a state of nature the Black Swans are generally seen floating on some lake in flocks of eight or nine. When disturbed, they generally fly off in line or single file; and are so shy, that it is difficult to get within gunshot. Their note is far from harsh, at least when uttered in captivity.

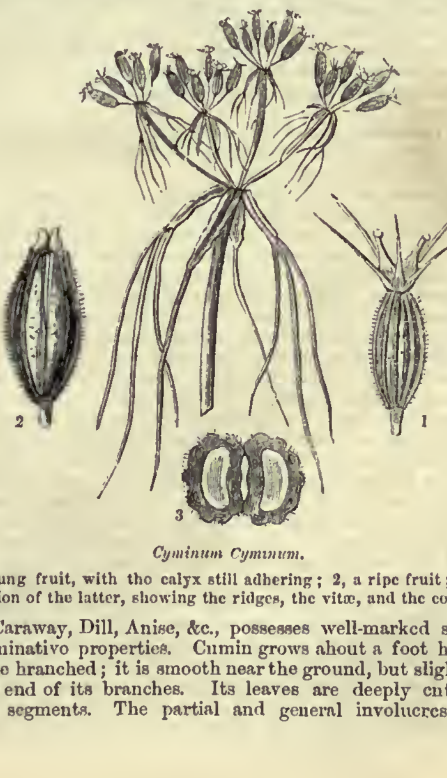
CYGNUS. [CYGNINÆ.]

CYMBA. [ACALEPHÆ.]

CYMBULA. [THECOSOMATA.]

CYME, an irregular kind of panicle, having a corymbose appearance, and in which each branch is stopped in its growth after producing a single flower, when it is forced to form lateral branches, which are themselves stopped after forming one flower. The common *Laurustinus* or the Elder-Bush offers examples of this sort of inflorescence.

CY'MINUM, or CUMINUM, a genus of Plants belonging to the natural order *Umbelliferæ*. *C. Cyminum*, Cumin, is a plant of annual duration, found wild in Egypt and Syria, and cultivated from time immemorial for the sake of its agreeable aromatic fruit, which, like



Cyminum Cyminum.

1, a young fruit, with the calyx still adhering; 2, a ripe fruit; 3, a transverse section of the latter, showing the ridges, the vittæ, and the commissure.

that of Caraway, Dill, Anise, &c., possesses well-marked stimulating and carminative properties. Cumin grows about a foot high, and is very little branched; it is smooth near the ground, but slightly downy near the end of its branches. Its leaves are deeply cut into long capillary segments. The partial and general involucres consist of similar leaves, but smaller. The flowers are white or reddish; the fruit is contracted at the side, surmounted by a calyx with long bristle-pointed divisions, and has each of its halves marked by nine unequal elevated ridges, all of which are slightly muricated, especially the secondary ones, under each of which there is a vitta. Two vittæ are present on the commissure, and the albumen is not involute.

Cumin is said to be employed in flavouring Dutch cheese. The fruits are carminative, but the smell is disagreeable. They are chiefly used in veterinary surgery. Combined with resin they make a warm stimulating plaster. [CUMIN, in ARTS AND SC. DIV.]

CYMODOCEA. [ISOPODA.]

CYMOPHANE. [CHRYSOBERYL.]

CYMOTHEA. [ISOPODA.]

CYNANCHUM (from κύων, a dog, and ἄγχω, to strangle), a genus of Plants belonging to the natural order *Asclepiadaceæ*. It has a 5-parted somewhat rotate corolla; a coronet of appendages consolidated, 5-20-lobed, when 5-lobed with the segments opposite the anthers; the pollen-masses ventricose, pendulous; the stigma usually apiculate, sometimes blunt, very rarely with a beak inclosed below the summit; the follicles smooth. The species are herbs or under-shrubs, with opposite leaves and mostly twining stems.

C. Vincetoxicum has an erect stem, a beardless corolla, a simple umbel with the pedicels three times longer then the peduncle; the corona 5-lobed. This plant is a native of sandy places in most parts of Europe, with the exception of Great Britain. It possesses emetic and purgative properties, and was once celebrated as an antidote for poisons, from which it has derived its specific name.

C. Monspeliacum, Montpellier Cynanchum, is an herbaceous twining glabrous plant, with roundish cordate-stalked leaves, with a semi-lanceolate contracted point; the segments of the corolla lanceolate, bluntish; the coronet tubular. It is a native of the sea-coast of Italy, of Spain, the south of France, and Greece. The juice of this plant is a drastic cathartic, and when dried it is used as a medicine under the name of Montpellier Scammony.

C. ovalifolium is a smooth twining plant, with oblong oval acuminate leaves; many-flowered cymes; peduncles not longer than the petiole; the coronet 10-cleft, about as long as the corolla; the stigma pointed, emarginate. This plant is a native of Penang, where, according to Dr. Wallich, it is used for the purpose of procuring from its sap caoutchouc, which is of an excellent quality.

C. Argel has erect, pale, round stems; the leaves scarcely stalked; about an inch long, ovate lanceolate, acute, smooth on each side, and rather wrinkled, glaucous on the under side; the corymbs small, axillary, with many smooth alternate branches; the sepals lancolate; the corolla white, but little longer than the calyx. It is a native of Upper Egypt. The leaves and the whole plant act as a powerful drastic purgative. This plant appears to be a native of the same districts as those from which the Alexandrian Senna is obtained, and all the samples of that senna contain these leaves. They do not however appear to be added for the purposes of adulteration, but are collected with the leaves of the senna through the ignorance of the persons employed in their collection. The leaves of Tinnivelly Senna are not found to contain those of the *C. Argel* mixed with them. Much of the unpleasant griping effect of the Alexandrian Senna is attributed by some writers on Materia Medica to the mixture of the leaves of the Argel. Senna leaves are also mixed with those of the *Gomphocarpus fruticosus*, which are in Syria also called Argel, or Arghel.

The *C. Ipecacuanha* of Willdenow, the *Asclepias asthmatica* of Roxburgh, is now referred to the genus *Tylophora*. [TYLOPHORA.]

CYNANTHUS. [TROCHILIDÆ.]

CY'NARA, a genus of Plants belonging to the natural order *Compositæ*, in many respects like the thistle, but having an involucre composed of thick fleshy spiny scales, and a remarkably thick fleshy receptacle, covered over with numerous bristles. The two species most known are the Artichoke and the Cardoon.

C. Scolymus, the Artichoke, so long cultivated in our gardens as a vegetable, came originally from the south of Europe, and though it has long been cultivated in the regions of the north, it does not resist the very severe cold of winter. Its perennial root is thick, fleshy, hard, branching, and gives rise to a cylindrical, glabrous, rather branching stem, from 2 to 3 feet high, to which are attached very large pinnatifid leaves, of a pale green above, whitish beneath, deeply serrated in lobes, and irregularly toothed. The heads stand singly at the top of the ramifications of the stem; they are as large as the doubled fist; their receptacle is very thick, fleshy, concave, furnished with simple bristles; the leaflets of the involucre are broad, thick, and terminated in a spiny point. All the florets are hermaphrodite, and of a clear violet colour; the tube of the corolla is very long; its limb has 5 very narrow segments; the staminal tube is very prominent, of the same colour as the corolla. The pappus is sessile and feathery. The root of the Artichoke is rather bitter, the stem still more so. It was formerly employed as a diuretic, but it has long been cultivated only as a kitchen-garden plant. Everybody knows that the heads of the plant are gathered before the expansion of the flowers, and that the receptacles or the base of the involucral scales are eaten either raw or after having been boiled in water. The Artichoke when cooked is an agreeable food, not very nourishing perhaps, but easy to digest. The receptacles, or artichoke bottoms, may be preserved for winter use by drying them after having blanched them in boiling water. The Arabians consider the root of the Artichoke an aperient; they call the gum of it Kunkirzud, and place it among their emetics.

C. carduncellus, the Cardoon. The country of the Cardoon is the same as that of the artichoke; it is found in the southern countries of Europe and in the north of Africa. Its thick and fleshy leaves cut into spiny lobes with very prominent ribs, its more slender stems terminated by heads of flowers three or four times smaller, with a thin receptacle, and the scales of the involucre armed with sharp spines, easily distinguish it from the artichoke. Some authors however have endeavoured to prove that the artichoke is only a variety of the Cardoon. This opinion however does not appear well founded; for if it were so among the great quantity of Cardoons that are cultivated in gardens, some plants would be found transformed into artichokes, which has never happened. In this species it is the rib, or the middle nerve of the leaves, which is eaten. When cooked it is tender, and its flavour greatly resembles that of the artichoke. It is in general a choice dish, and seldom seen except at the tables of persons in easy circumstances.

CYNARA'CEÆ, or CYNAROCEPHALÆ, one of the primary subdivisions, in the system of Jussieu, of the natural order *Compositæ*. It is included in the *Tubulifloræ* of De Candolle. It is characterised by an erect seed, the absence of albumen, a hemispherical involucre, the florets of the ray of the flower tubular, inflated, and regular. Of the three subdivisions of *Compositæ* this is the smallest. Its type is the genus *Cynara*, to which belongs the common Artichoke, *C. Scolymus*.

The genera of British plants belonging to this subdivision are as follows:—

Section I.—*Carlineæ*.		
	Saussurea	1 species.
	Carlina	1 species.
Section II.—*Centaureæ*.		
	Centaurea	7 species.
Section III.—*Carduineæ*.		
	Arctium	2 species.
	Onopordum	1 species.
	Carduus	12 species.
Section IV.—*Silybeæ*.		
	Silybum	1 species.
Section V.—*Serratuleæ*.		
	Serratula	1 species.

The *Cynaraceæ* differ from the *Corymbiferæ* in their active properties in possessing in a more intense degree the bitter principle of the whole order. None of them seem to possess a tendency to develop the narcotic principle which characterises the *Cichoraceæ*; nor is the volatile oil which gives to so many of the *Corymbiferæ* a peculiar aromatic smell developed in these plants. The *Carduus nutans* (Musk Thistle) is the only one which possesses any remarkable amount of odour. The prevalence of the bitter principle renders many of them useful stomachic, tonic, and febrifuge medicines. For these purposes *Centaurea*, *Calcitrapa*, *Cnicus benedictus*, *Carduus lanatus*, *Serratula arvensis*, and *Silybum Marianum* have been used. Some of them are said to be cathartic, and *Echinops sphærocephalus*, which has this property, is used in Languedoc as a remedy for rheumatism. The seeds of various species of *Onopordum* yield a fixed oil, which in some parts is expressed and used for domestic purposes. Many of the *Cynaraceæ* yield colouring-matters. The *Carthamus tinctorius* yields a yellow colour, and is employed to adulterate saffron; *Serratula tinctoria* yields a yellow dye of a fine colour. A pigment of a blue colour is obtained from the flowers of *Centaurea cyanus*. Some of them secrete small quantities of tannin, and are used in consequence as astringents in medicine, as the *Onopordum acanthium*. Galls also are found on the *Cnicus arvensis*, which possess astringent properties, owing to the tannin they contain. A number of species yield food. The bracts of the involucre are in some very large; and, as they contain starchy and other alimentary secretions, are used as diet by man. The Artichoke is a familiar instance. The heads of the *Onopordum acanthium* are often eaten in the same way. The tender sprouts of the *Arctium Lappa* are gathered and eaten in the north of Europe. They are cooked in the same manner as asparagus. The tubers of the *Cnicus tuberosus* are frequently cooked and eaten, and many other species yield starch in their roots. Animals do not generally like the plants belonging to the *Compositæ*. They seem however occasionally to eat them medicinally, and the ass prefers the thistle to most other kinds of food.

(Burnett, *Outlines of Botany*; Lindley, *Flora Medica*; Babington, *Manual of British Botany*.)

CYNA'RRHODON, a name given sometimes to the hep of the rose, which is a fruit composed of a succulent calyx-tube inclosing a number of hard dry hairy nuts.

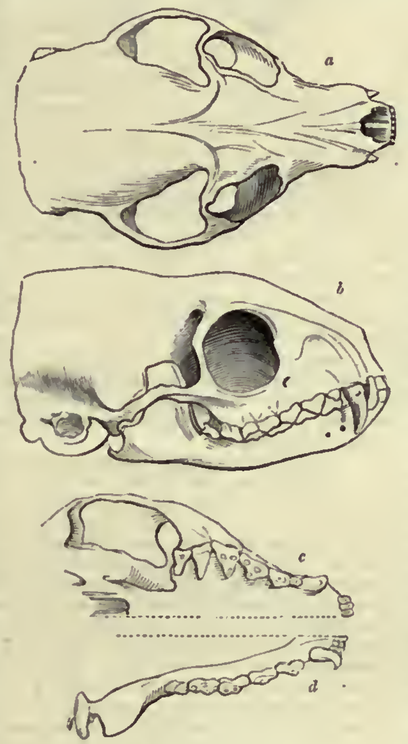
CYNICTIS, a genus of Animals belonging to the order *Carnivora*, established by Mr. Ogilby for an animal connecting the Family of the Civets with that of the Dogs.

It has the following generic characters:—

Dental formula:—Incisors, $\frac{6}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{6-6}{5-5}=38$.

Of these last the first three are spurious, the fourth is the carnassier, and the rest are tuberculated. Feet, digitigrade; toes, 5-4, with long falcular claws adapted for digging. Tail long, bushy.

"This system of dentition," says Mr. Ogilby, "is, in most respects, extremely similar to that which is common to the *Viverræ* in general, and particularly to the genus *Herpestes*, from which the *Cynictis* differs principally in the absence of the rudimentary false molar of the lower jaw, in having that of the upper jaw in contact with the canine, and in a few other circumstances of very minor importance when compared with the general character of the organisation. From the *Ryzæna* or Suricate, on the other hand, the dental system of *Cynictis* differs in the presence of the superior rudimentary false molar, being thus directly intermediate in point of dentition between this genus and the *Herpestes;* and it is not a little singular that it should bear precisely the same relation to both these genera in the form and number of its toes. The *Herpestes* have rudimentary false molars both in the upper and under jaws, and five toes both before and behind; the *Cynictis* has rudimentary false molars only in the upper jaw, five toes on the fore and only four on the hind feet; the *Ryzæna* has no rudimentary false molars in either jaw, and four toes only, as well on the anterior as on the posterior extremities. These traits of zoological character strongly point out the true natural relations of all these animals, and demonstrate the relative positions which they occupy in the system of nature. With the single exception of the *Proteles*, there is no other known genus of the *Viverra* family which possesses the same number of toes and complete digitigrade extremities which form so prominent a character in the *Cynictis*. Here however all analogy ceases between these two genera. It is true that we are at present ignorant of the adult characters of the dentition of the *Proteles;* when we become better acquainted with this important part of its organisation we may perhaps discover additional points of relation between it and the present genus; but in all its most striking external characters it is completely different, and seems to occupy an intermediate station between the Dogs, the Civets, and the Hyænas. In addition to these characters the *Cynictis* may be readily distinguished by its external form and appearance from all conterminous genera. It has a short head, contracted suddenly in front of the eyes, and forming a small naked muzzle, divided by a longitudinal furrow; the ears are short and elliptical, naked inside, and directed forwards; the body long and slender; the tail bushy, and two-thirds of the length of the body, and the whole external form and appearance not unlike that of a Ferret or Ichneumon. The temporal fossæ are separated from the orbits by a complete rim of bone."



Skull of *Cynictis*.

a, seen from above; *b*, profile of the same; *c*, half of cranium seen from below, showing the position of the teeth in the upper jaw; *d*, half of the lower jaw seen from above (from Mr. Ogilby's figure).

C. Steedmannii (Ogilby), named after Mr. Steedman, to whom zoologists are indebted for a knowledge of the animal. It has the following synonyms in the 'British Museum Catalogue':—The Meerkat, *C. Levaillantii*, *Herpestes penicillatus*, Cuv.; *Ichneumon albescens*, J. Geoffroy; *C. pictus*, A. Smith; *Mangusta Levaillantii*, A. Smith; Meerkat, Barrow; Rattel, Swainson; *C. Ogilbyii*, A. Smith.

The length of the head from the muzzle to the root of the ear is 2¼ inches; length of the ear ¾ of an inch; breadth of the ear 1⅜ inch; length of the body from the muzzle to the root of tail 1 foot 6 inches; length of the tail 1 foot; height at the shoulder 7 inches; height at the croup 7¼ inches. Hair moderately fine in quality, much resembling that of a dog, smooth and close on the body, long and bushy on the tail. The general colour, as well as the whole external appearance, precisely that of a small Fox; bright red over the entire body, head, and extremities; deep and uniform on the back, but mixed with silvery gray on the cheeks, neck, sides, and tail, arising from a mixture of hairs tipt with gray, and dispersed through the fur of these parts. The breast, belly, and legs unmixed red; and the tail, which precisely resembles the brush of a fox, covered with long bushy hairs of a sandy-red colour at the roots, dark brown in the centre, and gray at the points; the last two inches at the tip of the tail uniform dirty white. Hair of the body not annulated as in *Herpestes* and the Suricate, and altogether of a finer and more furry quality. External form and appearance comparable with those of the Ferret and Egyptian Ichneumon, but probably standing higher on the legs as being more completely digitigrade.

Cynictis Steedmannii (Meerkat).

It is a native of Uyteuhage, on the borders of Kaffraria. (Ogilby.)

Mr. Ogilby thus concludes his observations on this interesting animal:—"In consulting the works of travellers through the colony of the Cape of Good Hope I have been able to find but two notices which seem clearly to refer to this animal; one by Dr. Sparrman, the other by Mr. Barrow. The first of these authors, in the English translation of his 'Travels,' vol. ii. p. 184, has the following passage: 'Two other small animals, which probably likewise belong to the *Viverra* genus, I had only a hasty glimpse of in this colony. The one we saw and gave chase to between the two Fish Rivers made its escape from us however by running into a hole underground, and seemed to be somewhat less than a cat, though longer in proportion. The colour of it was a bright red.' It is true that this passage records no observation by which we can with certainty refer the animal to which it alludes to the *C. Steedmannii*, but the size, colour, and habitat are so perfectly similar in both cases, as to render their identity extremely probable. In the following extract however from Barrow's 'Travels,' vol. i. p. 185, the characters are fully reported: 'Upon these parched plains [those of Camdebo, on the eastern confines of the colony] are also found several species of a small quadruped which burrows in the ground, and which is known to the colonists under the general name of Meerkat. They are mostly of the genus of animals to which zoologists have given the name of *Viverra*. An eagle making a stoop at one of these, close to where we were passing, missed his prey, and both fell a sacrifice, one to the gun, the other to the dogs. Both the bird and quadruped appeared to be undescribed species. . . . The *Viverra* was wholly of a bright chestnut colour; the tail shaded with black hairs, bushy, straight, and white at the extremity; ears, short and round; on the fore feet five and on the hind four toes; the body and tail each one foot long.' "There can be no doubt," continues Mr. Ogilby, "of the animal to which this description refers, a description more minute and accurate than we generally find in the works of travellers. It agrees in every point with the species which forms the subject of the present memoir, except perhaps in the reported dimensions of the tail and body; but this difference most probably arises from the age or sex of the specimens, or from the measures of Mr. Barrow being taken in a straight line, whilst mine followed the different curvature of the head, neck, and body. The name Meer-kat, by which it appears this animal is known to the colonists, signifies a monkey, and is of very general acceptation in South Africa, being applied indifferently to the present species, the Cape *Herpestes*, Ground Squirrels, and various other small burrowing animals. Both the passages here quoted confirm the burrowing habits of the *C. Steedmannii*, which I had already inferred from the form of the claws."

CYNIPS. [GALLS.]

CYNOCEPHALUS. [BABOON.]

CY'NODON, a genus of Grasses belonging to the tribe *Chlorideæ*. It has a 1-flowered fingered spike, with a superior rudiment; the glumes nearly equal, patent; the paleæ equal, outer boat-shaped, compressed, embracing the inner; the styles long, distinct; the stigmas feathery, protruding below the summit of the floret.

C. Dactylon has 3-5 digitate spikes; smooth paleæ, the leaves downy beneath; the scions prostrate. It is a native of England, on the shores of Devon and Cornwall. *C. linearis* is a native of the East, and is known by the name of Durva-Grass.

(Babington, *Manual of British Botany.*)

CYNOGLOSSUM (from κύων, a dog, and γλῶσσα, a tongue), a genus of Plants belonging to the natural order *Boragineæ*. It has a 5-cleft calyx; a funnel-shaped corolla with the mouth closed, with prominent blunt scales; the stamens included, filaments very short; the nuts roundish-ovate, depressed, muricated, attached by their inner edge. The species are herbs, with soft leaves.

C. officinale, Common Hound's Tongue, has the leaves downy, acute; the lower leaves elliptical, contracting into a petiole, the upper leaves lanceolate, narrowed below, subcordate, half-clasping. The corollas are of a dull red colour. It is a native of Asia, Africa, North America, and Europe. It is found in Great Britain in waste ground. The whole plant has a disagreeable smell, resembling that from mice. It is said to possess narcotic properties, and was at one time used as a remedy in scrofula, but it is not employed in medicine at the present day.

C. montanum has the leaves slightly hairy, acute, nearly glabrous and shining above, scabrous beneath, inferior, oblong, narrowed into a long petiole, upper leaves lanceolate, slightly narrowed below, clasping. It is found in Great Britain by road-sides and in hedges in shady situations.

About fifty other species of *Cynoglossum* have been described, besides the British ones above named. They are all coarse plants, having only small flowers, so that few only are desirable for ornamental cultivation. They are however of the most easy culture, and will grow in almost any situation and soil. The greater number of the species are biennial, and may be propagated by sowing their seed in spring in the open border.

(Babington, *Manual;* Don, *Dichlamydeous Plants.*)

CYNOMORIA'CEÆ, an obscure order of Rhizanths, distinguished from *Balanophoraceæ* by their distinct stamens, and the imperfect perianth of the male flowers. The order is represented by *Cynomorium coccineum*, the *Fungus Melitensis* of the old herbalists, a plant once in repute for its astringent properties, but now valued only for its rarity, and the botanical interest that attaches to it. Dr. Walsh tells us that "it grows most plentifully on a detached rock on the south-west side of the island of Gozo. It is there much celebrated for its medicinal properties: the time of the discovery of its virtues is not known, but from some ancient manuscripts it appears to have been at a very remote period. It had been the usage of Malta to banish to Gozo all females of dishonest character, and here, according to tradition, they found a vegetable substance of an astringent quality, which proved very efficacious in removing the consequences of their irregular life. It was prepared in earthen pots, some of which have since been dug up in various places, marked with Phœnician characters indicating their use. The plant was also applied by them to the purposes of divination. It was laid between the breasts, and from some accidental circumstances of position, &c., they augured good or bad fortune. This practice was reproved, and said to be finally abolished, by a Capuchin missionary. This curious vegetable was subsequently esteemed as a remedy in dysentery, and its curative powers were long held in very high repute. About the year 1740 the Knights of Malta set such a very high value on this fungus, that they interdicted the approach of any person to the place where it grew, and guarded the passage with the strictest jealousy. In April, when the fungus was ripe, it was carefully gathered by persons appointed for that especial duty, and the precious morsels were deposited in a government office, whence some portions were sent as presents by the grand-master to different sovereigns, and the remainder distributed among the hospitals of the island. Even after the English took possession of Malta, and succeeded to the territorial rights of the order, and, amongst other things, to the possession of this rock, a custode was appointed to take care of it as heretofore, with a salary, which always makes an item in the public accounts of Malta. The fungus is thus continued to be guarded and regularly gathered, deposited in the state-office, and distributed among the hospitals; and when Dr. Hamilton, through the kindness of an official person in Gozo, was permitted to visit this rock, he was accompanied by the custode. The rock, as shown by the doctor's sketch, is difficult of approach: it is an isolated precipice, about 600 feet in height, detached from the neighbouring shore, and presenting very steep and inaccessible sides, in some places projecting considerably over the sea, so that the circumference of the base is less than that of the upper parts. It stands on the verge of a noble circular basin, formed by the surrounding cliffs, into which the sea enters by the chasms at each side of the fungus rock, the whole presenting the aspect of the crater of a volcano, raised from beneath, or extinguished by the irruption of the sea."

CYNOPTERUS. [CHEIROPTERA.]

CYNOSURUS, a genus of Plants belonging to the natural order of Grasses.

C. cristatus, a well-known pasture-grass, called by farmers Crested Dogstail, or Gold-Seed, is exceedingly abundant in all natural and artificial grass-land. It grows with a slender smooth stem to the height of one or two feet, and is terminated by a somewhat cylindrical spike-like panicle of short clusters of flowers; each cluster consists of two flowered spikelets resting upon pinnate bracts. The glumes are 2, about the length of the florets; the paleæ 2, of which the lowest is sharp-pointed. The styles are feathery; the fruit is a small yellow smooth shining seed-like body, whence the common name of Gold-Seed.

Crested Dogstail (*Cynosurus cristatus*).

Although this grass forms so constantly a portion of all good pastures, it is chiefly on account of the fineness and closeness of its herbage that it is valuable, the quantity of hay that it produces being inconsiderable. Mr. Sinclair hence observes, that "it is inferior for the purposes of hay, but admirably adapted for permanent pastures. The roots penetrate a great way under ground, from which circumstance it remains green after most other grasses are burnt by a continuance of dry weather. In irrigated meadows it arrives at a greater size than in any other situation." Sheep are said to be less liable to be affected by the disease called the 'foot-rot' when fed on pastures containing a considerable portion of this grass than on such as are composed of the more tender and soft-leaved sorts.

C. echinotus is another species of this grass, found in Guernsey and Jersey. It has an erect stem, one or two feet high; the scales of the appendage with long points. It is extremely rare.

CY'NTHIA, a genus of Ascidian *Mollusca*. It consists of those Ascidians whose body is sessile, and which have the branchial sac plaited longitudinally, and the reticulation continuous; branchial and anal orifices opening in four rays or lobes. Their external envelope or test is coriaceous.

Messrs. Forbes and Hanley, in the 'History of British Mollusca,' enumerate 13 species of this genus as natives of the seas of the British Isles.

C. rustica has the body more or less globular or botryoidal, rugose, usually of a rusty red; apertures sessile, placed apart, deeply tinged with rose-red. From half an inch to two inches in length. It is common on most parts of our coast, and is found attached to various kinds of sea-weeds.

C. claudicans has a tuberous body; the test wrinkled and furrowed in every direction; the orifices are small, deeply 4-lobed, and placed on slightly prominent conical projections. It is about an inch in height, and is found attached to oysters.

C. aggregata has a bottle-shaped body with terminal approximate orifices. It was found gregarious in vast numbers by Professor E. Forbes and Mr. M'Andrew in twelve fathoms' water at Dartmouth. It was found under large stones; and on many of the branching root-fibres there were small, tough, globular, imperforated, orange-coloured bodies of various sizes full of granules. This form seems to be intermediate, and between the single and social Ascidians, and "should probably rank as the type of a distinct genus." (Forbes and Hanley.)

CYPER'ACEÆ, *Sedges*, an extensive natural order of Glumaceous Endogenous Plants, having much the appearance of Grasses, with which

Cyperus fuscus.

1, a spikelet magnified; 2, a flower with its bract; 3, a fruit; 4, a section of a seed.

they are sometimes popularly confounded. They differ in their stems being usually solid, not hollow, and angular, not round; in the sheaths of their leaves not opening on one side, but forming perfect tubes when the stem is pulled through them; in their male florets having no paleæ nor any covering to the stamens except a single bract, while the bisexual florets have nothing more than a few hypogynous bristles superadded; and finally, in their embryo being inclosed in the albumen, and not lying at one side of it. There are other distinctions besides these, but what have been mentioned are the most remarkable. A large proportion of the order bears the name of Sedges, and hence the Sedge Family or Tribe is given to these plants as their English appellation. They are mostly inhabitants of marshy or swampy grounds; a few are met with on dry upland pastures, and a good many are alpine plants. They occur in all parts of the world, and are generally abundant, but little or nothing has been discovered of their uses; their most common application is to the manufacture of what are called erroneously rush-mats and rush-bottoms for chairs. The plant used in this country for such purposes is not any kind of rush, but the cyperaceous species *Scirpus lacustris*. It is not a little remarkable that, nearly as these plants are allied to Grasses, they scarcely at all participate in the nutritious quality of that useful order; it is only among the coarse bad herbage of marshes that they are allowed to form a constituent of hay.

The following is a synopsis of the British genera of this order:—

Tribe I. *Cypereæ.* Flowers perfect. Glumes 2-ranked. Perigone absent.

- *Cyperus* . . . . . 2 species.
- *Schœnus nigricans.*

Tribe II. *Scirpeæ.* Flowers perfect. Glumes imbricated on all sides. Perigone absent.

- *Cladium mariscus.*
- *Rhyncospora* . . . 2 species.
- *Eleocharis* . . . . 4 species.
- *Scirpus* . . . . . 14 species.
- *Blysmus* . . . . 2 species.
- *Eriophorum* . . . . 6 species.

Tribe III. *Elyneæ.* Flowers diclinous. Perigone absent, or formed of one or two scales.

- *Kobresia caricina.*

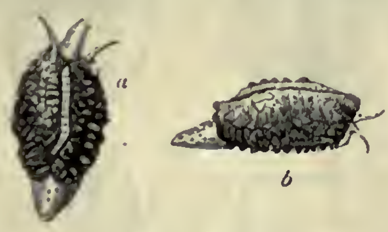
Tribe IV. Flowers diclinous. Nut completely inclosed in the urceolate perigone.

- *Carex* . . . . . 72 species.

(Babington, *Manual of British Botany*, 1851.)

CYPRÆ'IDÆ, the *Cowry Family*, Cowries, or sometimes Gowries—Porcellanen of the Germans; Porcelaines (Porcelain shells) of the French—a family of Marine Gasteropodous *Mollusca*, well known in commerce from one of the species (*C. Moneta*) being used in some parts of the East as a circulating medium.

This group of shells is characterised by the animal being unisexual, elongated; head distinct, with two conical or subulate tentacula of some length, at the external base of which are situated the two sessile eyes on small projections; mouth vertical, at the bottom of a small cavity, and containing a lingual riband, or lamina, beset with tentacles and prolonged in the abdomen. Branchial cavity open, situated near the back of the neck; gills arranged in a longitudinal pectinated series on the inside of the columella on the left side of the mantle; siphon very short, and formed in the mesial line by the edges of the two lobes. Mantle bilobated, the lobes very large with extended aliform edges, capable of being reflected over the back of the shell so as to join on the mesial dorsal line. Foot oval, elongated, very large. Vent at the extremity of a tube behind the branchial cavity. Male organ situated more forward, and communicating with the orifice of the deferent canal by means of a furrow. Adult shell involute, highly enamelled, oval or oblong, more or less rounded or cylindrical, with a small and imbedded spire; aperture longitudinal, nearly straight, toothed, or plaited, on each side, with a channel or groove at each end, inner lip flattened or sub-concave, outer lip involute. No operculum.



Cypræa (Trivia) Pediculus.
a, the animal seen from above; *b*, side view of the same.

Dr. J. E. Gray, whose arrangement we select as being in our opinion the best which has hitherto appeared, thus notices the very great change of form that the young shell undergoes in its progress to perfection:—"The shell alters its appearance considerably according to the age of the individual, and exhibits three very distinct stages. In the young or first stages the shell is generally smooth, of a plain grayish colour, or with three longitudinal bands, and the upper part of the inner lip is smooth, convex, the lower part flat or concave; the outer lip thin. In the second stage the shell begins to assume more the character of the genus, as the outer lip begins to be inflected or rather thickened, and approaches nearer the perfect appearance of the species as the second coat of colour is deposited; but

Cypræa Exanthema, illustrating the stages of growth.
a, young shell in the first stage, seen from above, view of the back; *b*, the same showing the columella and the thin edge of the outer lip; *c*, an advanced stage, view of back (the apex is already sinking, and the thickened lips are formed); *d*, still further advanced (the mantle has begun to secrete the enamelled spotted coat on the side, but the transverse stripes are still visible); *e*, the perfect shell, all traces of the transverse stripes lost under the enamelling of the thickened spotted coat; *f*, view of under side of the perfect shell.

differs from it in the want of thickness of the shell and the spire being more distinct, and in the want of the dorsal line, which is usually distinct in the third or perfect state, where the last coat has been deposited, and the aperture is more plaited on both sides. The colouring, or at least the disposition of the colouring here, is a much more certain characteristic of species than either the general outline of form or size, the latter of which is exceedingly various. In this family I have often observed full-grown specimens of *C. Arabica* from one to three inches long; this peculiarity is attempted to be explained by Lamarck and others, who assert that when the animal has formed a complete shell, as it has not the faculty of enlarging its size, it is obliged to quit its shell and form a new one, in the same manner as the *Annulosa* cast their skins, and by that means the same animal forms many shells; but I believe there is not the slightest ground for this notion."

The *Cypræidæ* abound both in the Old and New World, but their greatest development both in point of size and number of species takes place in warm climates. A very few species are inhabitants of the European seas. The family are littoral, and are generally found under stones or rolled corals.

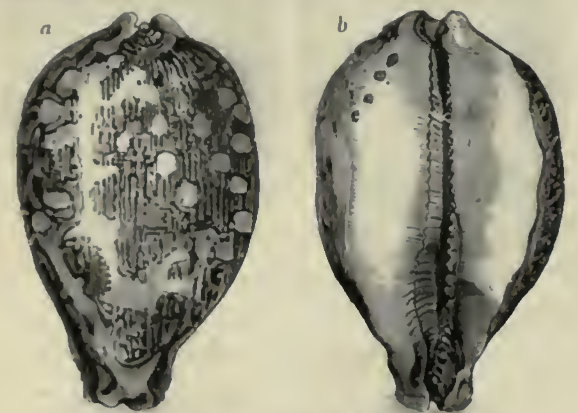
Genus *Cypræa*.—The young shell smooth, the adult with both lips toothed; the anterior and posterior canal distinct, recurved; the front end of the columella-lip smooth, edged by a single large oblique fold, separated from the teeth by a deep groove. (Gray.)

* Sub-Genus 1. *Cypræa*.—The front of the columella broad, deeply impressed; shell mostly smooth.

α. Shell smooth; columella-pit transversely ridged; teeth of inner lip generally long. (Gray.)

Under this division of the sub-genus Dr. Gray arranges 27 species, including some of the rarest forms—*C. aurora* (the Morning Dawn, or Orange Cowry), and *C. Princeps*, for example—together with *C. Tigris* (the Tiger Cowry), and other common species.

C. Mappa, the Map-Cowry. Shell more or less ventricose, ovate, varied with deep brown or yellow lines, and spots. Dorsal line laciniated. Margin thick, spotted with black; teeth yellow. It is found in the Indian Ocean.



Map-Cowry (*Cypræa Mappa*).
a, seen from above; *b*, seen from below.

There are many varieties, among which the rosy variety, the dark variety from the Pearl Islands, the citron variety, and the dwarf rich-mouthed variety from the Mauritius, are the rarest or most beautiful. The young shell is of a fawn colour with obsolete spots and dashes.

β. Shell smooth; columella-pit (nearly) smooth; teeth of inner lip short or indistinct.

Under this division of the sub-genus Dr. Gray arranges 15 species.

C. Talpa, the Mole-Cowry; Sardonyx Cowry of Gray. Shell oblong ovate, subcylindrical, yellowish, with three darker bands; the subangular base and teeth brown or black; mouth pale.

Mole-Cowry (*Cypræa Talpa*).

There is a variety (*Exustus*) shorter, darker, and with the teeth smaller and closer.

γ Shell with the back warty (rarely smooth), base ridged. Under this section Dr. Gray enumerates three species.

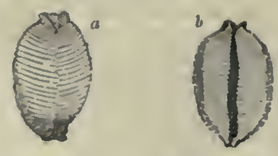
C. Cicercula, the Vetch-Cowry. Shell subglobose, yellow, brown, dotted, with a dorsal groove, and scattered tubercles over each extremity; base four-spotted, partly grooved.

Vetch-Cowry (*Cypræa Cicercula*).
a, seen from above; *b*, seen from below.

There is a larger variety which is more oblong, smooth, and is without the dorsal groove (*C. globulus*).

δ Shell with transverse ribs. Only two species are enumerated by Dr. Gray, and one of these, *C. rugosa*, Brod., is fossil.

C. Childreni, Children's Cowry, Gray.



Children's Cowry (*Cypræa Childreni*).
a, seen from above; *b*, seen from below.

ε Shell with longitudinal and transverse ribs.

C. Adamsonii, Adamson's Cowry, Gray, a very rare species, is the only representative of this group. Shell ovate; pear-shaped, white, brown mottled. It is a native of the Pacific Ocean (?). (Gray.)

Adamson's Cowry (*Cypræa Adamsonii*).

** Sub-Genus 2. *Aricia*.—Front of the columella flat, or nearly so; back of shell smooth.

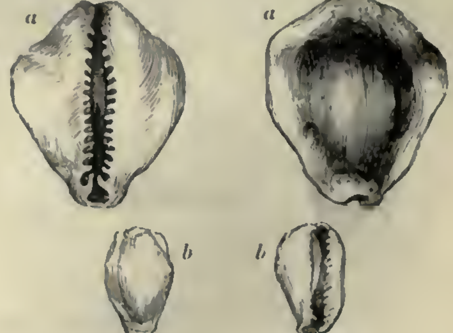
α Margin of the shell pitted on the upper edge. Fourteen species.

C. guttata, Gmel.; Blotched Cowry, Gray. Brown, pale spotted, base and margin white, brown-ridged: a beautiful and rare species. Locality, Red Sea (?). (Gray.)

Blotched Cowry (*Cypræa* (*Aricia*) *guttata*).

β Margin entire; teeth of both lips extended more or less over the base. Thirty-seven species.

C. Moneta, Money-Cowry, Linn. Shell yellow or white, with a yellow ring; margin and base tubercular; teeth of inner lip moderate.



Money-Cowry (*Cypræa* (*Aricia*) *Moneta*).
a, adult; *b*, young.

There are two varieties: *a*, without a ring; *b*, with the margin and base less tubercular.

The young are whitish with two dark bands (*C. icterina*).

γ Margin entire; teeth of inner lip very small, forming a slight ridge; front of columella-lip slightly concave, produced, and toothed internally. Two species.

C. angustata, Gray. Shell whitish brown, minutely brown dotted; base white; margin closely black dotted, ends blackish. Worn plain brown, varying in darkness. It is found in Australia.

Cypræa (*Aricia*) *angustata*.

*** Sub-Genus 3. *Naria*.—Front of the columella narrow, dilated into a sharp-toothed ridge; shell smooth.

This sub-genus is represented by one species.

C. irrorata, Gray. Shell ovate, purplish, yellow dotted; base white, flat; teeth large. It is a native of the South Seas. Most allied to *C. Felina*, variety 1.

Cypræa (*Naria*) *irrorata*.

Genus *Luponia*.—Shell like Cowry, but front end of the columella-lip crossed by several irregular ridges, without any distinct marginal one, internally narrow, flat; shell pear-shaped, smooth, or cross-ribbed. There are five species.

L. Algoensis, Algoa Lupon, Gray. Shell pale, brown dotted; base smooth; teeth of inner lip very small; margin black dotted. Variety with the teeth more or less obliterated. It is a native of the Cape of Good Hope.

Algoa Lupon (*Luponia Algoensis*).

Cypræovula.—Like Cowry, but front end of columella covered with regular cross-ribs, like rest of base, internally produced into an acute-toothed ridge. Shell pear-shaped, cross-ribbed.

C. Capensis, Cape Cypræovula, Gray. Pale brown; ribs very thin, continued, sharp. It is found at the Cape of Good Hope, but is very rare.

Cape Cypræovula (*Cypræovula Capensis*).

Trivia.—Like *Cypræovula*, but front of columella internally concave, ribbed. Shell subglobular, cross-ribbed.

a. Mouth wide; outer lip slightly inflexed; shell equally ribbed. In this section there are five species.

T. carnea, Flesh-Coloured Pig, Gray. Shell oblong, thin, pellucid, pure rose-coloured, with very thin distant continued ribs; lips whitish. Varies with an indistinct dorsal groove.

Dr. Gray observes that Pig is the common name of these shells on the coast, and that they are called Porcelli in Italy. He adds, that Porcellain, the common name for Cowries, is taken from the fancied resemblance of these shells to pigs, and refers to Fabius Columna, &c.

Flesh-Coloured Pig (*Trivia carnea*).

β. Mouth narrowish; outer lip wide; ribs of back subequal, linear. This section contains eighteen species.

T. Europæa, European Pig, Gray; *Cypræa Europæa*, Lam. Shell ovate, subglobose, ash- or flesh-coloured, with three black dots, and a whitish dorsal streak; ribs close, rather thick, whitish; base white; outer lip wide.

European Pig (*Cypræa* (*Trivia*) *Europæa*).
a, adult; *b*, young.

There is a variety with the back spotless, with an indistinct dorsal groove (*Cypræa Arctica*, Mont.). This shell is found on the British coast. It ranges from the verge of low water to as deep as 50 fathoms. It is also found in the coralline and red crag.

The young are white and smooth.

γ. Mouth narrowish; the outer lip arched; the ribs enlarged or tubercular near the dorsal groove. It contains seven species.

T. Pediculus, Louse-Pig, Gray; *Cypræa Pediculus*, Linn. Shell ovate, pale reddish, with six square black dorsal spots: ribs rather thick, subrugose, crowded; dorsal line narrow; base reddish. It is a native of the West Indies.

Louse-Pig (*Trivia Pediculus*).

δ. Mouth narrow; ribs tubercular; dorsal line distinct; front of columella smooth. In this section there are two species.

T. pustulata, Pimpled Pig, Gray; *Cypræa pustulata*, Lam., commonly called by collectors the Small-Pox Cowry. Purplish-brown; ribs studded with red-brown, black-edged warts. It is a native of the Pacific Ocean.

Small-Pox Cowry (*Trivia pustulata*).

Erato (Risso).—Spire conical; apex sub-mamillary, blunt; shell, when young, smooth; the adult with both lips finely crenulated; the columella concave, slightly radiatedly plaited or smooth, with two or three folds in front; the anterior canal straight, the hinder indistinct. This genus includes seven species.

E. scabriuscula, Roughish Tear-Shell, Gray; *Marginella Cypræola*, Sow. Shell ovate, turbinate, livid, purplish, minutely tubercular; spire conical; dorsal line impressed; mouth wide, whitish, inner lip largely plaited its whole length; teeth large; young, smooth; lip thin, toothless. It is found in the South Pacific, St. Helena.

Roughish Tear-Shell (*Erato scabriuscula*).

Ovulum (*Ovula*, Lam.).—The shell, when young, spirally striated when adult, covered with a smooth enamelled coat; the inner lip toothless; the outer toothed or crenated; the anterior and posterior canal more or less elongated.

α. The outer lip broad, inflexed, rounded, crenulated; extremities short; front of columella rounded.

In this subdivision Dr. Gray enumerates two species.

O. ovum; Ovula oviformis, Lam.; *Bulla ovum*, Linn.; Common Poached Egg. White; back rounded; inside orange-brown.

Common Poached Egg (*Ovulum ovum*), adult.

β. Outer lip inflexed, broad, toothed; ends short, curved, hinder end with a tooth on the inner side; front of the columella expanded beneath. One species only.

O. verrucosum; Ovula verrucosa, Lam.; *Bulla verrucosa*, Linn.; Two-Warted Poached Egg, Gray. Shell ovate; back angular; extremity rosy, with a depressed wart above. Young closely striated; ends brown-edged. Found in the Indian Ocean.

Two-Warted Poached Egg (*Ovulum verrucosum*).

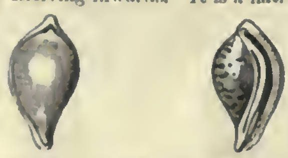
γ. Outer lip inflexed, rounded, narrow, toothed; rest like sect. β. It includes four species.

O. Margarita, Sow.; Pearl Poached Egg, Gray. Shell ovate, subglobose, white, pointed in front, ventricose; base convex; hinder tubercle rugose; front of columella concave; outer lip rounded. This with six brown dots artificially made is *Ovula punctata* of Duclos. A native of the Friendly Islands.

Pearl Poached Egg (*Ovulum Margarita*).

δ Outer lip slightly inflexed, narrow, keeled externally, with edge shelving inwards; the rest like the former. This section includes seven species.

O. pyriforme, Sow.; Pear-Shaped Poached Egg, Gray. Shell pear-shaped, yellowish-white, attenuated in front; front of columella concave; outer lip shelving inwards. It is a native of Australia.



Pear-Shaped Poached Egg (*Ovulum pyriforme*).

ε. Outer lip thickened, inflexed, toothless; extremities short; front of the columella flattened; hinder part with a fold obliterated by age. In this section there are nine species.

O. gibbosum; Ovula gibbosa, Lam.; *Bulla gibbosa*, Linn.; Gibbous Poached Egg, Gray. Shell oblong, blunt, white; margin yellow, covering nearly the whole shell; back with an angular rib. Varies in length and breadth. Found in the Atlantic Ocean.

Gibbous Poached Egg (*Ovulum gibbosum*).

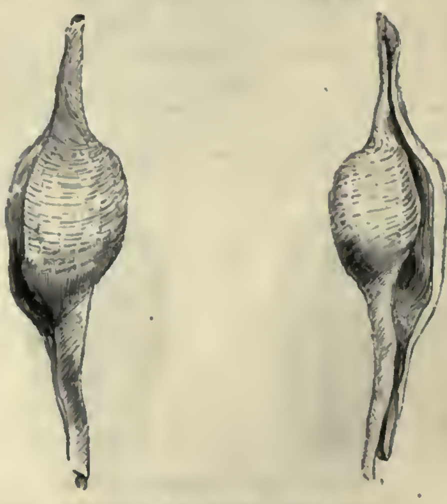
ζ. Outer lip thickened, inflexed, toothless; extremities rather elongated; the hinder conical, straight; the rest like the former. Four species are included in this section.

O. longirostratum, Sow.; Goodhall's False Spindle, Gray. Shell fusiform, white, thin; beak very long, curved; mouth linear, rather expanded in front. Found in the Adriatic.

Goodhall's False Spindle (*Ovulum longirostratum*).

η. Outer lip thickened, slightly inflexed, toothless; the front of the columella rounded, the extremities very long. (*Volva*, De Montf.) It embraces one species only.

O. volva; Ovula volva, Lam.; *Bulla Volva*, Linn., Common Weaver's Shuttle. Shell oval, flesh-coloured, striated; outer lip pink; the beaks long, flexuous. Locality, China.



Common Weaver's Shuttle (*Ovulum volva*).

On the position of this family amongst the *Mollusca*, Dr. J. E. Gray makes the following remarks:—"This family appears to be allied to the sub-family *Cassideæ*, amongst the *Buccinöideæ*, by means of the *Cassis Testiculus*, of which Lamarck observes, 'ce casque a un peu l'aspect de certains *Cypræa*;' but the affinity is not slight, for in the shape and form of the aperture, which has a groove or canal at each end, both of the lips plaited, and the front part of the columella flattened, it accords with those *Cypræa*; but the outer lip is not inflected, nor is the back of the shell covered with a china-like coat, but with epidermis, and the canal in front of the aperture is recurved. The *Ovulæ*, on the opposite side of the family, have certainly great affinity to the *Bullideæ* (*Bullidæ*), as is pointed out by Linnæus, who places them all in that genus, but *Bulla* differs most essentially from them: in the animals, by the position of their branchiæ and their being half hermaphrodite, and in the shell, by the aperture being rounded and quite entire at each end, and the edges not being thickened, nor the back covered with a shelly coat, for the shell is here covered with the soldered reflected lobes of the mantle; the connection is most apparent by means of *Ovula patula* and *Bulla Naucum*, in the latter of which there are some slight appearances of a curved canal at each end of the aperture, as in the character of the *Cpyrœideæ* (*Cypræidæ*), but it has not the enamelled back.

"This family has some analogy, in their polished coats, first to the *Marginellæ*, which induced Montagu to call a species of that genus *Cypræa voluta;* and indeed, such is the affinity between the young of this species, which has been called *Bulla diaphana*, that Dillwyn has considered it as the young of *Cypræa Europæa*; in which Montagu appears also to have coincided, until he observed a totally different construction in the animal: but I believe that *M. persicula* is the most analogical species of this genus; and secondly, to the *Olivæ*, which differ essentially in having an operculum, and all the characters of the *Buccinoideæ* (*Buccinidæ*)."

Messrs. Forbes and Hanley in their 'History of the British Mollusca,' place them after the *Conidæ*, and last of the families of the *Gasteropoda Prosobranchiata*.

Fossil Cypræidæ.

Fossil shells of this family do not appear to have been found below the Supracretaceous Group. Mr. G. B. Sowerby, speaking of the genus *Cypræa*, says, "Of these," the fossils, "we have several species in Britain, in the London Clay and Crag; many others are found on the Continent, as in the Calcaire Grossier in the environs of Paris; at Laugnan, near Bordeaux, and in Normandy; also in Italy and Piedmont; we have seen specimens of a very fine fossil species, nearly resembling *Cypræa mus*, from the Netherlands: they seem to be confined to the newer formations." Lamarck enumerates 18 fossil species of *Cypæa*, and two of *Ovulum*. Deshayes, in his 'Tables,' makes the number of living *Ovula* 18, and the number of fossil (tertiary) species 6. Three species, *O. Spelta*, *O. birostre*, and a new species, he makes both fossil (tertiary) and living in the Mediterranean, the Indian Ocean, and the Mediterranean respectively. The number of living species of *Cypræa* he makes 138, and the number of fossil (tertiary) 19.

Dr. Gray notes the following as fossil:—

Cypræa Physis, Brocchi (*C. Pyrula*, Lam.), Plaisantin or Placentin; *C. leporina*, Lam.; *C. gibbosa*, Gray; *C. tumidula*, König, Bordeaux: and he observes, that *C. annularia*, Brogn., appears to be an allied species; *C. fragilis*, Gray; *C. Deshayesii*, Gray; *Ovula tuberculosa*, Duclos; *C. inflata*, Lam., Grignon, allied to *Ovulum; C. subrostrata*, Gray, Nehove; *C. fabagina*, Lam.; *C. diluviana*, Gray; *C. rugosa*, Brod., Turin.

Luponia elegans, Gray (*C. elegans*, Defr.); *L. dactylosa*, Gray; *C. dactylosa*, Lam.; *C. Gervillii*, Sow.; *C. Georgii*, Defr.

Trivia Barcinensis, Gray (*C. Barcinensis*, König, Barcelona); *T. sphæriculata*, Cyp. Lam. (?), Italy; *T. acuticostata*, Gray, Italy; *T. pediculoides*, Gray, Italy; *T. Porcellus*, Gray, Crag (?); *T. Bronnii*, Gray, Italy; *T. solida*, Gray; *T. avellana*, Sow., M. C., Suffolk Crag, which, Dr. Gray observes, appears to be an allied species; *T. Duclosiana*, Gray.

Erato ventricosa, Gray, Italy.

Ovulum Lethesii (*Leathesii ?*), Sow., M. C.

The following species are described in Mr. Searles Wood's account of the Crag *Mollusca* (Pal. Soc.):—*Cypræa avellana; C. affinis; C. Anglicæ; C. retusa; C. Europæa; Erato lævis; E. Maugeriæ.*

CYPRESS. [CUPRESSUS.]

CYPRICARDIA. [SUBMYTILACEA.]

CYPRINA. [VENERIDÆ.]

CYPRINE. [IDOCRASE.]

CYPRI'NIDÆ, a family of Fishes of the section *Malacopterygii Abdominales*, the species of which are distinguished by their having the mouth small, formed by the intermaxillary bones, and generally devoid of teeth; the pharyngeans furnished with strong teeth, the branchiostegous rays few in number, and the scales generally of large size.

The principal genera belonging to this family are—*Cyprinus, Barbus, Gobio, Tinca, Cirrhinus, Abramis, Labeo, Catastomus, Leuciscus, Gonorhynchus, Cobitis, Anableps, Pœcilla, Lebias, Fundulus, Molinesia*, and *Cyprinodon.*

Cyprinus, as now restricted, contains the Common Carp and allied species, which are distinguished from those of the other genera above enumerated by their having one long dorsal fin, a small mouth devoid of teeth, the scales of large size, and the second rays of the dorsal and anal fins large, bony, and more or less serrated; branchiostegous rays three in number.

C. Carpio, Linn., the Common Carp, was introduced into this country at an early period (probably between the 14th and 15th centuries), but neither the date nor the country from which it was imported is precisely known. In Jenyns's 'Manual of British Vertebrate Animals' it is said to be originally from the middle of Europe; and since it thrives best in this part, such is probably the case. It now inhabits most parts of Europe, and in some places its growth is much attended to for the purposes of traffic. It frequents lakes, ponds, and rivers; in the last however it avoids those parts where the current is strong, preferring still water.

The food of the Carp consists chiefly of vegetable substances, which are masticated by means of the flat teeth which are situated on the pharyngeans; the larvæ of insects and worms however also afford it nutriment. This fish is of an elongate form, and rather thick; the back is considerably elevated, and the greatest depth of the body, which is beneath the commencement of the dorsal fin, measures rather more than one-third of the entire length: the head is large, and the mouth small in proportion; the lips are furnished with two barbules on each side, situated near the corners of the mouth: the dorsal fin commences in a line with the end of the pectorals, and occupies a space nearly equal to one-third of the entire length; the first ray is short and bony; the second is also bony but long, and serrated on the hinder part; the third ray is the longest, and is flexible, as are likewise the remainder of the rays: the anal fin terminates in a line with the dorsal, and like that has the two foremost rays bony and the second serrated; the pectoral fin has its origin immediately behind the free edge of the operculum; the caudal fin is forked, and the longest rays are double the length of those in the centre. The number of fin-rays are—dorsal, 22; pectoral, 17; ventral, 9; anal, 8; and caudal, 19. The lateral line is straight.

The general colour of the upper parts is a rich olive-brown, which is darkest on the head; the under parts are yellowish white, and the fins are brown; the ventral and anal fins are tinged with red.

As regards the size and weight of the Carp, we extract a few lines from Mr. Yarrell's valuable work. "Though not so rapid in their growth as some fish," says this author, "carp have attained three pounds' weight by their sixth year, and six pounds' weight before their tenth year. The largest I can refer to are thus noticed in Daniel's 'Rural Sports:'—'Mr. Ladbroke, from his park at Gatton, presented Lord Egremont with a brace that weighed thirty-five pounds, as specimens to ascertain whether the Surrey could not vie with the Sussex carp.' In 1793, at the fishing of the large piece of water at Stourhead, where a thousand large brace of killing carp were taken, the largest was thirty inches long, upwards of twenty-two broad, and weighed eighteen pounds.

"At Weston Hall, Staffordshire, the seat of the earl of Bradford, the painting of a carp is preserved, which weighed nineteen and a half pounds. This fish was caught in a lake of twenty-six acres, called the White Sitch, the largest of three pieces of water which ornamented this fine estate."

Carp are in season for the table from October to April.

C. gibelio, Bloch, the Prussian Carp, is another species of this genus now naturalised in this country, and which is said to have been introduced from Germany.

This species is considerably less than the Common Carp; its usual weight is about half a pound; it has been known however to weigh upwards of two pounds.

The Prussian Carp may at once be distinguished from the Common Carp by the absence of barbules on the lips. The greatest depth of the body is equal to one-third of the whole length, the tail included; the lateral line descends in a gentle curve from the upper angle of the operculum below the middle of the body, whence it is straight; the tail is forked; the longest rays are about one-third longer than the shortest rays; the dorsal and anal fins have a strong bony ray, as in the Common Carp, but these rays are not so deeply serrated. The number of fin-rays are—dorsal, 18; pectoral, 14; ventral, 9; anal, 8; and caudal, 19.

The colour of the upper parts is olive brown; the belly is almost white; the cheeks and gill-covers are of a brilliant golden-yellow hue; the fins are for the most part of an orange-red colour.

This fish is found in some of the ponds in the neighbourhood of London, and in other parts of England, but is rather local.

C. auratus (Linn.), the Gold Carp. The gold and silver fish, as it is termed, has been long known in this country: it is a native of China, and, according to Pennant, was first introduced into England in 1691, but was not generally known till 1728. The Gold Carp is now completely naturalised, both here and in other parts of Europe, where it has been introduced, and breeds freely, especially in ponds in warm and sheltered situations. In many of the streams of Portugal it abounds, whence they are brought over to this country in the trading vessels for sale.

This fish is too well known to require description. It is subject to much variation not only in colour but in the fins, which are sometimes double, and not unfrequently have triple tails; in the latter case however it appears that the tail is thus developed at the expense of part or the whole of some other fin. When young, the Gold Carp is of a very dark colour, approaching to black; this dark colour is replaced by the golden-red hue more or less early according to the constitution of the individual.

Of all fish the Gold Carp is most easily domesticated, and it may be kept for years in small glass vessels if care be taken to change the water every day in the summer, and twice or three times a week in the winter. Even this is not necessary if they are kept in vessels in which water-plants are permitted to grow, and a few fresh-water snails are added. In this way most of our fresh-water fish can be reared and treated, as pets in the drawing-room. [AQUAVIVARIUM.]

C. carassius, the Crucian or German Carp. This species was formerly confounded with *C. gibelio*. The following is Mr. Yarrell's description :—"The length of the head is to the depth of the body as 1 to 2; and to the whole length of head, body, and tail as 1 to 5; the depth of the body compared to the whole length as 2 to 5; the tail nearly square at the end."

This fish is much more rare than the Prussian Carp. Mr. Yarrell says he has never seen this fish except "from the Thames between Hammersmith and Windsor, where it attains considerable size, sometimes weighing a pound and a half; in one instance a specimen brought me in October 1829 weighed 2lbs. 11 ozs. Of its habits little is known."

In addition to the above species of *Cyprinus*, the following British fish belong to this family :—

Barbus vulgaris, Cuvier (*Cyprinus vulgaris*, Linn.), the Barbel. [BARBEL.]

Gobio fluviatilis, Cuvier (*Cyprinus Gobio*, Linn.), the Gudgeon. [GOBIO.]

Tinca vulgaris, Cuvier (*Cyprinus Tinca*, Bloch.), the Tench. [TINCA.]

Abramis brama, Cuvier (*Cyprinus brama*, Bloch.), the Bream, or Carp-Bream.

A. blicca, Cuv. (*Cyprinus blicca*, Bloch.), the White Bream or Bream-Flat.

A. Buggenhaggii, Thompson (*Cyprinus Buggenhaggii*, Bloch.), the Large-Scaled or Pomeranian Bream. [BREAM.]

Leuciscus Idus, Cuvier (*Cyprinus Idus*, Linn.), the Ide.

L. rutilus, Cuvier (*Cyprinus rutilus*, Linn.), the Roach.

L. vulgaris, Cuvier (*Cyprinus leuciscus*, Linn.), the Dace, Dare, or Dart.

L. Lancastriensis, Yarrell (*Cyprinus Lancastriensis*, Shaw), the Graining.

L. cephalus, Fleming (*Cyprinus cephalus*, Linn.), the Chub or Skelly.

L. eryothropthalmus, Cuvier (*Cyprinus eryothropthalmus*, Linn.), the Red-Eye, or Rudd.

L. cæruleus, Yarrell, the Azurine, or Blue Roach.

L. alburnus, Cuvier (*Cyprinus alburnus*, Linn.), the Bleak or Blick.

L. phoxinus, Cuvier (*Cyprinus phoxinus*, Linn.), the Minnow, Minim, or Birk. [LEUCISCUS.]

Cobitis barbatula, Linn., the Loach, Loche, or Beardie.

C. tænia, Linn., the Spined Loach, or Groundling. [COBITIS.]

CYPRINUS. [CYPRINIDÆ.]

CYPRIPE'DIUM, a genus of Plants belonging to the natural order *Orchidaceæ*, and the tribe *Cypripedieæ*. It has a patent perianth; a ventricose inflated lip; column trifid above; the lateral lobes bearing stamens, the middle lobe sterile, dilated; the two lower sepals combined; the germen straight.

C. calceolus, Lady's Slipper, has a leafy stem; the middle lobe of the column nearly ovate, obtuse, deflexed; the lip slightly compressed, shorter than the calyx. This plant has been found in Great Britain, but is extremely rare.

All the species are exceedingly elegant plants. They are mostly inhabitants of North America and Northern India. Two new species have been lately introduced. In their cultivation they require great care. They will only thrive in a shady border in peat soil. The American species should be covered with some dry straw in very severe frosts, or if there should be too much wet; they are not easily increased, but will perfect seeds in favourable situations, particularly if pains be taken to apply the pollen to the stigma.

(Babington, *Manual*; Loudon, *Encyclopædia of Plants*.)

CYPRIS. [BRANCHIOPODA.]

CYPSELAS. [HIRUNDINIDÆ.]

CYRENA. [VENERIDÆ.]

CYRILLACEÆ, *Cyrillads*, a natural order of Exogenous Plants. The order consists of shrubs with evergreen simple leaves without stipules. The flowers usually in racemes. The calyx 4-5-parted. It has 5 distinct petals, with an imbricated æstivation. The ovary is 2-3-4-celled, always composed of some number of carpels different from that of the calyx, corolla, and stamens; solitary pendulous ovules, a short style, the stigma with as many lobes as there are cells of the ovary. The fruit is a succulent capsule or a drupe; the seeds inverted; the embryo in the axis of a very large quantity of albumen, with a very long superior radicle. This order is related to *Olacaceæ* and *Pittosporaceæ*. All the species are inhabitants of North America. Nothing has been recorded of any uses to which they are applied.

CYRTANDRA'CEÆ, a small natural order of irregular-flowered Monopetalous Exogens, allied to *Bignoniaceæ* and *Gesneraceæ*. They are herbaceous plants, and in many cases stemless, with no tendency to twine; sometimes they are parasitical; their calyx, corolla, and stamens are those of *Bignoniaceæ*; but their fruit is a long slender pod, containing a multitude of seeds, that are terminated by long delicate tails, and are destitute of albumen. The pod is 2-celled, and each cell has its placentæ doubled back from the axis so as to form two plates at right angles with the dissepiment. The species inhabit the East Indies chiefly, a few only being met with in other warm parts of the world. They are all beautiful in their flowers, but they are of no known use. In his 'Vegetable Kingdom,' Dr. Lindley includes these plants in the order *Gesneraceæ*. [GESNERACEÆ.]

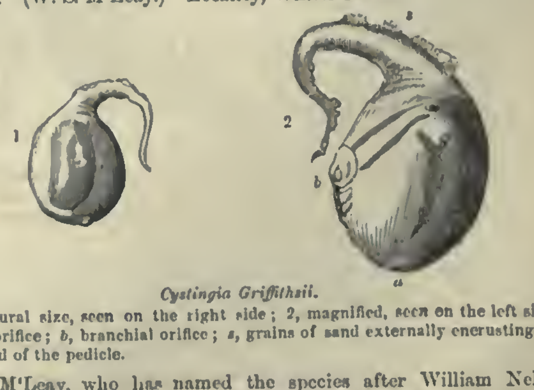
Streptocarpus Rexii.

1, a section across the ripe pod, showing the double placentæ.

CYRTO'CERAS, a genus of Fossil *Cephalopoda* belonging to the family *Ammonitidæ*, proposed by Goldfuss. It occurs in the Palæozoic Strata of Devon, the Eifel, and Ireland principally, and includes many species of great beauty and interest. The septa are pierced by a subdorsal siphon; the last whorl finishes in a straight extension. (*Phil. Pal.*, '*Foss. of Devon*.')

CYSTI'NGIA, a genus of Tunicated Ascidian *Mollusca*, established by Mr. W. S. M'Leay, who observes that it comes nearer to *Boltenia* than to any other hitherto described; and that they may prove eventually to be only two sub-genera, of which we want the intervening links to enable us to form an accurate notion of the genus to which they belong. It has the following characters :—Body with a subcoriaceous test, affixed by the summit to a very short pedicle, which is in the same line with the two orifices. The branchial orifice quadrifid and lateral, the anal irregular and terminal; both being so little prominent as not to alter the form of the body. Branchial pouch membranaceous, indistinctly reticulated, and divided into longitudinal folds. The tentacula of the branchial orifice composite. Intestinal canal lateral. Stomach very large, extending almost the whole length of the body. Ovaries two, composed of globular ova disposed in free racemes on each side of the body, with the branchial pouch and stomach between them. (W. S. M'Leay.)

C. Griffithsii has the envelope semipellucid, yellowish. Mantle very thin, and provided near the branchial and anal orifices with a reticulation of circular muscles nearly at right angles to each other. Tentacula about 10 or 12, compressed and laminated like those of the genus *Boltenia*. Branchial pouch having its net-work exceedingly lax, meshes irregular and indistinct, but apparently simple, the nervures being nearly of the same size. The longitudinal folds of the branchiæ, or rather (owing to the singular position of them in this genus) their transverse folds, about 14 or 15 in number. Length of the body, half an inch. (W. S. M'Leay.) Locality, Winter Island.



Cystingia Griffithsii.

1, natural size, seen on the right side; 2, magnified, seen on the left side *a*, anal orifice; *b*, branchial orifice; *s*, grains of sand externally encrusting the thick end of the pedicle.

Mr. M'Leay, who has named the species after William Nelson Griffiths, Esq., who found only one specimen during the third voyage under Captain (now Sir Edward) Parry, gives the following details of its organisation :—

"The body of this animal, so different in many respects from all other *Tethyæ*, is pyriform, and attached to a pedicle so short as scarcely to curve down farther than the branchial orifice. This pedicle is rather conical at its base, sub-cylindrical, and apparently very weak at its extremity. From this apparent weakness and imperfect formation of the pedicle, in conjunction with the circumstance of one side of the conical part in the only specimen that I have seen being incrusted with sand, I suspect that the animal can scarcely be said to be suspended by its pedicle, but rather reposes on the conical part of it; by which means the folds of the branchial pouch will take a vertical and the stomach a horizontal position, and thus be more in correspondence with the ordinary position of the stomach in the simple *Ascidiæ*, which is very rarely descending. The envelope of *C. Griffithsii* is exceedingly smooth, and so pellucid as to appear almost gelatinous. The original colour I cannot ascertain; but if it be the same as that of the specimen in spirits, it is cinereous, rather yellowish. The external orifices have scabrous veins, are very minute, and scarcely at all prominent. The branchial orifice is quadrifid, and placed exactly half-way down the side. The anal orifice is on the same line with it and the pedicle, but is placed opposite to this last, so as to be terminal, having its external surface apparently without rays; in both respects being totally different from the anal orifice of *Boltenia*."

Respiratory System.—"The entrance of the branchial cavity is provided with a circular range of 10 or 12 unequal tentacula, which are composite or divided into laciniæ at the extremity, which laciniæ are again so minutely divided as to be almost plumate. The branchial pouch has about fourteen folds, and its net-work is very indistinct and lax, the transverse nervures being perhaps the most visible, particularly towards the branchial orifice. The folds of the branchiæ are most easily seen on the inside of the branchial pouch."

Circulating System.—"The heart is situated horizontally between the lower part of the tunic and the stomach. It is large, ovoidal, and appears to be composed of several lobes, and is indeed of a structure different from that of such *Ascididæ* as are known.

"The dorsal sulcus is remarkably distinct, and proceeds from the immediate vicinity of the heart, or rather along the back of it to that of the branchial orifice. It may be seen through the external envelope of the body when this is viewed on the left side, and forms an arch inclosing a lesser and more pointed arch, which last appears to be nothing else than one of the folds of the branchial pouch. At the point where this last arch touches the dorsal sulcus there is in our specimen an orifice opening internally, and apparently communicating by a tube with a beautifully diaphanous longitudinal pouch, which contains nothing but two blackish nodules, one of which is longer than the other." The imperfection of the only specimen which M'Leay had for examination prevented him from accurately ascertaining the nature and use of this part of the organisation, which, he says, appears to have nothing similar to it in any of the other *Tunicata* hitherto observed.

Digestive System.—"The pharynx is situated rather higher than the branchial orifice; and the œsophagus, which is about half the length of the stomach, after descending to the highest part of the branchial vein, descends, and gives rise to a simple but enormous stomach, with very slight transverse striæ, and having a longitudinal division, marked somewhat deeply, and which runs almost the whole length of the body in a line between the base of the pedicle and the anal orifice. The intestine is exceedingly short, and apparently descending in a line with the stomach; the rectum is cylindrical, and anus simple. Such at least is the description of the digestive apparatus of this animal, if we give the name of pharynx to that end of the intestinal canal which opens into the branchial cavity, and the name of anus to that end of it which is free; and there is no doubt that such a description makes it an animal totally different from *Boltenia*, and in fact from all other species of *Tethyæ*, not only with respect to the singular form of the intestinal canal, but inasmuch as the branchial vein is thus placed, in relation to the pharynx, directly opposite to its position in all other animals of this group. I therefore am induced in some measure to suppose that there is a monstrous formation in the intestinal canal of the only specimen which I have had the means of examining; a supposition which must of course for the present throw doubt on any generic character which might be drawn from the above description of the intestinal canal. If indeed we could imagine that were it not for some monstrosity of structure, the intestinal canal would communicate with the branchial cavity by that end which, from its being free, I have been obliged to consider the anus, then the whole of the internal organs of nutrition would have a situation analogous to that of those of *Boltenia*. For instance, there would then be a short œsophagus opening near the anal orifice of the envelope, an ascending stomach, a long curved intestine, and descending rectum, while the branchial vein and heart would take their usual situation in respect to the pharynx and stomach. We know moreover, from those memoirs of Savigny, to which I have in the course of this paper had occasion to refer, that the digestive organs of the *Tunicata* are subject to analogous derangements, of which he has figured two remarkable examples in *Cynthia Momus* and *Phallusia Turcica*. It appears indeed to be a consequence of the low rank of these animals in the scale of being, and of their simple organisation, that the organs apparently most essential to their existence may undergo the greatest inversions without affecting their life; for the monstrous *Cynthia Momus* described by Savigny, as well as the *Cystingia* now under consideration, had its ovaries full of eggs."

Mr. Griffiths's specimen was taken in Fox's Channel, and two other specimens were obtained by the expedition under Captain Sir John Ross, near Felix Harbour; but as these were abandoned with the rest of the collection, it is probable, as Captain James Ross observes, that the individual from which Mr. M'Leay's description and drawings were taken is the only specimen ever brought to England.

CYSTIPHY'LLUM, a genus of *Madrephylliœa*, proposed by Lonsdale, to include species which have a vesicular internal structure, instead of clearly defined horizontal diaphragms and vertical lamellæ. It occurs in the Palæozoic Strata of Shropshire, Devon, and the Eifel.

CYSTO'PTERIS, a genus of Ferns belonging to the tribe *Aspidieæ*. It has the indusium attached by its broad hooded base under the sori, with a lengthened fringed free extremity, at first covering the thecæ.

C. fragilis, Brittle Fern, has bipinnate fronds; the pinnæ ovate-lanceolate; the pinnules ovate or ovate-lanceolate, toothed or pinnatifid. This is a remarkably variable species of fern. Three forms or varieties may be distinguished—*C. f. dentata*, with obtuse ovate pinnules, pointless, bluntly toothed or rarely pinnatifid, not decurrent; *C. f. angustata*, with pinnules linear, lanceolate, deeply and acutely pinnatifid or slightly toothed at the margin; the ultimate subdivisions oblong or linear, not dilated, rounded or ovate, sometimes notched at the end. The other form has the pinnules ovate, acute, pinnatifid, cut, and serrated, slightly decurrent. These plants are common in Great Britain, and found on rocks and walls, especially in limestone districts. They are of a diminutive size, and of a remarkably brittle nature, from which circumstance they have obtained their common name.

(Babington, *Manual of British Botany*; Newman, *History of British Ferns*.)

CYTACIS. [ACALEPHÆ.]

CYTHERÆA. [VENERIDÆ.]

CYTHERE, a genus of Entomostracous *Crustacea*, belonging to the legion *Lophyropoda*, the order *Ostracoda*, and the family *Cytheridæ*. The species are found very commonly in Great Britain. [BRANCHIOPODA.] Mr. Rupert Jones, in his 'Monograph of the Entomostraca of the Cretaceous Formation of England,' describes five fossil species belonging to this genus. [ENTOMOSTRACA.] The same author describes ten species of this genus as fossil in the Permian Rocks of England.

Cythereis is a genus separated from the group of species known as *Cythere*, by Mr. R. Jones. It has the following characters:—The animal is unknown. Carapace-valves or shell of an almost regular oblong shape, the dorsal and ventral margins lying nearly parallel to each other. Surface of a very irregular appearance, being wrinkled, ridged, and beset with tubercles, and crenulated or strongly toothed on the margins.

Dr. Baird has described three recent species, whilst nine fossil forms have been described by Mr. Jones from the Chalk.

Bairdia is a group of species formerly referred to *Cythere*, and separated by M'Coy. The valves externally are convex and smooth, sometimes finely pitted or spined, never ribbed or granulated; the hinge is simple.

This genus has no recent species. Six species have been found in the Chalk.

Cytherella, a genus separated by Jones from *Cythere*. It embraces species of *Cytherina* of other authors. The carapace-valves are oblong, and vary in the convexity and smoothness of the surface; the right valve is larger than the left, and its contact margin thicker than that of the opposite valve. Six fossil species have been described from the Chalk.

(Rupert Jones, *Monograph of the Entomostraca of the Cretaceous Formations of England*; W. King, *A Monograph of the Permian Fossils of England*, both published by the Palæontographical Society; Baird, *Natural History of the British Entomostraca*—Ray Society.)

CYTHEREIS. [CYTHERE.]

CYTHERELLA. [CYTHERE.]

CYTINA'CEÆ, *Cistus-Rapes*, a small natural order of Rhizanths, the type of which is *Cytinus Hypocistis*, a parasite found growing on the roots of certain kinds of *Cistus* in the south of France. Its stems are a few inches high, thick, succulent, reddish or yellowish, and covered by straight fleshy imbricated scales which are only abortive leaves. The flowers are nearly sessile, erect, arranged at the summit of the stem, yellowish and velvety on the outside. The relations of this order amongst the Rhizanths are evidently with *Rafflesiaceæ* and *Balanophoraceæ*. Like the Rhizanths generally they are also allied to *Fungi*, whilst their resemblance to certain Endogenous orders, as *Bromeliaceæ*, is evident. Griffiths regards the Rhizanths as reduced or degraded forms of Phænogamous Plants. The fruit is baccate, inferior, leathery, divisible into eight polyspermous lobes. The inspissated juice is used in French pharmacy as a styptic, but it is not admitted with us. Along with this genus are associated the curious genus *Hydnora*, Cape of Good Hope, which looks like a great star of the *Lycoperdon Apodenthus*, a minute parasite upon the branches of trees, and two other less known genera.

Cytinus Hypocistis.

1, a male flower; 2, a section of the same, very much magnified; 3, a female flower; 4, a section of the last.

CYTISUS, a genus of Plants belonging to the natural order *Leguminosæ*. It has a bilabiate calyx, the upper lip generally entire, the lower somewhat 3-toothed. The vexillum ovate and broad; the carina very obtuse, including the stamens, which are monadelphous. The legume is plano-compressed, many-seeded, not glandular. The species are small trees or shrubs, with ternate leaves and yellow-purple white flowers.

C. Laburnum, Common Laburnum, is a native of the mountains of Savoy and Switzerland. It is a small green branched tree. The young shoots are downy; the leaves on long stalks, leaflets rather glaucous, ternate, nearly sessile, oval, mucronulate, a little downy on the under side, the terminal one larger than the others; the petioles and subulate stipules downy. The racemes are pendulous, about 6 inches long, terminal, many flowered, frequent, and downy. The calyx campanulate, oblique, pushed inwards at the base, downy. The corolla large, and of a bright yellow colour. The legumes are downy, lineal, flat, thickened at each suture, rather contracted between the seeds. The seeds are oblong, compressed, shining, smooth, and of a deep greenish-black. They are highly poisonous, possessing narcotic acrid properties. The seeds of this plant are frequently sown in plantations infested with hares and rabbits, who will touch no other tree as long as a twig of Laburnum remains. Though eaten to the ground every season it rises again in the spring, thus affording a constant supply to these animals, so as to save other trees from their attacks.

C. Alpinus, Alpine Laburnum, has terete branches, petiolate leaves, ovate lanceolate leaflets, rounded at the base; pendulous recemes; pulverulous pedicels and calyces; glabrous few-seeded marginate legumes. It is a native of Carinthia, in groves. It is nearly allied to the *Laburnum*, but is distinct. The wood of both species is used by cabinet-makers on account of its hardness, durability, and beauty.

C. scoparius, Common Broom, is a large bushy shrub, with copious long, straight, angular, dark-green, smooth, tough branches. The leaves are deciduous, scattered, stalked, ternate, the upper ones generally simple, the leaflets uniform, obovate, obtuse, and entire; silky when young. The flowers are axillary, solitary or in pairs, on simple stalks, longer than the leaves, large and handsome, of a deep golden yellow, sometimes tinged with orange. The swelling ovary soon splits the tube of the filaments. The legume is brown, flat, above an inch long, nearly smooth at the sides, but fringed with harsh hairs at each margin. The *Cytisus* of Virgil was the *Medicago arborea* of botanists. For the medical properties of this plant see SCOPARIUS, in ARTS AND SC. DIV.

CYTOBLAST. In the development of the tissues of plants from the blastema, or cyto-blastema, which is a fluid consisting of water holding in solution sugar, gum, dextrine, &c., some of the granules assume a definite form, and become darker than the surrounding granules. These dark spots may be seen in the fluids of the growing parts of all plants. They are composed of some form of protein, and it is to these that Schleiden has given the name of Cytoblasts. The Cytoblast produces from its surface a cell: when the cell has become fully grown other Cytoblasts are produced in its interior, which, by producing other cells, burst the parent cell and increase the substance of the part in which they are found. A growing point of the same nature has been observed in the tissues of the animal kingdom, and it has been thus demonstrated that in the original growth of their tissues there is an identity between the animal and vegetable kingdoms. Although, when first made known by Schleiden, the Cytoblast was supposed necessary to the formation of every cell (and this led to the observation by Schwann of its extensive presence in the animal kingdom), it has since been pointed out by Mohl and others that the great mass of cells originates in the division of a protoplastic matter, which is not found in the form of a nucleus, but of a vesicle lining the interior of the cell. This substance has been called by Mohl the 'primordial utricle.' It is composed of the same material, and performs the same functions, as those attributed by Schleiden to the Cytoblast. Mr. Huxley proposes to call the proteinaceous formative matter originating each cell, under whatever form it occurs, the Endoplast. Thus the terms nucleus, protoplasm, primordial utricle, and endoplast may be regarded as synonyms of Cytoblast. [CELLS; TISSUES, VEGETABLE; TISSUES, ANIMAL; HISTOLOGY.]

CYTTARIA, a genus of Plants belonging to the natural order *Fungi*. One of the species, *C. Darwinii*, grows on the living branches of the South American beeches, and is described by Mr. Berkeley in the 'Transactions of the Linnæan Society.' It forms a principal part of the food of the natives of Tierra del Fuego during many months of the year.

D

DAB. [PLEURONECTIDÆ.]

DABCHICK. [COLYMBIDÆ.]

DABŒCIA (from St. Dabeoc), a genus of Plants belonging to the natural order *Ericaceæ*. It has a 4-parted calyx; the corolla oval, ventricose, the limb 4-toothed; 8 stamens inclosed, the filaments dilated, glabrous; the anther linear, sagittate at the base, the cells of the anthers parallel, loosened at the apex, dehiscing lengthwise; the stigma simple, truncate; the capsule 4-celled with a septicidal dehiscence. There is but one species, the *D. polyfolia*, which is a dwarf bushy evergreen shrub, a native of Ireland and the Pyrenees. This plant is the *Andromeda Dabœcia* of Linnæus, the *Erica Dabœcia* of Smith, the *Menziesia Dabœcia* of De Condolle, and the *Menziesia polyfolia* of Jussieu. In Ireland, which is its only locality in the British Islands, it is called Irish Whorts, Cantabrian Heath, and St. Dabeoc's Heath. It is a pretty shrub, and well fitted for decorating the fronts of shrubberies, or for rockwork. It may be propagated by dividing the whole plant, or by cuttings, or by layers. (Don, *Edinburgh Philosophical Journal*, vol. xvii.)

DACE. [LEUCISCUS.]

DACELO. [KINGFISHERS.]

DACNIS, Cuvier's name for a genus of Birds (the Pit-Pits of Buffon) which, he observes, represent the Carouges (*Xanthornus*) in miniature by their conical and sharp bill. *D. Cayana* is of a cerulean blue; forehead, shoulders, wings, and tail, black. It is a native of Mexico.

This pretty little bird is the Elotototl of the Mexicans. Hernandez says that it lives about the trees of the Tetzcocan Mountains; that it is eatable; that it does not sing, and that therefore it is not kept in the houses of the inhabitants.

Pit-Pit (*Dacnis Cayana*).

DACRYDIUM, a genus of Gymnogenous Plants belonging to the natural order *Taxaceæ*. One of the species, *D. taxifolium*, the Kakaterra-Tree of New Zealand, acquires a height of 200 feet. From its branches may be manufactured a beverage resembling in antiscorbutic qualities the well-known spruce-beer. (Lindley, *Vegetable Kingdom.*)

DACTYLIPORA. [POLYPIARIA.]

DACTYLIS, a genus of Plants belonging to the natural order of Grasses. *D. glomerata*, Cocksfoot-Grass, is an extremely common plant in fields and waste places, growing and flowering during a great part of the summer. It has in its wild state a coarse bluish rough herbage, and a flower-stem about three feet high, divided at the point into a loose panicle, each of whose divisions bears a cluster of flowers at its end. The glumes are 2, sharp-pointed, keeled, and rather unequal; they inclose from 3 to 6 florets, each of which consists of 2 rough-ribbed paleæ, the lower and outer of which is the broader, and tipped with a short bristle. In its uncultivated state this is a coarse hard grass; nevertheless it is readily eaten by cattle, horses, and sheep. It strikes its roots to a considerable depth in the soil, and on this account is capable of enduring the drought of dry sandy exposed land. Hence in such situations, where scarcely any other pasture can be procured, as in the naked brecks (or undulating downs) of Norfolk, it is of great value.

Mr. Sinclair assures us that Cocksfoot forms a part of the herbage of pastures most celebrated for fattening and keeping the largest quantity of stock in Devonshire, Lincolnshire, and the vale of Aylesbury; and he states that in the most skilfully managed of these pastures the foliage of the Cocksfoot was only to be distinguished by an experienced eye from the various species of fine pasture grasses with which it is combined. We would not however recommend any one laying down artificial grass to employ Cocksfoot where other grasses can be made to succeed, for we have invariably found it overgrowing the sorts with which it was mixed, and forming coarse tufts which neither feeding nor mowing has been able to keep down.

Cocksfoot Grass (*Dactylis glomerata*).
1, a spikelet much magnified; *a*, *a*, the glumes; 2, a floret with the paleæ.

DACTYLOPTERUS (Lacépède), a genus of Fishes belonging to the order *Acanthopterygii* and family *Loricati*. It has the following characters:—Head flattened, large, and long, and rising suddenly from the muzzle, which is very short; inferior angle of the pre-operculum furnished with an elongated strong spine; operculum without spines; mouth small; jaws furnished with masses of minute conical teeth; branchiostegous rays six in number; some of the anterior rays of the dorsal fin free; subpectoral rays numerous, very long, and connected by a membrane; ventral fins with four rays; body covered with hard carinated scales.

The fishes of this genus are classed with the gurnards; they may however be readily distinguished from the typical or true gurnards by the immense size of the pectoral fins.

In the true gurnards we observe three detached rays situated under the pectoral fins, but springing from the same base: in our present genus these rays are very numerous, immensely long, and connected by a membrane. By means of these large fins, the length of which is almost equal to that of the body of the animal, these fishes are enabled to sustain themselves in the air for several seconds, which they often do to escape from their enemies when pursued; but in quitting the waters to avoid their pursuers in that element, they not unfrequently fall a prey to the frigate-birds and albatrosses.

This genus contains but two species, one of which has been long known: it inhabits the Mediterranean, and is the *Trigla volitans* of Linnæus. It is commonly called the Flying-Gurnard and Flying-Fish; but there are other species of fish which have obtained this name, on account of their power of sustaining themselves for a few seconds out of the water. The other species inhabits the Indian Seas, and is the *Dactylopterus orientalis* of Cuvier.

Dactylopterus orientalis.

Dactylopterus volitans, the Flying-Gurnard, varies from 1 foot to 15 inches in length, and is of a brown colour above, with spots of a deeper tint: the sides of the body are red, and the under parts are of a pale rose-colour. The large pectoral fins are of a blackish tint, mottled and spotted with blue; the ventral and anal fins are of a rose-colour; the anterior dorsal is gray, with clouded markings of a deeper hue; the posterior dorsal is transparent, and its rays are of a pale colour, spotted with brown.

DADDY-LONG-LEGS. [TIPULA.]

DÆDALION. [FALCONIDÆ.]

DAFFODIL, the English name of *Narcissus Pseudo-Narcissus* and its allies, to which some recent botanists have given the generic name of *Ajax*. [NARCISSUS.]

DAGYSA. [SALPACEA.]

DA'HLIA, a genus of Plants belonging to the natural order *Compositæ*. Three species only are known, all natives of Mexico. Of these, two, *D. coccinea* and *D. Cervantesii*, were formerly cultivated in this country, but not sporting into varieties, and being much less beautiful than *D. variabilis*, they are not now seen in gardens. *D. variabilis* itself is, in its wild state, a bushy herbaceous plant, 7 or 8 feet high, with single purple or lilac flowers, and is by no means remarkable for its beauty. In cultivation however it is so readily improved in size and form, and sports into such endless varieties in stature, leaves, and flowers, that it has become the most extensively cultivated florist's plant of the present day. Its innumerable sorts are the glory of our gardens in the autumn, and are quite unrivalled at that season of the year: they are however destroyed by the earliest frosts. [DAHLIA, in ARTS AND SC. DIV.]

DAISY, or DAY'S EYE, the little perennial plant called *Bellis perennis* by botanists. Like most composite flowers, it has proved productive of varieties when domesticated; but they have almost disappeared, except from old-fashioned or cottage gardens. [BELLIS.]

DALBERGIA, a genus of Plants belonging to the natural order *Fabaceæ*, named in honour of Nicholas Dalberg, a Swedish botanist. It has a campanulate calyx, 5-toothed; a papilionaceous corolla, the petals of the keel connected to the apex; 8-10 stamens, sometimes all monadelphous, with the tube or sheath cleft in front, sometimes divided into two equal opposite bundles. It has a stipitate membranous compressed legume, which is flat, oblong, and tapers to both ends. The seeds, which vary from 1 to 3, are compressed and remote. The species are sometimes trees, but usually climbing shrubs, with impari-pinnate leaves.

D. Sissoo, has five alternate leaflets, glabrous above, pubescent beneath. It is a native of Bengal, where the timber is much prized, and is known by the name of Sissoo.

D. monetaria, another of the species, yields a resin very similar to Dragon's Blood.

There are about 22 species of this genus, none of which are of any known use except those mentioned.

DAMA. [CERVIDÆ.]

DAMALIS. [ANTILOPEÆ.]

DAMASK-ROSE. [ROSA.]

DAME'S VIOLET. [HESPERIS.]

DAMMARA, Dammer-Pine. [AGATHIS.]

DAMOMITE, a Mineral found in the United States. It is a hydrous silicate of alumina. [PREHNITE.]

DAMSON, or DAMASCENE (from Damascus), a race of plums cultivated in this country for the sake of their hardiness and prolific habits. They are a mere form of the domestic plum, from which there are no certain characters to distinguish them, except the abundance of their late oval fruit, and the property they possess of propagating by suckers. All the varieties are used for kitchen purposes principally, and are generally confined to the gardens of cottages or farm-houses, where the quantity of produce is more valued than its quality. Much the finest variety of this sort of plum is that called the Shropshire Damson, which is extensively multiplied in the nurseries by grafting. [PLUM, in ARTS AND SC. DIV.]

DANÆACEÆ, *Danæworts*, a small natural order of Plants related to the Ferns. They have all the habit of Dorsiferous Ferns, but their spore-cases are ringless and combined in masses, splitting irregularly by a central cleft. The species are all tropical. It embraces the following genera :—*Kaulfussia, Angiopteris, Danæa, Eupodium, Marattia*, and about fifteen species. *Angiopteris evecta* is said to be employed in the Sandwich Islands to perfume cocoa-nut oil. The rhizome of a species of *Marattia* is eaten by the Sandwich Islanders.

DANBURITE, an American Mineral. It occurs crystallised. Its primary form is an oblique rhombic prism. The colour honey-yellow, becoming nearly white by decomposition; streak white. Hardness 7·5. Lustre vitreous; translucent, transparent. Specific gravity 2·83. It is found at Danbury, Connecticut. The following is the result of an analysis by Shepard :—

Silica	56·
Lime	28·33
Alumina	1·7
Yttria	·85
Potash, Soda, and loss	5·12
Water	8· —100

DANDELION, a corruption of the French name Dent de Lion, or Lion's Tooth, a common weed, with a tapering milky perennial root, resembling that of succory. It is the *Leontodon Taraxacum* of botanists. [LEONTODON.]

DANEWORT. [SAMBUCUS.]

DAPE'DIUM, changed by Agassiz to *Dapedius*, one of the first described British genera of Fossil Ganoid Fishes. To *D. politum* of De la Beche ('Geol. Trans.,' 2nd series, vol i. pl. vi.) six others are added by Agassiz, all from the Lias.

DAPHNE, a genus of Plants belonging to the natural order *Thymelaceæ*, containing many species, inhabiting the more temperate parts of Europe and Asia. Among them some are cultivated in gardens for their beauty or fragrance, others are of medicinal importance, and a few are employed in the manufacture of hemp and paper. We shall briefly notice the more remarkable of these.

The genus *Daphne* is distinguished in its natural order by having 8 or 10 stamens inclosed within the calyx, a simple stigma, a succulent fruit, and a calyx, the orifice of whose tube is destitute of appendages.

D. Mezereum, the Mezereon of the gardens, is a deciduous plant, with white or purple fragrant flowers, sitting close to the stem, and appearing on the naked branches before the leaves are unfolded. It is a favourite in gardens, and succeeds in almost any well-drained light soil where the air is not poisoned by the smoke of coal-fires. It is found wild in the mountainous woods of many parts of the middle and south of Europe. It is met with in woods in various counties of England. The berries are smooth, shining, and bright red.

All the parts of this and indeed of the other species, as far as they have been examined, are extremely acrid and poisonous. If the bark is bruised and applied to the skin, it produces severe blisters, and is sometimes substituted for cantharides when that drug cannot be employed with safety. Taken internally, the bark, leaves, and fruit, act as cathartics, but require to be administed with extreme caution; for they are apt to produce dangerous and even fatal consequences. Linnæus speaks of a person having been killed by a dozen Mezereon berries; and they are employed in Sweden to poison wild animals. According to Fée, the very odour of *Daphne*, agreeable as it is, is attended with danger; he says that if kept in sitting-rooms they will bring on headache and fainting. It is moreover asserted that Russian and Tartarian women sometimes rub the berries of the Mezereon on their cheeks to produce a slight irritation, which of course gives the effect of rouge, only in a more permanent degree. (MEZEREON, in ARTS AND SC. DIV.)

D. Laureola, the Spurge Laurel, is another British species, found wild commonly in woods and hedges. It is a handsome evergreen bush, with the aspect of a laurel. The leaves are placed very close together; they are of a leathery consistence, deep green, lanceolate, acute, and narrowed to the base. The flowers are green, and grow in little short clusters, which are nearly concealed by the leaves. The berries are, when ripe, a deep purple black. We have no species that grows more readily beneath the shade of trees; and as its appearance is highly ornamental, it would be a most useful garden plant, if it were not for the dangerous berries, which children are apt to eat. An ointment for keeping open blisters is prepared from this plant.

D. pontica. One of the plants which is reputed to have contributed to the poisonous quality of the honey that was eaten by Xenophon's soldiers, is very like this species, and is often cultivated as a hardy evergreen.

D. Gnidium, the Garou-Bush, an evergreen with narrow sharp-pointed erect light-green leaves, and branching clusters of white fragrant flowers, is a common plant in dry waste places in the south of Europe. It will not live in the open air in England, except in the warmest counties. Both the berries and leaves are employed by the French as purgatives. The plant also affords a good yellow dye.

D. Cneorum, a native of grassy places in the Alps of Switzerland and the rest of Central Europe, with its trailing stems, numerous small narrow blunt deep-green leaves, and clusters of rich purple fragrant flowers, is one of the most beautiful of all plants, when it finds a soil and climate that suit it. At Bagshot, for instance, and in similar situations, it is under good management quite unrivalled by the other hardy shrubs among which it grows. It will not succeed where the soil is otherwise than sandy and peaty, nor can it bear the impure atmosphere of large towns.

D. collina, D. alpina, D. Neapolitana, and *D. Tarton-raira* are other species cultivated in gardens. The first has dull purple sweet-scented flowers, and is sufficiently common in collections; the others are rarer. All are impatient of wet in winter; but if at that season kept tolerably dry will bear considerable frost, and are desirable garden plants in the milder parts of England.

In addition to the acrid and dangerous properties which appear to be common to them all, some species are remarkable for the toughness of their fibre, and for the economical purposes to which they are applied. From *D. Cannabina* is prepared the best kind of writing-paper in China, according to Loureiro; but it must be observed that this statement, if true, is at variance with what is observed in Nepaul, where the daphne-paper is very brittle and bad.

D. Lagetta, the Lace-Bark-Tree of Jamaica, is most remarkable for the tenacity of the fibre of which its bark consists, and for the facility with which it may first be separated into thin layers and then into distinct meshes. If the inner bark of this plant be macerated in water it may be readily separated into layers no thicker than the finest lace, and which after having been pulled a little sideways resembles in some measure that fabric. King Charles II. is said to have had a cravat, frill, and ruffles of Lace-Bark presented to him by his governor of Jamaica.

DAPHNIA, a genus of Entomostracous *Crustacea*, belonging to the division *Branchiopoda*, the order *Cladocera*, and is the type of the family *Daphniadæ*. This genus is characterised by Baird as follows: Head produced downwards into a more or less prominent beak. Superior antennæ exceedingly small, 1-jointed, and situated under the beak; inferior antennæ large and powerful.

Several other genera have been formed out of the species that were formerly referred to the genus *Daphnia*. [BRANCHIOPODA.]

D. Pulex (Latreille), the Water-Flea, is the best known species of this genus. It is known by a multitude of names, the most common of which is the Water-Flea. The whole of the species however have this designation. The following are some of the synonyms :—

Monoculus Pulex, Linnæus.	*Daphne Pulex*, Müller.
Daphne pennata, Müller.	*Pulex arborescens*, Swammerdam.
Daphnia ramosa, Koch.	Puceron Branchu, Trembley.
Pou Aquatique, Joblot.	Le Perroquet d'Eau, Geoffroy.
Vermes minimi rubri, Bennett.	Animaletti Aquatici, Redi.

This little creature forms a beautiful object for the microscope. Its shell or carapace is transparent, and through it can be seen the whole of its interior organisation. The lower extremity of the valves terminates in a sharp spine, which is serrated at the edges. The head is large; the superior antennæ are very small, whilst the inferior antennæ are very large. The male is much smaller than the female, and is comparatively rarely met with. It is found commonly in ponds and ditches round London at all seasons of the year. It is frequent in the cisterns which supply the houses of London with water.

D. psittacea, Baird. It closely resembles the last species, but Dr. Baird says, upon close examination, "The form of the head and the serrated dorsal margin distinguish it very readily."

D. Schæfferi, is a larger species than *D. Pulex*. It is about the fifth of an inch in length and two lines broad. Their motion through the water is peculiar, being a tumbling wavy sort of movement. They remain at the bottom of the water. They are very much infested with species of *Vorticella*.

D. vetula is common round London, and has a smaller head than *D. Pulex*. It is the *D. sima* of Müller and *Monoculus simus* of Gmelin.

There are three other species noticed by Dr. Baird in his 'British Entomostraca.' *D. reticulata, D. rotunda*, and *D. mucronata*. The last is a rare species.

(Baird, *Natural History of British Entomostraca*.)

DAPILA. [DUCKS.]

DAPSUS, a genus of Coleopterous Insects. [EUMORPHUS.]

DAPTRIUS. [FALCONIDÆ.]

DAPTUS (Fischer), a genus of Coleopterous Insects belonging to the family *Harpalidæ*. It has the following characters :—Mentum deeply emarginated and without any tooth-like process in the middle; antennæ rather short, and moniliform; second joint of the labial palpi somewhat oval; four basal joints of the four anterior tarsi slightly dilated, short, and triangular; body more or less elongated, the elytra with their outer margins almost parallel.

D. vittatus is of a pale yellowish colour, with an oblong black spot on each elytron; the head and thorax are more or less clouded with brown or black in some specimens.

This species is about a quarter of an inch in length, and inhabits sandy districts in the vicinity of water in the southern parts of Russia and France.

D. incrassetus (Dejean) has the same colouring as the last, but it is of a larger size, being upwards of half an inch in length. It inhabits North America.

DARNEL. [LOLIUM.]

DA'RNIS (Fabricius), a genus of Insects belonging to the order *Hemiptera* and family *Cercopidæ*. The species of this genus have the posterior part of the pro-thorax prolonged so as totally to cover the upper part of the abdomen and wings, or nearly so: this portion of the pro-thorax is of the form of an elongated and arched triangle. [CICADELLA.]

DAROO-TREE is the *Ficus Sycamorus*, the Egyptian Sycamore. [FICUS.]

DART. [LEUCISCUS.]

DASYORNIS. [MERULIDÆ.]

DASYPROCTA. [AGOUTI.]

DASYPUS. [ARMADILLO.]

DASYURUS. [MARSUPIATA.]

DATE-PALM. [PHŒNIX.]

DATHOLITE, a Mineral which contains Boracic Acid, Silica, and Lime. It has been found at Arendahl in Norway, and a few other places. It occurs both massive and crystallised in rhombic prisms, the lateral edges and the solid angles of which are usually replaced by planes. The colour of *Datholite* is grayish or greenish white, and it is translucent. Its specific gravity is about 3. It yields to the knife. The fracture is imperfect conchoidal. The lustre is somewhat vitreous. According to the analysis of Vauquelin, it consists of

Boracic Acid	21·67
Silica	37·66
Lime	34·
Water	5·5
	98·83

DATISCA'CEÆ, *Datiscads*, a small natural order of Plants allied to *Begoniaceæ* and *Cucurbitaceæ*, and the other apetalous orders in their vicinity, but distinguished by its inferior ovary with parietal placentæ. It has unisexual flowers; the males have a calyx of several pieces, and from 8 to 15 stamens; the females have an obsolete superior calyx, and three little recurved stigmas at the apex of an oblong 1-celled ovary, with 3 many-seeded parietal placentæ. The seed-vessel opens at the end like that of *Reseda;* the seeds are

A male plant of *Datisca Cannabina*; A, a cluster of ripe fruit from a female plant.

inclosed in a finely netted bag, and contain a straight embryo without albumen. The order has 3 genera and 4 species. *Datisca Cannabina*, the commonest plant of the order, is an herbaceous diœcious perennial, with stems about 3 feet high, pinnated leaves with from 5 to 9 ovate-acuminate coarsely-serrated leaflets, and long racemes of flowers collected in clusters in the axils of long linear bracts. It is a native of the southern parts of Europe, where, especially in Candia, it is used on account of its bitter tonic properties as a substitute for Peruvian bark; it also affords a yellow dye.

DATU'RA, a genus of Solanaceous Plants, with a funnel-shaped angular 5-lobed calyx, a corolla of a similar form, but much larger, and a 4-celled capsule, which is either smooth or muricated externally; the base of the calyx moreover adheres to the seed-vessel in the form of a circular disc.

Several species of this genus are known in cultivation, the very large size of their funnel-shaped flowers rendering them conspicuous objects; they have however a nauseous odour, and are only handsome when in flower, for which reason they are not general favourites. They are all exotics, with the exception of the following, in whose properties they coincide.

D. Stramonium, the Thorn-Apple, is by no means an uncommon annual upon dunghills, rubbish-heaps, and waste-places near houses. It grows about 3 feet high, with a light-green stiff stout stem, which is slightly downy near the upper end. The leaves are broad, oval, stalked, sharp-pointed, sinuous, and angular. The flowers are large, white, or occasionally dull light purple, and grow singly from the side of the stem opposite the origin of the leaves; they are erect, and placed upon a very short peduncle. Their calyx is tubular, elongated, a little swollen at the lower end, with five prominent ribs, ending in as many sharp-pointed lobes; after flowering, it all drops off, except the base, which surrounds the fruit in the form of a circular disc. The corolla is much larger than the calyx, of a similar form, but its lobes are more taper-pointed. There are five stamens, which are inclosed in the tube of the corolla. The ovary is covered with small sharp points, and contains four cells, in each of which is a considerable number of ovules. The style is cylindrical, smooth, and enlarged at the upper end. The fruit is a spiny oval capsule of four imperfect cells, which communicate with each other in pairs. The seeds are brown, kidney-shaped, with a scabrous surface.

This plant is well known, under the name of *Stramonium*, as a powerful and dangerous narcotic. Its leaves and seeds are the parts employed, and they are found to possess properties similar to those of henbane and belladonna. The leaves are occasionally smoked, especially by country people, as a remedy for asthma; the seeds are employed by thieves to drug the beverage of their victims. In small doses they produce symptoms of frenzy; in larger quantities stupor and death. The poisonous principle of this and other species is considered a peculiar vegetable alkali, and called Daturine. [STRAMONIUM, in ARTS AND SC. DIV.]

D. arborea and *D. bicolor*, beautiful arborescent South American plants, the former with long white flowers, and the latter with yellow or scarlet ones, are noble objects in the gardens of this country. They participate in the properties of the true Daturas, but they are not now considered to be genuine species, on account of their calyx slitting on one side, and remaining permanent around the base of the fruit. They are stationed in a genus called *Brugmansia*.

DAUCUS, a genus of Plants belonging to the natural order *Umbelliferæ*. It has hispid fruit, of a somewhat compressed ovate or oblong form, the primary ridges filiform and quite bristly, the secondary ridges prominent, winged, and divided at the edge into a number of fine teeth or hooks. De Candolle enumerates 38 species, chiefly biennials, but it is doubtful whether several of them are not mere varieties of each other.

D. Carota, the only one to which general interest attaches, is the Carrot. This plant, which grows wild all over Europe in chalky soil, is believed to be the origin of our garden carrot, but there is no record of its having first begun to change its hard wiry juiceless wild root for the nutritious succulent carrot of the gardens. De Candolle gives for the range of the wild plant the meadows and pastures of Europe, the Crimea, and Caucasus, whence it has been transported into China, Cochin China, America, and elsewhere. [CARROT, in ARTS AND SC. DIV.]

D. gummifer is known by having its radical leaves triangular. It is found on the sea-coast of the south of England, and is also called *D. maritimus*.

DAVILLA, a genus of Plants belonging to the natural order *Dilleniaceæ*. It has 5 very unequal sepals, which increase after flowering; from 1 to 6 petals, with linear filaments dilated upwards. The single carpel is testaceous, from 1 to 2-seeded, inclosed in the two inner concave valve-like sepals. The seeds are solitary, enveloped in an arillus, which is only open at the apex.

D. elliptica has a shrubby erect much-branched stem, with hairy branchlets. The leaves are elliptical, obtuse at each end, entire, between crustaceous and leathery, rough and hairless above, downy and netted beneath; the petiole villous on the under side. The racemes are hairy and bracteolate; the sepals silky. The petals from 1 to 6, somewhat obcordate. This plant is an astringent, and furnishes the vulnerary called Sambaibinha in Brazil.

D. rugosa is also a native of the forests of Brazil, and has a twining stem with hairy twigs. The leaves are oblong, remotely and obsoletely serrated, rough and hairless above, shaggy beneath on the principal veins. The petioles are very shaggy beneath. The peduncles and pedicels hairy. It has two or three petals. Like the former species it is an astringent, and is used in swellings of the legs and different parts of the body in South America.

DAVITE, a name given to a Sulphate of Alumina, found in a warm spring which contains sulphuric acid, near Bogota in Columbia. It occurs massive, is of a fine fibrous structure, a white colour, and silky lustre. It is very soluble, and has a very astringent taste.

DAVYNE, a Siliceous Mineral, found in cavities in some of the masses ejected from Vesuvius. The primary form is a rhomboid, but it occurs in regular hexagonal prisms, with the terminal edges truncated. Its fracture is conchoidal; cleavage parallel to the planes of the hexagonal prism. It is transparent, colour white or yellowish-brown. Streak white, lustre vitreous, pearly upon the cleavage planes. Hardness, 5·0 to 5·5. Specific gravity, 2·4.

DAY-LILY. [HEMEROCALLIS.]

DEAD-MAN'S FINGERS [ALCYONIDÆ.]

DEAD-MAN'S TOES. [ALCYONIDÆ.]

DEAD-NETTLE. [LAMIUM.]

DEADLY-NIGHTSHADE. [ATROPA.]

DEAL-FISH. [TRACHYPTERUS.]

DEATH-WATCH. Every one has heard of the Death-Watch, and knows of the superstitious notion of the vulgar, that in whatever house its drum is heard one of the family will die before the end of the year. These terrors in particular instances, when they lay hold of weak minds, especially of sick or hypochondriac persons, may cause the event that is supposed to be prognosticated. A small degree of entomological knowledge however would relieve them from their fears, and teach them that this heart-sickening tick is caused by a small beetle giving a call to its companion.

Authors were formerly not agreed concerning the insect from which this sound of terror proceeded, some attributing it to a kind of wood-louse and others to a spider. The earliest scientific account of it is probably that by Mr. Benjamin Allen, written in 1695, and published in the 'Philosophical Transactions,' vol. xx. p. 376, where the writer calls it *Scarabœus galeatus pulsator;* followed, vol. xxii. p. 832, by another account from the celebrated Dr. William Derham, dated Upminster, July 21, 1701. Swammerdam ('Bibl. Nat.' edit. Hill, i. 125), and Shaw ('Nat. Misc.' iii. 104), have also written upon this insect. It is a received opinion now, adopted upon satisfactory evidence, that the sound called the death-watch is produced by certain beetles belonging to the timber-boring genus *Anobium*. Latreille observed *Anobium striatum* to produce the sound in question; but the species whose proceedings have been most noticed by British observers is *Anobium tessellatum*. When spring is far advanced these insects commence their ticking, which, as already mentioned, is only a call to each other, to which, if no answer be returned, the animal repeats it in another place. It is thus produced: raising itself upon its hind legs, with the body somewhat inclined, it beats its head with great force and agility upon the plane of position; and its strokes are so powerful as to make a considerable impression if they fall upon any substance softer than wood. The general number of distinct strokes in succession is from seven to nine or eleven. They follow each other quickly, and are repeated at uncertain intervals. In old houses, where these insects abound, they may be heard in warm weather during the whole day. The noise exactly resembles that produced by tapping moderately with the nail upon the table; and when familiarised the insect will answer very readily the tap of the nail. (Brand's 'Popular Antiq.'; Kirby and Spence's 'Introd. to Entomology,' edit. 1828, i. 36; ii. 382; Wallis's 'Hist. Northumb.' i. 367.) The superstition that the clicking of this insect is a death-omen is mentioned by Baxter in his 'World of Spirits,' p. 203.

This is only one of many instances in which natural occurrences have been regarded with superstition and terror, and is a good illustration of the folly and danger of referring material phenomena to spiritual causes.

DEATH'S-HEAD MOTH. [SPHINGIDÆ.]

DECAPODA. [CRUSTACEA.]

DEER. [CERVIDÆ.]

DEER-LIKE ANTELOPES. [ANTILOPEÆ.]

DELPHINAPTERUS. [CETACEA.]

DELPHI'NIUM, a genus of Plants belonging to the natural order *Ranunculaceæ*. It consists of annual or perennial herbaceous plants, with irregular spurred flowers, the colours of which are often of the most vivid blue. They are very nearly allied to the Aconites, from which they differ merely in their upper sepal being lengthened at the base into a spur instead of at the back into a helmet, and in the petals having no spur at all, but being deformed stalked bodies altogether different in form, and often in colour, from the sepals.

The species abound in the temperate parts of the northern hemisphere, and are often cultivated in gardens under the name of Larkspurs.

D. consolida is a hardy annual, of which many varieties are known as Rocket Larkspurs. It is found wild in sandy and chalky fields in Great Britain.

D. Barlowii is a magnificent double-flowered perennial hybrid; and the Bee-Larkspurs, consisting of *D. grandiflorum*, *D. Sibiricum*, *D. Chinense*, *D. mesoleucum*, and many more, are amongst the most showy plants of our gardens. These latter derive their name from a striking resemblance on the part of the petals to the black body of an humble-bee covered with yellow hairs; the head and legs of the insect being supposed to be immersed in the cup of the flower.

The only species that has been applied to any useful purpose is Stavesacre (*D. Staphisagria*), an annual inhabiting the warmer countries of the south of Europe. It has an upright branched stem about two feet high covered all over with close velvety down, and generally of a greenish purple colour. Its lower leaves are round, on long stalks, heart-shaped at the base, and divided into 5, 7, or 9 deep lobes of an oval or lanceolate figure; they are sharp-pointed, and either undivided or cut into a few lateral incisions; on the upper side they are deep green and almost smooth; on the under they are paler and velvety. The flowers are a dull grayish green, arranged in a lax spike at the extremity of the ramifications of the stem; their stalk is short and velvety, and has three linear short bracts. The sepals are green and velvety externally, with a short spur curved downwards. The four petals are separate from each other and smooth; the two upper are oval and rather long; the two lower have short stalks and a rounded, irregular, toothletted limb. The fruit is composed of three woolly capsules filled with grayish irregularly-triangular compressed very acrid bitter seeds. [STAPHISAGRIA, in ARTS AND SC. DIV.]

DELPHINORHYNCHUS. [CETACEA.]

DELPHINUS. [CETACEA.]

DELTHY'RIS. Dalman proposed this generic name as a substitute for the *Spirifera* of Sowerby, but few writers on fossil *Brachiopoda* have adopted it.

DELUNDUNG. [PRIONODON.]

DEMOISELLE. [GRUIDÆ.]

DENDRO'BIUM, an extensive genus of East Indian Epiphytical Plants, found in the whole of the damp tropical parts of Asia, and a little beyond the tropics in Japan and Australia, but unknown in the rest of the world. Above a hundred species are enumerated by systematic writers: *D. Pierardi*, *D. cucullatum*, *D. chrysanthum*, *D. aureum*, *D. fimbriatum*, *D. moschatum*, *D. densiflorum*, *D. pulchellum*, *D. nobile*, and a few more, are known in the collections of this country.

DENDROCITTA. [CORVIDÆ.]

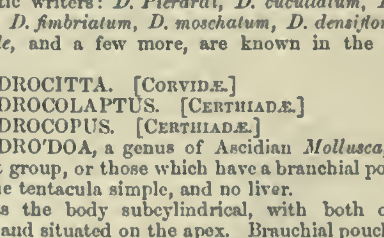
DENDROCOLAPTUS. [CERTHIADÆ.]

DENDROCOPUS. [CERTHIADÆ.]

DENDRO'DOA, a genus of Ascidian *Mollusca*, belonging to the aberrant group, or those which have a branchial pouch with only eight folds, the tentacula simple, and no liver.

It has the body subcylindrical, with both orifices exceedingly minute, and situated on the apex. Branchial pouch marked with only eight folds, and having the reticulation continuous. Orifices terminal. Tentacula simple. Liver none. Ovary unique, branched, situated beneath the mantle and the branchial pouch. (W. S. M'Leay.)

D. glandaria. Body subcylindrical, with a round summit. Envelope whitish, subpellucid, coriaceous, and smooth, having its base rough with agglutinated pebbles: internally it has a pearly lustre, and is thickest towards the base. Orifices so little prominent as to be scarcely perceptible without a lens; separate from each other, and opening with four indistinct rays. Mantle muscular, but of uniform substance. Tentacula about twenty-six, simple, subulate, alternately long and short. Anterior nervous tubercle with many spirals. Branchial cavity occupying the whole length of the animal. Pharynx situated at the bottom of the cavity of the body. Œsophagus descending, and turning short round near the cardia into a cylindrical horizontal stomach, which is striated internally, and occupies with the pylorus (which turns round and lies parallel to it) the whole of the bottom of the cavity. Intestine very long. Rectum ascending, almost vertical; terminated by an anus, margined.



Dendrodoa glandaria.

a, natural size, seen on the right side: the base encrusted with pebbles, has the appearance of the cup of an acorn; *b*, the same seen obliquely, so as to show the top, which is a little compressed, and exhibits four points: the two lowest and largest are false orifices; the two smallest (which are so small as to be almost invisible to the naked eye) are the real orifices, the highest being the anal, and the other the branchial orifice.

Ovary one, situated on the left side, between the branchial pouch and the tunic. It consists of a trifurcated cylindrical stem, having at the base on one side a forked branch, on the other a simple one, all of the same thickness. Mr. M'Leay remarks that the organs of digestion have great affinity in external structure and position to those of *Cynthia pantex* of Savigny, except that the stomach and intestine are horizontal, and the anus simply margined, and that, different as this species is in external appearance from all other *Ascidiæ*, internally it agrees with the *Pandeciæ* in almost every essential respect but the ovary. He observes that this singular animal completes the circle of the genus *Ascidia* in the most beautiful manner. It agrees with the first sub-genus, *Cynthia*, in the nature of its branchial reticulation and of its digestive apparatus; but *Cynthia* has two ovaries, the right one contained in the intestinal loop, and the left one coating the tunic. The first of these, or the right ovary, is the only one possessed by *Pandecia*, and the left is the only one possessed by *Dendrodoa*. Mr. M'Leay concludes by stating that the distinction between the aberrant groups of *Ascidia* depends thus upon the nature of their system of generation, as that which exists between the two normal groups depends on their system of respiration.

(*Anatomical Observations on the Natural Group of Tunicata*, &c., by W. S. M'Leay, ; *Linn. Trans.*, vol. xiv.)

DE'NDRODUS, a genus of Placoid Fishes, from the Old Red-Sandstone of Elgin, Moray, and Russia. Professor Owen has described five species, and Agassiz a sixth.

DE'NDROMUS, a genus of Animals belonging to the order *Rodentia*, established by Dr. A. Smith in his 'Contributions to the Natural History of South Africa,' with the following characters:—

$$\text{Incisors, } \frac{2}{2}; \text{ Molars, } \frac{3-3}{3-3} = 16.$$

The upper incisors with a longitudinal furrow on their anterior face; the lower long, slender, with the cutting edge cuneated.

The upper first molar with six tubercles in a double row, and two indistinct ones besides, of which one is at the anterior part of the crown of the tooth, the other near another tubercle of the internal series, behind the tarnsverse incisorial lamina; the second molar with two or three longitudinal incisorial laminæ by the external margin of the crown, in the middle of which lie three or four obtuse transverse tubercles disposed in a row; the third molar has two transverse incisorial laminæ with an interjacent furrow. Below, the first molar has six tubercles disposed in a double series; the second, four obtuse tubercles arranged in the same order; the third is very small, with some transverse laminæ and furrows intermingled. No canines. Rostrum acute. Lip slit. Ears oblong, rather naked, and internally, near the skull, with two transverse membranaceous valvules, of which the lower lies over the external auditory meatus. Tail elongated, annulated, with scattered hairs. Feet divided, ambulatory; the anterior with three toes, and a wart in lieu of hallux; the posterior five-toed: claws falcular.

D. Typus. Above, brown, passing to ferrugineous; beneath, reddish-white; whiskers long, partly black and partly white; upper lip white; ears without and within slightly covered with a fine short reddish-white fur; extremities the same; tail pointed, considerably longer than the body, and of a faint grayish-brown colour; along the centre of the back, particularly towards the tail, an indistinct black line. Length from point of nose to root of tail, 3½ inches: length of tail, 4½ inches.

It inhabits South Africa, where it is found upon the branches of trees, &c., in which situations it constructs its nest and brings forth its young. Dr. Smith observes that the position of this little animal among the family of mice is not well determined; but that perhaps its place is after the Mouse. ('Zool. Journ.,' vol iv. p. 438.)

DENDROMUS. [DUCKS.]

DENDRONESSA. [DUCKS.]

DE'NDROPHIS (Fitzinger), a genus of Serpents placed by Cuvier under the great genus *Coluber*, and stated by him to be the *Ahætulla* of Gray. The species of this genus have, like the *Dipsas* of Laurenti, a line of wider scales along the back, and narrower scales along the flanks, but their head is not larger than their body, which is very slender and elongated. Their muzzle is not elongated, and they are not venomous. They inhabit India and Africa.

DENDROPHYLLIA. [MADREPHYLLIÆA.]

DE'NDROPLEX, a genus of Birds established by Mr. Swainson, and placed by him in the family *Certhiadæ* (Creepers), and sub-family *Certhiana*, which have the tail graduated and rigid.

The bill is very straight. Wings moderate, rounded; third, fourth, and fifth quills longest.

Mr. Swainson observes that he knows not whether the type of this genus has been described, and states that the living bird has all the manner of a *Picus*. Except in its perfectly straight bill, he adds, it differs not from *Dendrocolaptes*. ('Zool. Journ.,' vol. iii. p. 354.)

DENTA'LIUM, a genus of Gasteropodous *Mollusca*, whose place in the animal series was first satisfactorily determined by M. Deshayes. Rondelet considered the *Dentalia* as marine shell-worms (vermisseaux de mer), though he noticed them as worthy of particular attention. Lister introduced them at the end of the Limpets (*Patellæ*). Lang followed in nearly the same steps, separating, after the *Patellæ*, a section wherein he arranged, together with the *Dentalia*, all the calcareous tubes of Annelides then known. Breyne placed his genus *Tubulus*, containing the *Dentalia*, &c., at the head of his Monothalamous Shells, the first of the two grand orders, the Monothalamous and the Polythalamous, into which he divided the Testaceans. In this position *Dentalium* was separated from the *Patellæ* by all the other univalve shells comprised in the *Cochlidia*, as well as by the Polythalamous series; in short, by the entire interval of the Univalve Testaceans; Breyne, as M. Deshayes observes, having probably considered the *Patellæ* as the passage from the univalves to the bivalves, for he places them immediately before the latter. Tournefort gave the *Patellæ* a position at the head of the univalve shells, and at the end, before the bivalves, he placed the *Dentalia*, *Entalia*, and the other marine testaceous tubes. D'Argenville, in his 'Zoomorphose,' appears to be the first who attempted to give any notion at all approaching to reality of the animal, the result of a note and drawing which had been sent to him from India. Though the materials were too incomplete to furnish secure data for fixing its position, they gave information which former authors had not enjoyed, and there was certainly enough to prevent D'Argenville from placing it in the heterogeneous third division of his system, denominated by him the Multivalves. Linnæus arranged it immediately after *Patella*, and before *Serpula*, stating the animal to be a *Terebella*, and the shell to be univalve, tubular, straight (recta), monothalamous, and pervious at each extremity. Bruguière gave it nearly the same position: but if both these zoologists were right in making *Dentalium* follow *Patella*, they were as far wrong in placing it by the side of *Serpula*, *Teredo*, *Sabella*, and above all, *Aspergillum*. Lamarck, in his 'Système des Animaux sans Vertèbres' (1801), arranged *Dentalium* with *Terebella*,

1, *Dendrophis Ahætulla*, one fourth of the natural size; 1 *a*, head; 1 *b*, disposition of the scales above and below the vent. (Iconog.)

and other genera analogous in appearance. In the 'Philosophie Zoologique' he separated the class of worms of the 'Système' into two other classes, and formed the Annelides, with the section of External Worms (Vers Extérieurs). He elevated, observes M. Deshayes, this division sufficiently in the series of *Invertebrata*, the presence of a heart and a circulation making it approximate to the Mollusks; whilst the Worms, very inferior in organisation, remained between the soft *Radiata* and the Insects. In this new class, adds M. Deshayes, we find the *Dentalia* in the same section with *Serpula*, *Spirorbis*, and *Siliquaria*. This arrangement was not altered in 'L'Extrait du Cours,' published in 1811. But, in the great work of the 'Animaux sans Vertèbres,' Lamarck, assisted by the labours of Savigny, and deceived moreover by the communications of M. Fleuriau de Bellevue, considered *Dentalium* as approximated to *Clymene*, and placed it in the family of Maldanians of M. Savigny. Systematic authors generally, not knowing more than Lamarck did, that knowledge being confined to the tube, followed Lamarck's opinion. Cuvier, in the first edition, placed it among the Annélides Tubicoles, between *Aspergillum* (*Penicillus*, Lam.) and *Siliquaria*. Savigny, in his 'Système des Annélides,' gave a summary description of the animal, but it was too incomplete to decide the question finally, though sufficient to overthrow the observations of M. Fleuriau de Bellevue. The *D. Entalis*, which was sent to Savigny by our countryman Leach, gave sufficient information to that celebrated zoologist to enable him to say that the animal had no trace of rings, that it had no hairs (soies) on the lateral parts of the body, that it was essentially muscular, and that it could no longer remain among the *Chætopods*.

D. Entalis was the species on which M. Deshayes made his observations; and in a very interesting and elaborate paper read before the Society of Natural History of Paris, on the 18th of March, 1825, he gave the facts which led him to the conclusion stated at the commencement of this article. The following is a summary of his description: but we must premise that M. Deshayes's specimens were forwarded to him in spirit, and were consequently a good deal contracted :—

Externally the animal is conical and elongated, like the shelly investing tube (dorsal surface corresponding with the convexity of the shell; ventral surface corresponding with the concavity); smooth and truncated obliquely at the anterior end, the centre of the truncation with a small pyramidal process, which is the extremity of the foot. The posterior parts are less muscular, and the termination is usually a funnel-shaped expansion, variously developed in different individuals; for in some it is firm and well developed, and in others it is scarcely perceptible. This expansion is separated from the rest of the body by a strongly-defined contraction. There is a muscular ring, broader on the ventral than on the dorsal surface, above this contraction, and by that ring the animal is attached to the shell, which on its inner surface presents, at about one-fifth of its length from the posterior extremity, a corresponding impression in the shape of a horse-shoe, the interrupted portion being on the concave side. On the dorsal surface a small elevation is perceptible, at about one-third of its length from the anterior end, indicating the place of the head. The whole extent below this is occupied by two muscles on each side, distinctly observable through the abdominal parietes. These muscles are symmetrical, flattened, and directed obliquely from the sides of the foot towards the dorsal surface and the posterior extremity of the animal, giving rise to and becoming commingled with the muscle of attachment. On the abdominal surface, likewise, there are on each side, at about one-third of its length from the anterior end, two symmetrical organs deeply jagged, and of a dark brown colour: these form the liver. Below this point, nearly the whole of the abdomen is visible through its transparent parietes filled by granulations contained in the very large ovary, and by the straight descending intestine which terminates at the expanded extremity in a mesial vent. The whole of the anterior part of the animal is invested by a fine membrane, which is fixed posteriorly to the origin of the foot, and is free in front, where its circumference is thickened. It is perforated in its centre, and M. Deshayes considers this to be the mantle. The thickened portion is produced by a circular sphincter, which, when contracted, wrinkles the skin, closely embraces in its opening the extremity of the foot, and thus cuts off any external communication. M. D'Orbigny, jun., who furnished a drawing of the living animal in an expanded state, makes the dilated lobes of the foot resemble a flower whose undulated and small corolla supports in its centre a pistil thickened towards the middle, and pointed at its free end.

On slitting the mantle down the middle of its dorsal surface, separating it from its insertion to the right and left, and turning it downwards and to the right, the foot, the head, and the branchiæ appear.

The foot is elongated, subcylindrical, slightly conical, and flattened from above downwards, fleshy throughout, and situated at the inferior and anterior part of the head, having its upper and under surfaces slightly grooved in the middle. The anterior extremity is largest, and its centre is occupied by a sort of conical nipple, broader at its base, being there partly covered by two small notched lateral lobes, the notches corresponding with the grooves of the foot. The posterior extremity has a bifurcated appearance, owing to the attachment there of the retractor muscles; its middle portion projects a little into the abdominal cavity, giving support to the stomach and the other principal viscera.

The head consists only of a mouth, and is situated superiorly at the hinder extremity of the foot. It is bell-shaped, and flattened from before backwards. Two black points on its sides might be mistaken for eyes, but these are the jaws situated within the mouth, and visible through the thin substance of which it is composed: they are spherical, horny, rough on their outer surface, cleft in the middle, and bearing a considerable resemblance to a small bivalve shell. There are two lips deeply cleft at the margin, or, more properly speaking, furnished each of them with three pairs of labial tentacles, those of the posterior lip, the middle pair especially, being much larger than

1. Shell of *Dentalium Entalis*, natural size. 2. Shell magnified, broken longitudinally, showing the animal in a contracted state; *a*, the posterior extremity prolonging itself into a small accidental tube. 3. Magnified, representing the animal at the moment of its advancing out of the shell; *a*, *b*, the foot, the lobes of which are developed in the form of a corolla; *c*, a part of the collar. 4. The animal magnified, abdominal aspect; *a*, extremity of the foot; *b*, the collar; *c*, *c*, the mantle; *d*, *d*, the liver; *e*, the intestine; *f*, the ovary; *g*, the muscle of insertion; *j*, *h*, the pavilion and its neck; *i*, the vent. 5. Magnified, dorsal aspect; *a*, extremity of the foot; *b*, the collar; *c*, *c*, the mantle; *d*, slight projection produced by the head and the branchiæ; *e*, *e*, internal retractile muscles; *f*, *f*, external retractile muscle; *g*, neck of the pavilion; *h*, the pavilion. 6. Magnified: the mantle has been slit in the dorsal and mesial line, detached in part from its posterior insertion, and turned aside showing, *a*, the extremity of the foot which closes the aperture *j*, of the collar *l*, *m*, of the mantle *n*, *o*, *p*; *b*, *b*, lobes of the foot; *c*, the foot itself, presenting a depression or channel running its whole length; *d*, the head; *e*, the cerebral ganglion; *f*, *f*, the two buccal jaws; *g*, *g*, the pedicles or branchiferous membranes; *h*, *h*, *i*, *i*, the branchiæ; *p*, *p*, *q*, *q*, the retractor muscles; *s*, the muscle of insertion; *t*, the neck of the pavilion. 7. fig. 4 natural size. 8. fig. 5 natural size. (Deshayes.)

those of the anterior. There is a naked space in the centre of the anterior lip indicating the aperture of the mouth, which is contracted into a short fleshy œsophagus, terminating rapidly in a thick pear-shaped stomach, supported by and closely adhering to the extremity of the foot, and containing within, near the cardiac opening, a rather complicated tooth-like apparatus. By a distinct vessel from each of the symmetrical lobes of the liver its secretion is poured into the stomach, which terminates below in a slender, transparent, straight, mesial intestine, opening, as before observed, at the dilated posterior extremity.

The heart is symmetrical, situated above the stomach, and contained in a pear-shaped pericardium. A vascular trunk issues from the anterior extremity of this sac, passes in the direction of the neck, and divides into two large branches, one being distributed to each of the branchiæ.

The branchiæ two, symmetrically situated on the lateral and posterior parts of the neck, and supported on a divided pedicle or branchiferous membrane, formed of many very fine soft flexible tentacular filaments with club-shaped terminations, and appearing from their position to be equally adapted for directing nourishment towards the mouth, and for fulfilling their important office of aerating the blood.

The nervous system is apparently ganglionic; the cerebral ganglion, the only one yet detected, is small, quadrilateral, considerably elongated, and placed longitudinally on the middle of the posterior surface of the head. Two very minute filaments issue from its inferior angles and pass to the œsophagus; they have not been traced beyond it.

M. de Blainville ('Malacologie,' 1825) agrees with M. Deshayes in the conclusion to which the latter came, namely, that *Dentalium* is a true Mollusk, and he makes it the type of his first order *Cirrhobranchiata*, of his first section of his third sub-class, *Paracephalophora Hermaphrodita*, placing it next to *Patella*. M. Rang (1829) follows De Blainville in referring it to his order *Cirrhobranchiata*, of which Rang makes it the only family, as does De Blainville, and he gives it a situation between *Fissurella* and *Patella*. Cuvier, in the last edition of the 'Règne Animal' (1830), still retains *Dentalium* among the Annélides, placing it immediately after *Siphostoma* of Otto; but he adds, that the recent observations of Savigny, and above all those of Deshayes, render such a classification very doubtful. The animal, he observes, does not appear to possess any sensible articulation, nor any lateral hairs (soies), but it has anteriorly (en avant) a membranous tube, in the interior of which is a sort of foot, or fleshy and conical operculum, which closes its orifice. On the base of this foot, he adds, is a small and flattened head, and on the nape are to be seen the plumose branchiæ. If, he continues, the operculum recals to mind the foot of the *Vermeti* and *Siliquariæ*, which have already been transferred to the class of mollusks, the branchiæ remind us of *Amphitrite* and *Terebellum*; and he concludes by remarking that ulterior observations on their anatomy, and principally on their nervous and vascular systems, will resolve this problem. Dr. J. E. Gray, who has compared the description of the animal given by M. Deshayes with specimens in the British Museum, is, he informs us, satisfied with the correctness of that description, and he considers that the most natural situation of *Dentalium* is nearest the *Fissurellæ*, but still far from them. The apices of the British species, he observes, often appear to be either broken off, or to have fallen off of themselves, like the tips of decollated shells; and he adds, that when the tip is broken, the animal forms a slight tube within, which is more or less produced beyond the tip; and that the late Dr. Turton described a specimen in this state as a species under the name of *D. labiatum*. Dr. Gray thinks that there is only one species found on our coasts, the other so-called species being mere varieties depending either on the worn or broken state of the specimens. In his 'Spicilegia Zoologica' he has described a *Siphunculus* which inhabits these shells, and which, he believes, has been considered by some authors to be the real inhabitant of the shell.

The geographical distribution of the genus is very much extended; few seas are without some of the species, which vary much in size. They are found sometimes in deep water, frequently near the shore. Professor E. Forbes has dredged the British species *D. Entalis* and *D. Tarentinum* at from ten to fifty fathoms' depth. About 30 recent species have been described, and 70 fossil.

M. Deshayes separates his species into four groups:—

1.

Shell not slit at its posterior extremity.

a. Longitudinal striæ.

Example, *D. Elephantinum.*

b. No longitudinal striæ.

Example, *D. Entalis.*

2.

Shell slit at its posterior extremity.

a. Longitudinal striæ.

Example, *D. striatum.*

b. No longitudinal striæ.

Example, *D. eburneum.*

3.

Shell having a marginal rim; not slit at its posterior extremity.

Example, *D. strangulatum.*

Fossil Dentalia.

"Of fossil species," says Mr. G. B. Sowerby, "there are many, particularly in the marine beds of the Tertiary Formations; the London Clay and the Calcaire Grossier swarm with several sorts not easily distinguishable from the recent species, among which we may particularly remark the fossil species from Piacenza, which so nearly resembles *D. Elephantinum* that Brocchi has not hesitated to refer it to that species, and the *D. eburneum* of Lamarck, which he says inhabits India, and is found fossil at Grignon. Deshayes in his 'Tables' gives the number of living species as 23, of the fossil (tertiary) 34, and the following, *D. Elephantinum, D. dentalis, D. novem costatum, D. Entalis, D. eburneum, D. fissura*, and *D. strangulatum*, as both living and fossil. Mr. Mantell in his tabular arrangement of the organic remains of the county of Sussex ('Geol. Trans.' vol. iii., second series, 1829), notes a species, which he does not name, in the blue clay of Bracklesham; *D. planum*, in the arenaceous limestone or sandstone of Bognor; *D. cylindricum*, in the sand on Emsworth Common; *D. striatum, D. ellipticum*, and *D. decussatum*, in the Gault, or Folkstone marl; and one or more, unnamed, in the Shanklin sand (Lower Greensand). Dr. Fitton figures one species, *D. medium*, from the Greensand of Blackdown, in his interesting 'Observations on some of the Strata between the Chalk and Oxford Oolite in the South-East of England.' ('Geol. Trans.' vol. iv., second series, 1836.) And he notes *D. ellipticum* in the Gault at Copt Point, on the authority of the Rev. G. E. Smith. In his 'Systematic and Stratigraphical List of Fossils' four named species, including *D. ellipticum, D. medium*, and an uncertain species, are noted from the Gault of Kent, South Wilts, and Cambridge, and the sands of Blackdown. Dr. Lea, in his 'Contributions to Geology' (1833), describes two new species, *D. alternatum* and *D. turritum*, from the Tertiary Beds of Claiborne, Alabama, and gives the following summary:—'In Great Britain 14 species have been obtained from the Lias to the Crag. M. Deshayes's 'Tables' give 34, of which 13 are from the Paris basin, the Eocene period. In this country (America) Dr. Morton has observed casts in the Upper Greensand of New Jersey and Delaware; and Mr. Say one species, the *D. attenuatum*, in the Tertiary of Maryland.'"

DENTA'RIA, a genus of Plants belonging to the natural order *Cruciferæ*, the sub-order *Siliquosæ*, and the tribe *Arabideæ*. It has a lanceolate compressed pod, flat nerveless valves, a capitate stigma; the seeds in a single row, the funiculus dilated, winged.

D. bulbifera, the Coralwort, is the only British species of this genus. It has a simple stem, alternate leaves, the lower leaves pinnate, the upper leaves simple, the axils of the leaves producing bulbs. It has a thick fleshy rhizoma with tooth-like knobs, hence its name. The flowers are rose-coloured or purple. It is a rare plant in England, but it is found in the neighbourhood of Tunbridge Wells.

(Babington, *Manual of British Botany.*)

DENTATI. [AMMONITES.]

DENTEX, a genus of Fishes belonging to the family *Sparidæ*. It has the following characters:—Body deep, compressed; dorsal fin single; head large; teeth conical, placed in a single row, four in the front above and below elongated, and curved inwards, forming hooks; teeth on the branchial arches, but none on the vomer or palatine bones; nose and suborbital space without scales; branchiostegous rays 6. There are several species of this genus.

D. vulgaris, the Four-Toothed Sparus, is regarded as a native of England. Only one specimen however seems to have been taken in this country, and that by Mr. Donovan in 1805 off Hastings. It is a very common fish in the Mediterranean, and is the *Dentex* of the Romans. It is remarkable for the great length of the four anterior teeth in each jaw. It acquires sometimes a large size weighing from 20 to 30 pounds, and measuring 3 feet in length. Mr. Donovan's specimen weighed 16 pounds. "A more voracious fish," says Mr. Donovan, "is scarcely known; and when we consider its ferocious inclination and the strength of its formidable canine teeth, we must be fully sensible of the great ability it possesses in attacking other fishes even of superior size, with advantage. It is asserted, that when taken in the fisherman's nets, it will seize upon the other fishes taken with it, and mangle them dreadfully. Being a swift swimmer it finds abundant prey, and soon attains to a considerable size. Willughby observes that small fishes of this species are rarely taken, and the same circumstance has been mentioned by later writers. During the winter it prefers deep waters, but in the spring or about May it quits this retreat, and approaches the entrance of great rivers, where it deposits its spawn between the crevices of stones and rocks.

"The fisheries for this kind of *Sparus* are carried on upon an extensive scale in the warmer parts of Europe. In the æstuaries of Dalmatia and the Levant, the capture of this fish is an object of material consideration, both to the inhabitants generally as a wholesome and palatable food when fresh, and to the mercantile interests of those countries as an article of commerce. They prepare the fish according to ancient custom, by cutting it in pieces and packing it in barrels with vinegar and spices, in which state it will keep perfectly well for twelve months."

(Yarrell, *British Fishes.*)

DENTIPORA. [MADREPOREA.]

DENTIROSTRES. [BIRDS.]

DENTITION, the formation and evolution of the teeth. The varied processes by which the teeth are formed, developed, and arranged are among the most curious and complicated operations of the animal economy. The different stages of dentition, in the human being, mark distinct epochs of human life, in which many important changes occur in the physical frame, simultaneously with which new mental powers are developed.

The teeth differ in their organisation in several important respects from all other organs of the body. They are of a bony structure, and are placed in the arches of the upper and lower maxillary or jaw-bones. They consist of two sets, of which the one is intended to last only for a short time, while the other is destined to last during the whole term of life. The first are called the temporary and the second the permanent teeth. The temporary teeth, 20 in number, are in general considerably smaller than the permanent, have a less firm and solid texture, and their characteristic forms and prominences are much less strongly marked. The permanent teeth, 32 in number, are arranged in perfect uniformity, 8 on each side of each jaw, those of the one side exactly corresponding with those of the opposite. They are divided into four distinct classes, which present specific differences in size, form, development, articulation, and use; namely, on each side of each jaw, two incisores, one cuspidatus, two bicuspides, and three molares.

For our knowledge of the early history of the development of the teeth we are principally indebted to Professor Goodsir of Edinburgh, who in 1839 published his views upon this subject. In giving an account of his researches and the additional facts that are known on this subject, we shall employ the lectures of Mr. Tomes on 'Dental Physiology,' as one of the most recent and complete works on the subject.

Preparation is made for the development of the teeth at a very early period of fœtal existence. At the sixth week of the existence of the human embryo, on examining the mouth, a groove is observed which is called the primitive dental groove, and in it the first germs of the teeth are observed. At the seventh week a slight projection of the mucous membrane at the bottom of this groove takes place, and which soon increases in size and forms a papilla. This papilla is the first condition of the tooth-pulp, and is composed of a mass of cells, each containing a nucleus, or cytoblast. No vessels are yet seen in the pulp, but they pass under it to the mucous membrane. As the papilla increases in size the vessels become elevated, and pass into its substance. The first papilla thus formed constitutes the follicle of the anterior temporary molar tooth, those of the upper jaw appearing before those of the lower. Subsequently the papillæ of the other teeth are developed, and by the tenth week we have in the dental grooves 20 papillæ corresponding to the 20 temporary teeth. As the papillæ grow the walls of the dental groove increase, and send out laminæ towards each other, which meeting, unite, and form septa. By these means the papillæ are inclosed in a series of cells or cavities with open mouths called follicles. The septa are all developed by the thirteenth week, leaving behind in the dental groove an open portion.

A change now comes on in the shape of the papillæ, which, instead of remaining as hitherto simple round blunt masses, become changed into special characteristic forms. The papillæ, from their more rapid growth, protrude also from the open mouths of the follicles. With this change in the shape of the papillæ a growth of lids or opercula to the open mouths of the follicles takes place. At the fourteenth week the inner lip of the dental groove has increased in size, and applies itself in a valvular manner to the outer lip. The relative growth of the papillæ and follicles is now reversed, the former beginning to sink by the increased growth of the latter. At this time also a secondary dental groove is observed, which is destined to furnish the papillæ of the permanent teeth. It gradually appears in the form of small crescent-shaped depressions immediately behind the inner opercula of each of the follicles of the first or milk series of papillæ. By the fourteenth or fifteenth week, through the adhesion of the opercula in the first groove, the follicles have become sacs, and the same change subsequently occurs in the secondary groove inclosing the permanent teeth. The space left open in the primitive dental groove at the end of the sixteenth or seventeenth week exhibits papillæ which represent the anterior permanent molar teeth.

From the time of the closure of the milk follicles the pulps gradually assume their peculiar shape, and those destined for the formation of the molar teeth are divided at the base for the growth of their several roots. With these progressive changes, the sac growing faster than the pulp, an intervening space is formed, in which is developed a soft granular substance, which for a time increases in quantity, and is adherent to the inner surface of the sac, but not to the pulp, though closely applied to the surface of the latter.

At this stage of their growth each sac receives a twig from the dental artery; but this does not penetrate the granular substance.

The next step in the general process of development is the appearance of caps of tooth-substance upon the tips of the pulps, and is accompanied by a diminution of the granular substance, which entirely disappears when the tooth-substance is perfectly developed. From the last-mentioned period up to the eighth month the cavities devoted to the ten anterior permanent teeth gradually recede from their position between the milk-sacs and the gums, and are now posterior to the milk-sacs. This separation of the sacs has led to the notion that the permanent sacs are formed from the temporary ones by a process of gemmiparous fission; but the observations of Professor Goodsir have demonstrated that this view is entirely erroneous.

At about the time of birth the fangs of the incisors begin to be formed. This process is attended with three separate actions:—1, elongation of the base of the pulp; 2, deposition of dentine upon it; 3, adhesion of the contiguous portion of the sac to the surface of this dentine.

The central incisors pass through the gum, or are cut as it is called, about the eighth or ninth month after birth. The crown of the tooth being perfected, and the formation of the fang advanced by the triplex action already described, an action is set up by which the edge of the tooth passes through the gum. Here then terminates the saccular stage of the tooth, the sac having been opened by the passage of the tooth through the gum. It must be borne in mind that with the development of dentine for the fang the sac becomes adherent to its surface, but not to the surface of the enamel. A probe might be passed down the surface of the enamel to the neck of the tooth so soon as the sac is opened by the edge of the tooth. When once the tooth is cut growth progresses rapidly. The tooth however appears to grow more rapidly than it really does, and from the following causes:—The sac being opened, and its inner surface thereby rendered continuous with that of the gum, a strong disposition to contract seems to come into force in that portion lying against the enamel, and as the gum constitutes one fixed point, and the adhesion of the sac to the neck of the tooth the other, the lower is as it were lifted out of the gum by the shrinking of the sac between these two points. As a consequence of this movement, the distance between the unfinished end of the fang and the fundus of the alveolus is lengthened. The socket now rapidly adapts itself to the neck of the tooth, to which it becomes accurately moulded. The pulp elongates itself and diminishes at its base, till at the completion of a tooth it has diminished to the size of a thread and is constituted principally of the dental vessels and nerves. As the temporary teeth have advanced towards the surface, the sacs for the permanent teeth have receded behind them, and have become inclosed in proper bony crypts, from each of which a foramen proceeds. In the sacs for the front teeth these foramina open immediately posterior to the milk teeth, but those for the bicuspids open into the alveoli of the milk molars. From the apex of each sac a fibrous cord proceeds through the foramen to join the gum near the neck of the corresponding milk tooth, excepting in those under the milk molars, in which the fibrous cord unites with the periosteal lining of the temporary alveolus. These cords, or gubernacula as they are called, are formed of the obliterated portion of the pulp follicle, which it will be remembered was rendered external to the sac by the development and subsequent closure of the opercula. It seems the union of the two sides is sometimes incomplete, so that the cord is in fact a tube closed at its two extremities. The gubernaculum lengthens as the sac recedes from the surface, and disappears only after the tooth passes through the gum. From observing the position and the disappearance of the gubernaculum many have supposed that it leads or directs the developing tooth to its proper situation in the alveolar arch. Professor Goodsir, when speaking of the use of the cords and foramina, says:—

"The cords of communication which pass through these foramina are not tubular, although in some instances a portion of the unobliterated intra-follicular compartment of the original little cavity of reserve may be detected in them; they are merely those portions of the gum which originally contained the lines of adhesion of the depressions for the permanent teeth in the secondary dental groove, and which have been subsequently lengthened out in consequence of the necessarily retired position in which the permanent teeth have been developed during the active service of the temporary set.

"The cords and foramina are obliterated in the child, either because the former are to become useful as 'gubernacula,' and the latter as 'itinera dentium,' or, much more probably, in virtue of a law which appears to be a general one in the development of animal bodies, namely, that parts or organs which have once acted an important part, however atrophied they may afterwards become, yet never altogether disappear so long as they do not interfere with other parts or functions."

The sacs of the permanent teeth are supplied with blood-vessels first from the gums but afterwards from the milk-sacs. As the sacs sink deep into the alveolus they receive vessels from the proper dental canals.

Mr. Goodsir divides dentition into three stages: "First, the follicular, in which stage is included the papillæ when it existed as a simple prominence from the mucous membrane, and extends to the closure of the opercula. Secondly, the saccular, which commences with the closure of the opercula, and ends with the passage of the tooth through the gum. Thirdly, the eruptive, which commences when the tooth appears through the gum, and extends to the period when the permanent teeth are fully developed. These three stages, when considered in reference to any particular tooth, are well defined, but when viewed in reference to the whole set, or two sets, they are intermingled; thus, when one tooth-germ is in the saccular, another is in the follicular stage; again, when the temporary teeth are in the eruptive, the permanent teeth are in the saccular condition."

For an account of the development of the tissues which form the tooth, we must refer our readers to the article TEETH, in which the tissues themselves are described.

The age at which the teeth first make their appearance varies considerably, frequently without any apparent reference to the constitutional powers of the child. Instances are not wanting in which children have been born with two or more teeth. In many other cases the teeth have not come through the gum until fourteen or sixteen months, or even as late as two or three years. In general, however, dentition may be said to commence at the age of from five to eight months. The following table from Mr. Tomes's Lectures gives the result of the observations of several writers on this subject:—

Authors.	Central Incisors.	Lateral Incisors.	Canines.	1st Molar.	2d Molar
	Months.	Months.	Months.	Months.	Months.
Fox	6, 7, 8; extreme cases 4 to 13	7, 8, or 9	17 to 18	14 to 16	24 to 30
Hunter	7, 8, or 9	7, 8, or 9	20 to 24	20 to 24	20 to 24
Bell	5 to 8	7 to 10	14 to 20	12 to 16	18 to 36
Dr. Ashburner	7th, lower jaw; 8th, upper jaw	9th, upper jaw; 10th, lower jaw	16, 17, 18, 19 or 20	12 to 14	22 to 30

These periods are however only given as a general rule, liable to continual exceptions, not only in the time at which the different teeth appear, but also in the relative order of their precedence.

According to Dr. Ashburner, who has paid great attention to this subject, and who has had ample opportunities of observation, the teeth of the first dentition commonly cut in couples; the two anterior incisors of the lower jaw appear first; then, in perhaps from fifteen to twenty days the two anterior incisors of the upper jaw come through; to these succeed the lateral couple of incisors of the lower jaw; then come those of the upper jaw. After these the two molar teeth nearest to the lateral incisors of the lower jaw appear; then the first molars of the upper jaw; after which come the lower two canine; then the upper canine; then the two second molar of the lower jaw; and afterwards the corresponding molar of the upper jaw. The period occupied in the process is about two years from the appearance of the first tooth.

The first formed of the permanent teeth are the anterior molars, on which the first point of ossification may be seen at birth. At about the age of twelve months the ossification on these teeth has proceeded to a considerable extent; also on the permanent incisors, and it has commenced on the lower cuspidati, the upper ones being generally two or three months later. About the time when all the temporary teeth have made their appearance, ossification is found on the points of the bicuspids, and the bony shells of the teeth before mentioned have acquired considerable size.

Most of the permanent teeth are larger than those which precede them. They are placed during their progress a little behind them; hence they are confined within the segment of a smaller circle; consequently, as they approach more and more nearly to their ultimate size, they must become very much crowded in the jaw. "The examination of the maxillary bone of a child of about five years old," observes Mr. Bell, "will show this fact in a very striking manner. At this period the jaws being considerably deepened by the development of the alveolar processes, the sockets in which the permanent teeth are lodged will be found placed beneath those of the temporary, some higher than others, and the bony shells are closely packed in such a manner as to occupy the least possible space. Thus, in the upper jaw, the central incisors are situated immediately beneath the nose, the lateral incisors thrown back behind the points of the cuspidati, and the bases of the latter scarcely a quarter of an inch below the orbit; in the lower jaw the cuspidati are placed at the very base of the bone, with only a thin layer beneath them; but the crowding is much less considerable than in the upper jaw, from the smaller comparative size of the incisors.

"At from six to seven years of age the whole of the permanent teeth are more or less ossified, excepting the dentes sapientiæ; so that, previously to the shedding of any of the temporary teeth, there are at this time no less than forty-eight teeth in the two jaws; namely, twenty deciduous, the whole of which are perfected, and twenty-eight permanent, in different degrees of development, within the bones."

At a particular epoch of human life, the temporary teeth are exchanged for a more numerous set, of a stronger and more durable structure, and of increased power of mastication. The original teeth become loose in their sockets, their roots are eaten away, their crown crumbles and recedes from the gums, and at last they fall out. This change takes place in the temporary teeth exactly in the order in which they were originally formed, and in which they cut through the gums. Thus, the central incisors of the lower jaw fall away first, then those of the upper jaw, then go the interior lateral incisors, and so on.

The mode in which this change is effected, which constitutes the shedding of the teeth, is by a process of absorption. The anterior parietes of the cavities in which the permanent teeth are contained are removed by the absorbent vessels, in consequence of which the teeth are allowed to advance; next the sockets, then the roots, and lastly the crowns of the temporary teeth are absorbed. This absorption cannot be solely the effect of pressure produced by the advancing permanent teeth, for the process goes on when such pressure cannot possibly have existed; it is, in part at least, like the preparation of the cell for the reception of the permanent pulp, a true process of anticipation. Neither do the advancing permanent teeth displace the receding deciduous teeth; but the jaw grows and enlarges consentaneously with the increasing bulk and number of the teeth which it is destined to receive.

The change of the temporary for the permanent teeth commences, in the majority of instances, at about seven years of age; "though," says Mr. Bell, "I have occasionally known it to occur as early as five and as late as eight years and a half." The first permanent molars usually pierce the gum before the loss of the temporary central incisors, and their appearance may be considered as indicative of the approaching change. The following are about the medium periods at which the different permanent teeth are generally cut, but so irregular are they in this respect that comparatively little dependence can be placed on such a statement. Those of the lower are here indicated, and they most commonly precede the upper by about two or three months:—

Anterior Molars	6½ years
Central Incisors	7 "
Lateral Incisors	8 "
Anterior Bicuspids	9 "
Posterior Bicuspids	10 "
Cuspidati	11-12 "
Second Molars	12-13 "
Third Molars, or Dentes Sapientiæ	17-19 "

It has been supposed that the permanent teeth are subject to much irregularity in the time of their appearance. This however is an error, as within a limited period the appearance of the teeth in healthy children is very constant. The following extract from Mr. Saunders's work on 'The Teeth a Test of Age,' will be found to confirm this:—

"Thus, then, it appears that of 708 children of nine years old, 389 would have been pronounced on an application of this test to be near the completion of their ninth year; that is, they presented the full development of that age. But on the principle already stated—that of reckoning the fourth tooth as present when the three are fully developed—a still larger majority will be obtained, and instead of 389 the proportion will be as follows: of 708 children no less a number than 530 will be fully nine years of age. What, then, are the deviations in the remaining 178? They are the following: 126 would be pronounced eight years and six months, and the remaining 52 eight years of age; so that the extreme deviations are only twelve months, and these only in the inconsiderable proportion (when compared with the results obtained by other criteria) of 52 in 708.

"Again, of 338 children under thirteen years of age, no less than 294 might have been pronounced with confidence to be of that age. The remaining 44 would have been considered as follows: 36 in their thirteenth and 8 near the completion of their twelfth year."

Such are the main phenomena which relate to the process of dentition when this operation is performed in a perfectly natural and healthy manner. But this process is exceedingly apt to become deranged, producing evils in the system often most serious, and even fatal; and the preceding account of the natural process will enable us readily to understand the nature, extent, and causes of the diseases which so often result from the morbid progress of the function. DEODARA. [ABIES.]

DERBYSHIRE SPAR. [FLUOR-SPAR.]

DERCÆA. [STENELYTRA.]

DERMATINE, a Mineral found in the serpentine quarry near Waldheim. It occurs in reniform masses, rarely globular, and in thin coatings or crusts. Its colour is dark olive-green or liver-brown. Streak yellow inclining to gray. The fracture is conchoidal. It feels greasy, but does not adhere to the tongue. Its hardness is about 2·0. Lustre somewhat resinous. Specific gravity, 2·136. The following analysis is by Ficinus:—

Silica	35·800
Magnesia	23·700
Protoxide of Iron	11·333
Protoxide of Manganese	2·250
Alumina	0·416
Lime	0·833
Water and Carbonic Acid	25·200

DERMATOBRANCHUS, a genus of Molluscous Animals established by M. Van-Hasselt, and arranged by him among the *Nudibranchiata.* It has the following characters:—Animal depressed, semicircular, provided with a considerably large foot, and protected above by an enlarged mantle, rounded anteriorly, narrowed posteriorly, beset with elongated striæ or pustules, which are branchial. A pair of short, approximated, contractile tentacula situated between the head and the mantle. Eyes none (?). Three apertures on the right side of the body, the anterior opening near the head for the generative apparatus, the second for the vent, and the third for the urinary organ. It is an inhabitant of the coast of Java.

DERMESTES. [DERMESTIDÆ.]

DERME'STIDÆ, Leach (from Δερμήστης, a moth or worm that eats skins), a family of Animals belonging to the order of Coleopterous Insects of the section *Necrophaga* (M'Leay). They have the following characters:—Antennæ short, 11-jointed, terminated by a compressed club, consisting of 3 or 4 joints; palpi small; mandibles short, thick, and generally dentated; head deeply inserted into the thorax; body generally oval, and more or less furnished with scales or hairs; legs short; tarsi 5-jointed. The species of this family are for the most part of small size: their larvæ (at least those which are known) are covered with hair, and feed upon animal substances. It includes the genera *Dermestes, Ctesias, Megatoma, Attagenus, Aspidiphorus, Nogoderma, Anthrenus, Globulicome, Limnichus*, and *Trogoderma*. The species of many of these genera whilst in a larva state do great mischief in houses. They are especially destructive to the collections of the naturalist. The perfect insects are harmless, living on flowers. They are found throughout Europe, Australia, Africa, and America.

The distinguishing characters of the genus *Dermestes* are:—Antennæ scarcely differing in the sexes; the basal joint thick, the six following joints nearly of equal size, the eighth broader than long, the ninth and tenth very broad and nearly of equal size, the eleventh also broad but not equal in size to the two preceding; palpi short and thick; body of an elongated oval shape.

D. lardarius is about a quarter of an inch in length and of a dull black colour; the basal half of each elytron is of an ashy tint, and has three black spots.

This insect is sometimes very abundant in houses in the neighbourhood of London and elsewhere, and when this is the case is very destructive, since it will devour almost any animal substance, but we believe only in a dried state.

D. vulpinus is about the same size as the last, from which it may be distinguished by the elytra being totally black, and the sides of the thorax and under parts of the body being covered with white scales.

This insect is brought over in great abundance in ships laden with hides. We have seen them in skins of quadrupeds both from India and America. The larva is about half an inch in length, and covered with blackish-brown hairs. Like the perfect insect it feeds upon dried skins, and hence when abundant is very destructive to this sort of property. In the 14th vol. of the 'Linnean Transactions' is a notice of the occurrence of several specimens of this insect, and also of another beetle (*Necrobia violacea*) in the Egyptian mummy; and in the 'Transactions of the Entomological Society,' vol. i., the Rev. F. W. Hope describes several species of Coleopterous Insects which had been found in the heads of Egyptian mummies. They are as follows:—*Necrobia Mumiarium, D. pollinctus, D. Roei*, and *D. elongatus*. Accompanying these insects there were also found some fragments of a species of *Pimelia*—probably the *P. spinulosa*.

D. murinus is also about a quarter of an inch in length, and of a black colour; the upper parts of the head, thorax, and elytra, are mottled with scales of an ashy tint; the scutellum is of a fulvous colour; the under parts of the body are white.

The species is common in various parts of England, and is found in dried animals which have been suspended in the open air by gamekeepers and other persons.

In the genus *Ctesias* (Stephens) the two basal joints of the antennæ are thick; the six following are nearly of equal size and rather slender; the ninth joint is rather long and of an obconic form; the tenth joint is shorter than the last; and the terminal joint is conical. These three joints form together an elongated knob.

C. Serra is about an eighth of an inch in length, of a black colour, with yellowish antennæ. It is found under the loose bark of elm-trees. The larva is covered with long hairs.

Megatoma (Herbst).—In this genus the two basal joints of the antennæ are thick; the four following are slender; the seventh and eighth joints are larger than the last-mentioned, and the remainder form an elongated club; the terminal joint is twice as long as the others in the male, and but slightly elongated in the female.

Attagenus (Latreille).—Antennæ with the basal joint thick; the second less robust and shorter; the three following joints slender; the sixth, seventh, and eighth joints gradually increasing in size; the remainder forming a 3-jointed club, of which the terminal joint is extremely long and almost cylindrical in the male, and of an elongated oval form in the female.

A. Pellio is about an eighth of an inch in length, and of a black colour; the base of the antennæ is yellowish, and there is a round white spot in the middle of each elytron.

This insect is common in houses, and is very frequently found in quills, upon the pith of which it probably feeds.

DERMO'CHELYS. [CHELONIA.]

DERRIAS. [BABOON.]

DESMAUS. [SORECIDÆ.]

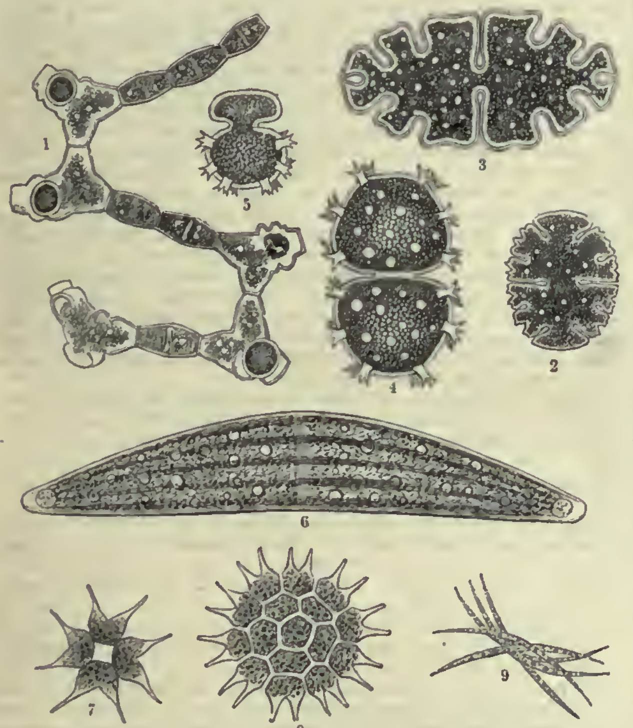
DESMIDIEÆ, a group of organised beings regarded by some naturalists as Animals and by others as Plants. The botanists who have adopted them into the vegetable kingdom have regarded them as *Algæ*, and allied to the *Diatomaceæ*. Some however who admit the vegetable characters of *Desmidieæ* deny them to *Diatomaceæ*. Dr. Lindley admits the *Desmidieæ* as a sub-order of the *Diatomaceæ*, which he characterises as crystalline angular fragmentary bodies, brittle, and multiplying by spontaneous separation. Amongst this group of beings the *Desmidieæ* are characterised as being 'cylindrical.' The following is the definition of this family as given by Mr. Ralfs in his 'British Desmidieæ,' a work which has greatly increased our knowledge of these obscure beings:—"Freshwater figured, mucous, and microscopic *Algæ*, of a green colour. Transverse division mostly complete, but in some genera incomplete. Cells or joints of two symmetrical valves, the junction always marked by the division of the endochrome, often also by a constriction. Sporangia formed by the coupling of the cells and union of their contents." It will be seen from this definition that Mr. Ralfs regards these beings as plants. The principal points on which he relies for establishing this position are the occurrence of conjugation and swarming, and the presence of starch amongst the *Desmidieæ*.

The occurrence of a union or conjugation of the two filaments for the production of spores, has long been known amongst certain forms of *Confervæ*. This has been seen by many observers to occur amongst the *Desmidieæ*. In the *Euastrum rupestre* (*fig.* 3 represents the genus) Nägeli describes this process. Two individuals are placed close together, and push out short processes, which meet, and by the absorption of the wall constitute a canal, into which the entire contents of the two cells thus connected enter, and combine together to form one mass which constitutes a single cell. This process is not always identical in different species. In *Closterium* (*fig.* 6) the middle of the cell-membrane dehisces with a transverse fissure, and the entire contents from two contiguous opened cells coalesce into a single round or angular mass. Siebold says, with regard to the spores or green bodies which result from the union of the cells, that they are not in all cases developed into a single *Closterium*, like spores; but that, as in the case of other *Algæ*, such as *Vaucheria* and *Œdogonium*, there are two sorts of spore-formations, and that under certain circumstances these green bodies represent a germ, capsule, or sporangium, in which, by a process of division, several young *Closteria* come to be perfected. The union of the cells of *Didymoprium Borreri* is seen in *fig.* 1.

The process above described appears to be one entirely confined to the vegetable kingdom, as it has never been observed amongst unicellular organisms, which are regarded as decidedly animal.

The process of swarming is one which, although a few years ago its distinguishing feature would have been regarded as entitling the organism exhibiting it to a place in the animal kingdom, is by Mr. Ralfs and other English naturalists regarded as purely vegetable. It has been observed in many species of *Confervaceæ*, more especially in *Achlya prolifera* [ACHLYA] and *Conferva ærea*. The following is M. Agardh's account of this curious phenomenon in the latter plant. After describing the green matter in the joints, he says:—"The granules of which it is composed detach themselves from the mass one after another, and having thus become free they move about in the vacant space of the joint with an extreme rapidity. At the same time the exterior membrane of the joint is observed to swell in one point till it there forms a little mamilla, which is to become the point from which the moving granules finally issue. By the extension of the membrane for the formation of the mamilla, the tender fibres of which it is composed separating, cause an opening at the end of the mamilla, and it is by this passage that the granules escape. At first they issue in a body, but soon those which remain, swimming in a much larger space, have much more difficulty in escaping; and it is only after innumerable knockings (titubations) against the walls of their prison that they succeed in finding an exit. From the first instant of the motion, one observes that the granules or sporules are furnished with a little beak, a kind of anterior process always distinguishable from the body of the sporule by its paler colour. It is on the vibrations of this beak that the motion, as I conceive, depends; at least I have never been able to discover any cilia. However I will not venture to deny the existence of these; for with a very high power of a compound microscope one sees the granules surrounded with a hyaline border, as we find among the ciliated *Infusoria* on applying a glass of insufficient power. The sporules during their motion always present this beak in front of their body, as if it served to show them the way; but when they cease to move, by bending it back along the side of their body, they resume the spherical form; so that before and after the motion one sees no trace of this beak. The motion of the sporules before their exit from this point consists principally in quick dartings along the walls of the articulation, knocking themselves against them by innumerable shocks; and in some cases we are almost forced to believe that it is by this motion of the sporules that the mamilla is formed. Escaped from their prison, they continue their motion for one or two hours; and retiring always towards the darker edge of the vessel, sometimes they prolong their wandering courses, sometimes they remain in the same place, causing their beak to vibrate in rapid circles. Finally they collect in dense masses, containing innumerable grains, and attach themselves to some extraneous body at the bottom or on the surface of the water, where they hasten to develop filaments like those of the mother plant." This process, to which the name swarming has been given, has been observed by Mr. Ralfs, Dr. Hassall, and others in various species of *Desmidieæ*, more especially in *Sphæroplea crispa* and *Draparnauldia tenuis*. No similar movements to these have been anywhere observed amongst the ova of the animal kingdom.

The presence of starch in the *Desmidieæ* is a third point relied on by Mr. Ralfs as distinguishing the vegetable kingdom. The existence of this substance is easily ascertained by the well-known reaction of iodine upon it. Meyen first discovered this substance in the *Algæ*, and Mr. Ralfs and others have confirmed the correctness of his observations. At the same time it should be stated that starch, although not found present in the tissues of the lower animals, has recently been detected in the brain of man by Mr. Busk ('Microscopical Journal,' vol. ii. p. 105). This may lead to the discovery of the existence of this substance more generally in the animal kingdom than has been hitherto supposed.



1. *Didymoprium Borreri*, with the cells uniting to form the green matter. 2. *Micrasterias crenata*. 3. *Euastrum oblongum*. 4. *Xanthidium armatum*. 5. The same with a frond acquiring a new segment by division. 6. *Closterium Lunula*. 7. *Pediastrum simplex*. 8. *Pediastrum Boryanum*. 9. *Ankistrodesmus falcatus*.

The following reasons are given by Mr. Dalrymple, after giving an account of the structure of *Closteria*, for placing the species of this genus amongst animals :—

1st. That while *Closterium* has a circulation of molecules greatly resembling that of plants, it has also a definite organ unknown in the vegetable world, in which the active molecules appear to enjoy an independent motion, and the parietes of which appear capable of contracting upon its contents.

2nd. That the green gelatinous body is contained in a membranous envelope, which, while it is elastic, contracts also upon the action of certain reagents, whose effects cannot be considered purely chemical.

3rd. The comparison of the supposed ova with cytoblasts and cells of plants precludes the possibility of our considering them as the latter, while the appearance of a vitelline nucleus, transparent but molecular fluid, a chorion, or shell, determines them as animal ova. It was shown to be impossible that these eggs had been deposited in the empty shell by other *Infusoria*, or that they were the produce of some Entozoon.

4th. That while it was impossible to determine whether the vague motions of *Closterium* were voluntary or not, yet the idea the author had formed of a suctorial apparatus forbade his classing them with plants.

On these reasons, Mr. Ralfs remarks, that the peculiar organ—the terminal globules—of the *Closteria* are as much vegetable as animal. That the throwing off the contents of the cell through chemical reagents, is as much vegetable as animal. "If fresh water touches *Griffithsia setacea*, the joints burst and spirt out their contents." That the supposed ova contain starch, and are therefore vegetable. That he cannot discover that the orifices at the extremities of some of the *Desmidieæ* are tubes, or that they possess a suctorial power.

The *Desmidieæ* are all of an herbaceous green colour, and from this circumstance are easily discovered amongst the other microscopic beings with which they occur. They are mostly inhabitants of fresh water. Mr. Thwaites records two or three species from brackish water. They are remarkable for the very definite outline which their forms assume, especially in the genera *Micrasterias* (*fig.* 2), *Euastrum* (*fig.* 3), *Xanthidium* (*fig.* 4), and *Pediastrum* (*figs.* 7, 8). Their most obvious characteristic however is their evident division into two valves or segments. The point of union between the two segments is in general very definitely marked. In *Pediastrum* and *Scenedesmus* it is less obvious than other genera. It is at this point of union that the cell opens and discharges its contents. "An uninterrupted gradation," says Mr. Ralfs, "may be traced from species in which these characters are inconspicuous to those in which they are fully developed: thus in *Closterium* and some species of *Penium* there is no constriction; in *Tetmemorus*, in some *Cosmaria*, and in *Hyalotheca*, it is quite evident, although still but slight; in *Didymoprium* and *Desmidium* it is denoted by a notch at each angle; but in *Sphærozosma*, *Micrasterias* (*fig.* 2), and some other genera, the constriction is very deep, and the connecting portion forms a new cord between the segments, which appear like distinct cells, and are so considered by Ehrenberg and others." He further adds, "That the frond in *Euastrum* (*fig.* 3) and allied genera is really a constricted cell, and not a binate one, will, I am persuaded, be apparent to any one who traces the gradations mentioned above."

The manner in which the cells of the *Desmidieæ* are multiplied, is by means of repeated transverse divisions. This process may be seen in *Euastrum*, the new segments appearing at the constricted part of the original segments. At first the new segments appear as two roundish hyaline bodies formed of the substance of the connecting tube. These lobules increase in size, acquire colour, and gradually put on the appearance of the old portions. As they increase in size the original segments are pushed away from each other, and at length an entire separation takes place, each old segment taking with it a new segment to supply the place of the old one. This process is seen going on in *fig.* 5. This process is repeated again and again, so that the older segments are united successively, as it were, with many generations. This multiplication however has its limits, for the time comes when the segments gradually enlarge whilst they divide, and at length the plant ceases to grow. When this occurs no more segments are produced, the internal matter changes its appearance, increases in density, and contains starch-granules. The spore is now formed, which is to give birth to a new individual, and the old one perishes. The separate cells formed by this process of segmentation must be regarded as continuations of the same individual. They are like the grafts and buds from a tree; they continue the individual.

The reproduction of the *Desmidieæ* seems to take place in two ways: first, by the formation of granular contents in the cell, which have the power of moving, burst the cell, and produce the phenomena of swarming above referred to; and secondly, by the formation of a sporangium, or case containing spores, after the union or conjugation of the cells before described. The sporangia assume a variety of forms, and are sometimes covered with spines, and Mr. Ralfs says, "That the orbicular spinous bodies so frequent in flint are fossil sporangia of *Desmidieæ*, cannot, I think, be doubtful, when they are compared with figures of recent ones."

Movements of the cell-contents of *Desmidieæ*, similar to the cyclosis of higher plants, have been observed by Dalrymple, Bailey, and others. These movements consist of definite currents of the cell-contents, passing in two opposite directions, the one along the side of the cell, and the other along the periphery of the gelatinous mass in their interior. Labarzewski, a German observer, states that these currents are intermittent, lasting each time for about seven seconds.

The part fulfilled by the *Desmidieæ* in creation is little known. They undoubtedly purify the water in which they live in the same manner as other plants, and furnish food to a number of fresh-water animals. As they do not attach themselves to external objects they are seldom found living in running streams. They are sometimes found in the beds of large rivers, and several species are enumerated by Drs. Lankester and Redfern, in their report on the 'Microscopical Characters of the Water of the Thames.' The best places for procuring them are small shallow pools which do not dry up in the summer. Mr. Ralfs says, however, that the same species never occur in the same pools two years in succession. They prefer open moors and exposed places, and are rarely found in woods, shady places, or deep ditches. They are seldom found in turbid water of any kind. In this respect they are the opposite of their congeners the *Diatomaceæ*, which almost as a rule are found where the *Desmidieæ* are not.

The best way of procuring them for examination is to take a piece of linen, lay it on the ground in the form of a bag, and then, by the aid of a tin box or ladle, scoop up the water, and strain it through the bag. After this process has been repeated a few times, the specimens of *Desmidieæ* will be found in great abundance on the linen, which, if kept moist, will allow of the growth and development of these beautiful objects for many months.

The study of this family will undoubtedly amply repay the naturalist for years to come. Comparatively little is known of the species beyond the continent of Europe. The following is an analysis of the genera found by Mr. Ralfs in the British Islands :—

*

Plant an elongated jointed filament. Sporangia orbicular, smooth.

1. *Hyalotheca.*—Filament cylindrical. Two species.
2. *Didymoprium.*—Filament cylindrical, or sub-cylindrical. Joints with two opposite or dentate projections. (*Fig.* 1.) Two species.
3. *Desmidium.*—Filament triangular, or quadrangular; joints connected by a thickened border. Two species.
4. *Aptogonum.*—Filament triangular or plane, with foramina between the joints. One species.
5. *Sphærozosma.*—Filament plane, margins incised or sinuated; joints with junction-glands. Two species.

**

Frond simple from complete transverse division, distinctly constricted at the junction of the segments, which are seldom longer than broad; sporangia spinous or tuberculated, rarely if ever smooth.

6. *Micrasterias.*—Lobes of the segments incised or bidentate. (*Fig.* 2.) Thirteen species.
7. *Euastrum.*—Segments sinuated, generally notched at the end, and with inflated protuberances. (*Fig.* 3.) Eighteen species.
8. *Cosmarium.*—Segments in front view neither notched nor sinuated; in end view elliptic, circular, or cruciform. Thirty-three species.
9. *Xanthidium.*—Segments compressed, entire, and spinous. (*Figs.* 4 and 5.) Six species.
10. *Arthrodesmus.*—Segments compressed, and having only two spines or mucros. Two species.
11. *Staurastrum.*—End view angular, radiate, or with elongated processes which are never geminate. Forty species.
12. *Didymocladon.*—Segments angular, each angle having two processes, one inferior and parallel with the similar one of the other segment, the other superior and divergent. One species.

***

Frond simple, from complete transverse division, generally much elongated, never spinous, frequently not constricted at the centre. Sporangia smooth.

13. *Tetmemorus.*—Frond straight, constricted at the centre, and notched at the ends. Three species.
14. *Penium.*—Frond straight, scarcely constricted at the centre. Eight species.
15. *Docidium.*—Frond straight, much elongated, constricted at the centre, truncate at the ends. Seven species.
16. *Closterium.*—Frond crescent-shaped or arcuate, not constricted at the centre. (*Fig.* 6.) Twenty-two species.
17. *Spirotænia.*—Frond straight, not constricted at the centre; endochrome spirally twisted. Two species.

****

Cells elongated, entire, fasciculated.

18. *Ankistrodesmus.* Cells aggregated into faggot-like bundles. (*Fig.* 9). One species.

*****

Frond composed of few cells, definite in number, and not forming a filament. (Sporangia unknown).

19. *Pediastrum.*—Cells arranged in the form of a flattened star, their outer margin bidentate. (*Figs.* 7 & 8.) Eleven species.
20. *Scenedesmus.*—Cells oblong or fusiform, entire, placed side by side in a single row, but during division into two rows. Six species.

(Ralfs and Jenner, *British Desmidieæ;* Siebold, *On Unicellular Plants and Animals*, in *Mic. Journal*, 1853; Meneghini, *On the Animal Nature of Diatomaceæ*, translated by Ray Society, 1854; A. Braun, *On Rejuvenescence in the Plant*, translated by Ray Society, 1854; Lindley, *Vegetable Kingdom*; Nägeli, *Gattungen einzelliger Algen physiologisch und systematisch bearbeitet*, Zurich, 1849; Cohn, *On the Natural History of Protococcus pluvialis*, translated by Ray Society, 1854.)

DESMOPHY'LLUM, a genus of Fossil Radiate Animals belonging to the Zoophites found in the London Clay of Sheppey. ('Geol. Trans.,' N. S., vol. v. t. 8, f. i.)

DESVAUXIA'CEÆ, *Bristleworts*, an obscure and little known natural order of Plants, consisting of a few Australian sedge-like herbs, of no known utility. They are nearly related to *Restiaceæ* and *Eriocaulaceæ*, and are principally charaterised among other Glumose Endogens by having several carpels placed in the middle of each flower. The most recent character is the following, given by Endlicher in his 'Genera Plantarum':—

Dwarf Australian herbs with the appearance of a pigmy *Cyperus* or *Scirpus;* the roots fibrous or fasciculated. Culms filiform, undivided, leafless. Leaves radical, between thread-shaped and bristly, sheathing at the base. Spikelets hermaphrodite, in two ranks, 1-flowered, or terminal and solitary with one or many florets. Glume single, anterior, or two nearly opposite each other, coarse. Paleæ none, or delicate, single or double, parallel with the glumes. Stamen single, anterior. Filament filiform, simple. Anthers turned inwards, 1-celled, attached by the back above the base. Ovary either single and sessile (we would exclude this character) or several attached to a common axis at different heights, imbricated downwards, 1-celled. Ovule solitary, suspended from the apex of the ovary, orthotropous, with the foramen regarding the base of the ovary. Styles filiform, simple, united to each other at the base. Stigmas simple, or with a feathery beard. Utricles membranous, dehiscing lengthwise at the side. Seed orthotropous, pendulous; skin leathery and rather hard. Albumen fleshy and abundant. Embryo antitropous, lenticular, applied to the albumen at the extremity of the seed opposite the umbilicus; the radicular extremity papillose, and regarding the base of the fruit. ('Genera Plantarum,' p. 119.)

There are 4 genera and 15 species in this order.

DETRI'TUS and DEBRIS, two words now universally received into the language, the former of Latin, the latter of French origin. They are very frequently employed in works of geology and physical geography, when treating of the formation of alluvial deposits. By Debris, in geological language, is meant generally the fragments of rocks, boulders, gravel, sand, trunks of trees, carcasses of animals, &c., detached from the summits and sides of mountains by the effect of the elements, or resulting from sudden convulsions at the surface of the earth. By Detritus we understand the same Debris finely comminuted or pulverised by attrition. Debris in general comprises Detritus; but Detritus excludes the idea of the larger Debris.

Modern Debris seldom extends beyond the foot of the mountains whence it is derived, the channels of torrents, and the higher parts of the beds of rivers; Detritus alone, except in the case of such things as float, being carried down to the mouths of large streams. The boulders which lie strewn over such great extents of land, and which are found at great depths below the surface-soil, together with fossil-trees, bones of animals, &c., are the Debris of a former age, no cause now in action being apparently capable of bringing them to such distances from their original sites.

DEUTZIA, a genus of Plants belonging to the natural order *Philadelphaceæ*, inhabiting the North of India, China, and Japan. The tube of the calyx is campanulate, tomentose, the limb 5- or 6-cleft. The petals 5 or 6, and oblong. The leaves are opposite, petiolate, ovate, acuminated, serrated, wrinkled, and veined.

D. scabra has its leaves covered with stellate siliceous hairs, which makes them very rough, and renders them of use to cabinet-makers as polishing agents. The siliceous bodies are beautiful objects viewed by reflected light under the microscope.

DEVIL IN A BUSH, } Vulgar names of the genus *Nigella.*
DEVIL IN A MIST, } [NIGELLA.]

DEVIL'S APPLE. [MANDRAGORA.]

DEVIL'S BIT, the vulgar name of *Scabiosa succisa.* [SCABIOSA.]

DEVIL'S LEAF. [URTICA.]

DEVONIAN SYSTEM. A great portion of the Palæozoic Strata of North and South Devon has been thus termed by Sedgwick and Murchison ('Geol. Trans.'), and also referred to as of coeval formation with the Old Red-Sandstone of Herefordshire. Further investigation has shown that a portion of the strata in North Devon belongs to the Carboniferous System, and is equivalent to the lowest shales and sandstones thereof. The Old Red-Sandstone must certainly be admitted to be coeval with some parts of the Devonian Strata, which besides contain several red-sandstone members; but there is reason to think that the true place of much of the stratification of South Devon, on the ordinary geological scale, is rather about the upper part of the Old Red-Sandstone; and this mode of viewing these rocks harmonises with the distribution of organic remains in the Silurian, Devonian, and Carboniferous Deposits.

The following table by Professor Sedgwick gives at one view the relation of the rocks which enter into the composition of the Devonian Formation:—

Lower or Plymouth Group.	Dartmouth Slate, Plymouth Limestone and Red Grit, and Liskeard Slate.
Middle or Caithness Group.	Hereford Sandstone, Marl, and Cornstone, Dipterous Flag.
Upper or Petherwin Group.	Petherwin Slate and Clymenia Limestone, Marwood Sandstone.

The Devonian Formation is represented in Belgium and the Rhenish provinces, in Russia, America, and probably also in Van Diemen's Land.

With regard to the development of this great system, Mr. Jukes says—"The history of the production of the Devonian Rocks seems to be this:—At the close of the Silurian period, or during its later portion, great dislocations and elevations took place, by which the Silurian Rocks, and especially the Lower Silurians of the larger and more northerly portions of the British Islands, became much broken and contorted, and in many places lifted up into dry land. Granite was protruded into them in the south-east of Ireland, and probably also the granites of the north-east of Ireland and of the north of England and south of Scotland, were formed at this time. Great denudations also took place, by which some of the granite of the south-east of Ireland (if not that of the other districts) was brought to the surface. Upon the uneven ground thus formed, as it was slowly depressed again, the Old Red-Sandstone was deposited, consisting largely of the detritus produced by this denudation.

"But in the south-west of Ireland and England neither disturbance nor denudation took place to anything like the same amount, the locality remaining probably a pretty deep sea, in which fine-grained mechanical and some chemical depositions were formed, partly contemporaneously with the Old Red-Sandstone proper, and partly subsequent to it.

"If we are allowed to continue this hypothetical history a little longer, we should say that at the close of the Devonian period a subsidence of almost the whole country had occurred, and in the sea thus formed was deposited the Carboniferous Limestone, resting in level sheets on the floor of the Old Red-Sandstone, that had filled up and levelled the hollows and inequalities in the older rocks. When the Carboniferous Limestone had been formed, the Coal-Measures were accumulated on the top of it, setting in first of all as thick sandy deposits, and then as alternations of sandy and shaly beds, with an occasional bed of coal. The depression being suspended, and the sea, having been partially filled by the accumulation of the Carboniferous Limestone, was made still shoaler by the sandstones and shales of the Millstone Grit and Coal-Measures, so that, according to some, it was entirely filled up to its surface, in order to produce a bed of coal, while every one agrees that it must have nearly been so.

"Depression then recommenced, allowing the accumulation of several thousand feet of coal-measures, all successively produced in comparatively shoal water."

(Jukes, *Physical Geology*.)

DEWBERRY, a kind of bramble, the *Rubus cæsius* of botanists. [RUBUS.]

DEWEYLITE, a name for Serpentine. [SERPENTINE.]

DEXAMINE, a genus of Amphipodous *Crustacea*, established by Dr. Leach. The following are its characters:—Antennæ 3-jointed, the last segment composed of a number of minute joints; first segment shorter than the second; upper antennæ longest. Eyes oblong, not prominent, inserted behind the superior antennæ. Legs fourteen; first and second pairs monodactyle, with a small compressed hand; other pairs furnished with simple claws. Tail, on each side, with three double styles; above, with one small style on each side. Body, (including the head) 12-jointed. (Leach.)

D. spinosa. Body shining, the ninth, tenth, eleventh, and twelfth segments produced into a spine; front produced and bent downwards between the antennæ. The first joint of the upper antennæ beneath, towards their tips, have a little spine-like process. Length three-quarters of an inch. (Leach.)

Dr. Leach says that it is very common on the southern coasts of England, and is often taken by the shore-net, or beneath stones amongst the rocks at low tide. The legs, he observes, are easily broken, which will account for Montagu's having described and figured it (*Cancer* (*Gammarus*) *spinosus*) without the monodactyle hands.

DEXIARIÆ, a family of Dipterous Insects of the section *Creophilæ*. This family, established by M. Robineau Desvoidy, is composed chiefly of Meigen's genus *Dexia*. The species may be distinguished from those of neighbouring groups by the greater length of their legs: the body is generally elongated and cylindrical, but sometimes thick, depressed, or rounded. The fore part of the head is, in most of the species, furnished with a ridge situated between the deep grooves in which the antennæ are placed; the antennæ are rather short, and the stylet is generally plumose; the eyes are separated in both sexes, and the males are usually larger than the females. These flies are of inoffensive habits; they are usually seen on flowers, the juices of which afford them nourishment.

The chief characters of the genera contained in the *Dexiariæ* are thrown into a tabular form by M. Macquart, in the following manner:—

Genus 1. *Prosena*, St. Fargeau.

Proboscis long.
Proboscis short.
Body cylindrical.
First posterior cellule of the wings closed.
Second and third joints of the antennæ of equal length.

Genus 2. *Zeuxia*, Meigen.

Third joint of the antennæ longer than the second.

Genus 3. *Dinera*, Desvoidy.

First posterior cellule of the wings open.
Antennæ not extending to the epistoma.

Genus 4. *Dexia*, Meigen.

Antennæ extending to the epistoma. Legs very long.

Genus 5. *Scotiptera*, Macquart.

Body tolerably broad, depressed.
Fore part of the head arched (colours brilliant).

Genus 6. *Rutila*, Desvoidy.

Fore part of the head flat (colours, black or yellow).
Stylet of the antennæ naked.

Genus 7. *Gymnostyla*, Macquart.

Stylet of the antennæ covered with fine hairs.

Genus 8. *Omalogaster*, Macquart.

Of the genus *Prosena* Macquart describes only two species, one of which inhabits Europe, and the other is from Brazil.

Of the genus *Zeuxia* but one species is known.

The genus *Dinera* contains five species, one of which inhabits Brazil, and the others are found in various parts of Europe.

The genus *Dexia* contains twelve species, almost all of which are European.

The genus *Scotiptera* contains two species; they are of considerable size, and inhabit Brazil.

Rutila.—The species of this genus appear to be confined to Australia; they are generally of large size.

The genus *Gymnostyla* contains three species, two of which are from Brazil and the third is from Surinam.

The last genus, *Omalogaster*, contains four species, all of which are inhabitants of Europe.

DEXTRINE is a vegetable substance found in the interior of the cells of plants. It can be artificially procured by treating starch with diastase. Mulder has shown that dextrine may also be obtained from cellulose both by sulphuric acid and by diastase. The quantity of diastase required is extremely minute; if too much be used, or the process continued too long, grape-sugar is produced. It is by these or similar means that nature converts cellulose into dextrine, and dextrine or starch into sugar. As in malting barley, diastase is naturally produced with the starch, there is no reason why it should not in a similar manner be produced in the growing plant, and thus convert the cellulose into dextrine. [DIASTASE.]

The sap of nearly all plants contains a certain amount of dextrine, which, having the same chemical composition ($C_{12}\ H_{10}\ O_{10}$) as gum, and in many other points resembling it, has been in most analyses put down as gum. If one equivalent of water (HO) be taken from one equivalent of cellulose ($C_{24}\ H_{21}\ O_{21}$), two equivalents either of gum or dextrine [$2\ (C_{12}\ H_{10}\ O_{10})$] are formed. Thus a part of the cellular membranes may be converted into dextrine by catalysis without destroying the cells, if the vegetable sap, while passing through them, contains only a very minute quantity of diastase, or of a substance resembling it.

Gum and dextrine have been frequently confounded. The most important difference between them is, that the latter may be changed into grape-sugar by sulphuric acid or diastase, while the former is incapable of undergoing that change.

Dextrine belongs to that class of matters which are taken into the blood; all the starch taken as food being converted by the gastric juice into it. The gums are not taken up; they become mere excretions, and are apparently of little or no importance.

There seems every reason for believing that dextrine is the source of the cellular matter, for it is a universal constituent of all parts of plants. We are justified in assuming that the sap of plants must contain the elementary matter of cellulose in a state of solution, so as to be able to penetrate through the cell-walls, and to supply new substance to increase the number of cells. No material but dextrine is fitted for this office, though in young plants sugar also contributes to it. By the production, during germination, of dextrine and sugar, we are led to believe that the cellulose of the young plant is really formed from this dextrine and from the sugar in the germinating cotyledons. Whilst many full-grown plants do not contain sugar, all contain dextrine, so that the use of the latter in the formation of cells cannot be doubted.

Dextrine is not merely a source of cellulose, but likewise of starch, sugar, gum, and perhaps other vegetable substances; it is almost as valuable to plants as protein is to animals, for it is a constituent from which their organism derives its most important products. The composition of dextrine being $C_{12}\ H_{10}\ O_{10}$, the formation of cellulose is accomplished by every two equivalents of dextrine taking up one eqivalent of water. Thus

$$2\ (C_{12}\ H_{10}\ O_{10}) + HO = C_{24}\ H_{21}\ O_{21} = \text{Cellulose.}$$

Starch and gum contain the same elements in the same proportions as dextrine, and hence for their production require merely a re-arrangement of the molecules. For an account of the relation of Dextrine to the other secretions of plants, see the article SECRETIONS, VEGETABLE.

DIA'COPE, a genus of Fishes belonging to the section *Acanthopterygii* and family *Percidæ*, and belonging to that section of the family in which the species have less than seven branchiostegous rays, and an interrupted lateral line.

This genus is allied to *Serranus*, but may be distinguished by there being a notch or emargination in the lower part of the preoperculum, into which is fitted a projecting tubercle.

Many large and beautiful species of this genus inhabit the Indian seas. *Diacope octolineata*, a very beautiful species, caught off the coast of the Mauritius, is of a brilliant reddish-yellow colour, shaded into white on the belly, and is adorned with four longitudinal blue stripes on each side of the body; these stripes are margined with black. It is about 10 inches in length.

Some of the species are known to have attained the length of 3 feet and upwards.

DIADE'LPHIA, the seventeenth class in the Linnæan system of arranging plants. Strictly speaking it ought to contain no genera but those which have their stamens united into two equal or unequal parcels; but as it consists principally of Leguminous genera it is customary to place in it all the Papilionaceous plants which have united stamens, whether in one parcel or two. This and similar plans render the Linnæan system more natural, but destroy its use as an artificial guide to the determination of the name of a plant.

DIADEMA. [CIRRIPEDIA.]

DIALLAGE. [AUGITE.]

DIAMOND, a crystalline gem, which, on account of its high lustre and extreme hardness, has always been regarded as the most valuable of the precious stones; the former of these qualities arises from its great refractive power, and on account of its hardness its lustre remains undiminished. It is commonly colourless or grayish, but sometimes green, yellow, red, brown, blue, and black; the two last-mentioned colours are the rarest. Its lustre is adamantine; refraction single; transparent, but sometimes rendered opaque by foreign matter. Hardness 10, exceeding that of any other, and scratching every other substance; owing to its hardness it can be cut, or rather worn down, only by rubbing one diamond against another, and it is polished by the friction of portions of the gem itself reduced to powder: it is broken without difficulty. The specific gravity of the diamond is from 3·48 to 3·55; streak grayish; fracture conchoidal; cleavage parallel to the planes of the regular octahedron, which is its primary form, subject however to numerous varieties, and the faces are frequently curvilinear. When rubbed it phosphorises, and becomes positively electrical, and is therefore a non-conductor of electricity. When heated, without the contact of air, it suffers no change, but if ignited in contact with it, it is totally converted into carbonic acid gas, proving that it is carbon in a state of purity.

For ornamental purposes diamonds are cut into two shapes: namely, Rose-Diamonds and Brilliants, the former being, for the most part, made out of the octahedral crystals, and the latter from those with curvilinear faces. The weight and consequently the value of diamonds are estimated in carats, each of which is equal to 3·166 grains. In the formation of either a brilliant or a rose-diamond so much is cut away that the weight of the polished gem is not more than half that of the rough crystal out of which it was formed.

Newton, considering the fact that transparent bodies which are uninflammable refract light nearly in the ratio of their density, while those which are inflammable have refractive powers that are greater than their density, was led to conclude that the diamond, on account of this great refractive power, was "probably an unctuous substance coagulated."

In 1695 experiments were made at Florence, which proved the diamond to be dissipated by intense heat in the focus of a burning lens. Several chemists proved that diamonds lost no weight when heated without the contact of air, and on the contrary, that they were dissipated when heated in it; but it was first shown by Lavoisier that carbonic acid was obtained by the combustion of the diamond, and he concluded that it contained carbon, and had great analogy with this combustible body.

These researches were not however sufficient to afford complete proof of the nature of the diamond; but this was accomplished by the succeeding experiments of Smithson, Tennant, Guyton Morveau, Allen and Pepys, and Davy, who all arrived at the same conclusion, which is, that although there exists in many respects so great a difference between the properties of the diamond and charcoal, they are identical in their chemical nature. Thus, whenever by combustion 6 parts of charcoal, or an equal weight of diamond, are combined with oxygen, the quantity of oxygen absorbed always amounts to 16 parts, and the result of their combustion is 22 parts of carbonic acid.

Diamonds occur in India in the district between Golconda and Masulipatam, near Panna, in Bundelcund, also on the Mahanuddy, and in Ellore. They have been obtained in Borneo, on the west side of the Ratoos Mountain, with gold and platina. The Brazilian mines were first discovered in 1728, in the district of Serra do Frio, to the north of Rio de Janeiro. The largest diamonds are procured on the river Jequitinhonha, which is called the Diamond River, also Rio Pardo. In the Ural Mountains diamonds were detected in 1829, by Humboldt and Rose, in their journey into Siberia. In the United States the diamond has been met with in Rutherford county, North Carolina, and Hale county, Georgia. They have been found on the river Ginul, in the province of Constantine, in Africa. They have also been discovered in Australia, and of such size as to render it probable they may add yet more to the mineral treasures of that country.

The rocks in which the diamond occurs in Brazil are either a ferruginous quartzose conglomerate, or a laminated granular quartz called *Itacolumite*. The latter rock occurs in the Urals, and diamonds have been found in it; and it is also abundant in Georgia and North Carolina. In India the rock is a quartzose conglomerate.

In most instances diamonds are obtained from alluvial washings. In Brazil the sands and pebbles of the diamond streams are collected and washed under a shed by a stream of water passing through a succession of boxes. A negro washer is stationed at each box. When a diamond is found weighing 17½ carats the negro is entitled to his liberty.

"The largest diamond of which we have any knowledge is mentioned by Tavernier as in the possession of the Great Mogul. It weighed originally 900 carats, or 2769·3 grains, but was reduced by cutting to 861 grains. It has the form and size of half a hen's egg. It was found in 1550, in the mine of Colone. The diamond which formed the eye of a Brahminican idol, and was purchased by the empress Catharine II. of Russia from a French grenadier, who had stolen it, weighs 193 carats, and is as large as a pigeon's egg. The Pitt, or Regent Diamond, is of less size, weighing but 136·5 carats, or 419½ grains; but on account of its unblemished transparency and colour it is considered the most splendid of Indian diamonds. It was sold to the Duke of Orleans by Mr. Pitt, an English gentleman, who was governor of Bencolen, in Sumatra, for 130,000*l*. It is cut to the form of a brilliant, and is estimated at 125,000*l*. Napoleon placed it in the hilt of his sword of state. The Raja of Mattan has in his possession a diamond from Borneo weighing 367 carats." (Dana.)

The great diamond mentioned in the above extract as in the possession of the Great Mogul appears to be the identical diamond which, under the name of Koh-i-Noor, excited so much attention at the Great Exhibition in 1851. Some doubt is thrown on Tavernier's statement of its being cut. This precious gem has seen a variety of fortunes. Its early history is mythical. From the Great Mogul it passed into the possession of the reigning family of Cabul. When Shah Suja was driven from Cabul he became the nominal guest and actual prisoner of Runjet Sing, who spared no means to obtain possession of the precious gem. In this he succeeded in 1813. After the death of Runjet the diamond was preserved for a while by his successors. It was occasionally worn by Khunuk Sing and Shire Sing. After the murder of the latter it remained in the Lahore treasury until the supercession of Dhuleep Sing and the annexation of the Panjab by the British government, when the civil authorities took possession of the Lahore treasury, under the stipulation previously made that all the property of the state should be confiscated to the East India Company, in part payment of the debt due by the Lahore government and of the expenses of the war. It was at the same time stipulated that the Koh-i-Noor should be surrendered to the Queen of England. It arrived in this country on the 30th of June, 1850, and on the 3rd of July was presented to her Majesty. Since its public exhibition in 1851 it has been submitted to the process of cutting, which has much enhanced its beauty and value.

The diamond is cut by taking advantage of its cleavage, and also by abrasion with its own powder, and by friction with another diamond. It is a process of great labour, and many hours are spent in producing a single facet. Diamonds were first cut in Europe in 1456 by Louis Berquen, a citizen of Bruges.

The diamond is used for cutting glass. [DIAMOND, in ARTS AND SC. DIV.] It is also employed for the lenses of microscopes. It has but little chromatic aberration, but the frequent irregularity of its structure is a drawback to its employment for this purpose.

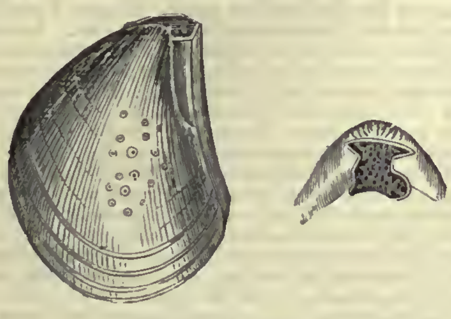
(Dana, *Manual of Mineralogy*; *Catalogue of Great Exhibition of* 1851, Class xxiii.)

DIAMOND-BEETLE. [CURCULIO.]

DIANÆA. [ACALEPHÆ.]

DIA'NCHORA, a Fossil genus of *Conchifera* allied to *Spondylus*, established by Mr. Sowerby in his 'Mineral Conchology.' It has the following characters:—Shell delicate, adherent, regular, symmetrical, equilateral, subauriculated, inequivalve; one valve hollowed within, convex without; the other flat. Hinge consisting of two distant condyles.

Cuvier ('Règne Animal') places the genus between *Pachytes* and *Podopsis*, M. de Blainville between *Plagiostoma* and *Podopsis*, and M. Rang between *Pecten* and *Pedum*. M. Deshayes, in his edition of Lamarck, after observing that *Pachytes* had been formed at the expense of *Plagiostoma*, states that his examination of the species had satisfied him of the identity of the genera, and that the same examination instituted with regard to *Dianchora* had convinced him that the characters of the last-named genus were identical with those of *Pachytes* and *Podopsis*. A further inquiry terminated in the conclusion that the so-called genera, *Podopsis*, *Dianchora*, and *Pachytes*, were only *Spondyli*, whose internal lamina had been dissolved, and had left naked the external or conical lamina. [SPONDYLUS.] The subjoined cut will convey to the reader the form of one of the so-called species.



Dianchora striata.

Four species of this genus have been found in the Chalk and Green-sand :—*D. lata*, Sowerby; *D. obliqua*, Mantell; *D. striata*, Sowerby; *D. truncata*, Lamarck.

DIA'NDRIA, the second class in the Linnæan system of arranging plants. It comprehends all genera with flowers having only two stamens, provided the stamens are neither united at their base, nor combined with the style and stigma, nor separated from the pistil.

DIANTHUS, a beautiful genus of Silenaceous Dicotyledonous Plants, with a calyx closely covered at the base by two, three, or four opposite pairs of decussating rigid sharp-pointed bracts. The petals are always more or less lacerated at the end, and in some species are divided into fine capillary segments. There are 10 stamens, 2 styles, and the capsule is 1-celled, with numerous black seeds containing a straight embryo. In all cases the leaves are long, narrow, 1-ribbed, sharp-pointed, and destitute of all lateral reticulated veining. De Candolle enumerates 113 species, of which some must undoubtedly be reduced to simple varieties. They are found in all the temperate parts of Europe and Asia, from Ireland to the eastern coast of China and Japan; two have been met with in the United States of America, and four at the Cape of Good Hope. Most of them are perennial herbaceous plants with permanent leaves and stems, and hence they ought perhaps to be considered under-shrubs; a few become woody and form genuine bushes.

D. barbatus, the Bearded Pink or Sweet William, has aggregate flowers in bundles; calycine scales ovate, awl-shaped, equal in length to the tube; the petals bearded; leaves lanceolate and nerved. It is a native of the south of France and Germany, in gravelly or sandy places. The flowers are very variable in colour, from dark purple to white, or variegated or speckled, single and double. Sweet William is a very favourite and old-fashioned inhabitant of the garden, and was much esteemed in the time of Gerarde for its beauty.

D. Caryophyllus, the Carnation, is a native of the south of France, and in England on old walls in Kent and Norfolk. It has solitary flowers; the calyx-scales broadly obovate, pointed, four times shorter than the tube; the leaves with smooth linear margins; the petals crenate, dentate, ovate, glabrous; the stem barren, elongated, procumbent, branching; the seeds pyriform, nearly flat; the flower-stems are from 12 to 18 inches high; the calyx-teeth not ciliated, longer than the capsule. The flowers are of all colours, excepting blue: in the British species they are of a pale pink, and in all cases fragrant. The flowers of the variety of this species, known as the Clove-Pink, are used to give a colour and fragrance to an officinal syrup used in pharmacy. A small variety of the species is known by the name of Picotees.

D. plumarius is the type of the Common Garden-Pink. It is a native of Europe, and is found in England on old walls and ruins. It has solitary flowers, two or three on a stem; the calyx-scales are roundish-ovate, shortly mucronate, four times shorter thau the tube; the leaves rough at the margin, linear, subulate; the petals digitate, multifid as far as the middle, with the central entire part obovate, downy; the stem barren, procumbent, rooting, much-branched; tho seeds flat, orbicular, with a point on one side; the flowering stems are from 6 to 12 inches high; the calyx-teeth are ciliated at the margin, slightly shorter than the capsule. The flowers are either double or single, white, pink, spotted, or variegated, and sweet-scented.

Of the species of this genus six are British, and are described by Mr. Babington in his 'Manual of British Botany.'

For the cultivation of the Carnation, Pink, &c., see PINK, in ARTS AND SC. DIV.

DIAPENSIA'CEÆ, *Diapensiads*, a very small natural order of Monopetalous Exogenous Plants, formerly referred to *Convolvulaceæ*, but in reality are more nearly allied to *Loganiaceæ* and *Stilbaceæ*. Only two genera, *Diapensia* and *Pyxidanthera*, are known; they consist of small depressed half-shrubby species, with the habit of a minute-leaved *Phlox*. Their calyx grows in a broken whorl; the corolla has an imbricated æstivation with five lobes, and as many stamens growing from its margin in the sinuses; the anthers have a broad connective, and burst transversely; the ovary is 3-celled, with a good many ovules growing upon central placentæ; finally, the embryo lies across the hilum, in the midst of fleshy albumen. No use has hitherto been made of these plants. (Lindley, *Vegetable Kingdom.*)

DIAPHRAGM (Διάφραγμα), *Septum Transversum*, *Transverse Partition*, *Midriff*, a circular Muscle, placed between the thorax and abdomen, forming a moveable partition between these two great cavities. Its borders, which are broad and fleshy, are moveable; its central portion, which is tendinous, is fixed and immoveable. When not in action, its upper surface, or that towards the thorax, is convex, presents the appearance of an arch, which reaches as high as the fourth rib, and is covered by the pleura, the membrane which lines the cavity of the thorax. Its under surface, or that towards the abdomen, is concave, and is covered by the peritoneum, the membrane which lines the cavity of the abdomen. It is perforated by several apertures, through which important organs pass from the thorax into the abdomen, and from the abdomen into the thorax. In its tendinous portion, between what is called its crura, or legs, there is an oval aperture through which the aorta, or great artery of the trunk, passes from the thorax into the abdomen, and the thoracic duct enters from the abdomen into the thorax. A little above this and to the left of it, in the fleshy portion of the diaphragm, is an aperture through which the œsophagus passes in its course from the mouth to the stomach. On the right side of the diaphragm, in its tendinous portion, is a third aperture, through which the inferior vena cava passes from the abdomen to the heart.

The diaphragm is a muscle of extreme complexity in its structure, and next to the heart performs the most important function of any muscle in the body. Its most important office is connected with tho function of respiration, and it is the principal agent both in enlarging the cavity of the thorax in inspiration and in diminishing it in expiration. These actions it performs by virtue of the power of alternate contraction and relaxation which it possesses in common with all muscles. When in the state of relaxation, as in expiration, its broad lateral moveable borders present an expanded arch, the convexity of which reaches, as has been stated, as high as the fourth rib; when in action, as in the state of inspiration, the fibres composing the lateral borders contract, whence this moveable partition descends, until from the form of an arch it presents a plane surface, increasing the capacity of the thorax by all the space that intervenes between the fourth rib and the lowest point to which the diaphragm is capable of descending. The fibres then relaxing, the moveable borders are pushed up by the contraction of the powerful muscles of the abdomen, until the diaphragm again assumes the form of an arch, diminishing the capacity of the thorax by all the space that intervenes between the lowest point to which it descends and the fourth rib. These alternate actions, which are performed in regular and uninterrupted succession, day and night, during our sleeping and our waking hours, from the moment of birth to that of death, constitute the principal portion of the mechanical part of the function of respiration or breathing, by which air and blood flow to and from the lungs. During these actions the central portion of the diaphragm, on which the heart rests, and to which the pericardium is attached, never moves; so that though the diaphragm is in constant motion it never disturbs the action of the heart, which it assists in supporting, and the function of the circulation is not disordered by the movements which are indispensable to the function of respiration.

There is a fixed relation between the action of the diaphragm and of the abdominal muscles. When the diaphragm contracts tho abdominal muscles relax; when the abdominal muscles relax the diaphragm contracts. The diaphragm is the antagonist of the abdominal muscles in inspiration; but it acts in concert with them in vomiting, in the discharge of the contents of the bowels and of the urinary bladder, and in assisting the expulsion of the fœtus in parturition. To produce the respiratory movements, and to assist in the expulsion of the fæces, the urine, and the fœtus, may be considered the natural and regular offices of the diaphragm; but it conduces to the performance of many other actions. It is the principal agent in vomiting, yawning, coughing, laughing, crying, and in hiccup, which may be regarded as its more powerful and irregular actions.

For diagrams representing the position of the diaphragm and its relation to the other organs of the body, see ABDOMEN and HEART.

DIASPORE, a Mineral. It is a dihydrate of alumina, and occurs massive and crystallised. Its primary form is a doubly oblique prism. The colour is slightly greenish-gray and yellowish-brown. Its hardness is 6·0 to 6·5. It is slightly translucent. The specific gravity is 3·43. It is found at Kosoihrod in the Orenburg government of Asiatic Russia. The massive variety occurs in slightly curvilinear laminæ of a shining pearly lustre and greenish-gray colour; also in cellular masses, constituted of slender crystals, which have a pearly lustre, and intercept each other in every direction; of a brown hue externally, but prefectly transparent and colourless when reduced to thin laminæ. The following is an analysis by Hess:—

Alumina	85·14
Water	14·56

The brown variety, analysed by Children, gave—

Alumina	76·06
Water	14·70
Oxide of Iron	7·78
Loss	1·46

DIASTASE, a substance formed during the germination of plants. It can be artificially prepared by reducing freshly germinated barley into a pulp, with half its weight of water, and then pressing out the liquor strongly. To the clear liquid just sufficient alcohol is to be added to destroy its viscidity and allow of its being filtered; by this an azotised substance is precipitated, which must be considered as vegetable albumen, since it coagulates at 167° Fahr. Having separated this, alcohol is again to be added as long as the liquid becomes turbid; the precipitate is to be purified by solution in water and precipitation by alcohol repeatedly; the precipitate is at last to be dried in thin layers upon glass at a temperature between 104° and 122° Fahr.

The properties of diastase are the following:—It is solid, white, not crystalline, soluble in water, but insoluble in alcohol unless it be weak; the aqueous solution is nearly tasteless, and without any chemical action, not precipitating subacetate of lead. The aqueous solution quickly changes, becoming acid: dry diastase undergoes the same change in a longer time, but when boiled in water the alteration is immediate. Common malt is stated in general not to contain more than 1-500th of its weight of diastase: one part of it is sufficient to convert 2000 parts of starch, thickened with water, into a mixture consisting of much dextrine and a little sugar. It has not yet been obtained absolutely pure. There can be little doubt that diastase is one of the forms of protein; and its reaction upon starch is not different from that which takes place with some other forms of the same substance. Schleiden includes it amongst the nitrogenous substances of plants, to which he gives the name Schleim (mucus).

(Schleiden, *Principles of Scientific Botany*, p. 23.)

DIA'STYLIS, a genus of Crustacean Animals established by M. Say.

It has the following characters.—Four antennæ placed nearly on the same line; the intermediate antennæ bifid, having a peduncle of three joints, the external simple, with the first joint long, and without a scale. External jaw-feet very large, pediform, very much approximated to the front, with the first joint long and compressed, and the others very small, cylindrical, and nearly equal. Corselet smooth, of six segments, of which the first, larger than all the others together, is terminated anteriorly by a short obtuse triangular rostrum, crenelated on its lateral edges. Six pairs of bifid feet; those of the first pair truncated at the end, and shorter than the external jaw-feet; those of the second terminated in a point; those of the third, fourth, and fifth pairs raised, pointed, without a nail, and terminated by strong hairs. Abdomen narrower than the thorax, formed of six segments, the last two of which support the natatory feet. Tail biarticulated, provided on each side of the first segment with a single bifid style, and on the extremity of the second with a simple cylindrical style.

D. arenarius. Length one-fifth of an inch. It is an inhabitant of the coasts of Georgia and Florida.

M. Say is of opinion that the *Cancer scorpionides* of Montagu, from the English coasts, and the *C. Esca* of Gmelin, from those of Norway, ought to be referred to this genus.

DIATOMACEÆ, or DIATOMEÆ, a group of organised beings which naturalists have placed in the animal and vegetable kingdoms, according as they have regarded their structures as most allied to the one kingdom or the other. These organisms consist of a single cell, and are remarkable for possessing a hard shell-valve or frustule, which is composed of silex or flint, and which remains permanent after its organic tissues have perished.

The following is a definition of this group of beings by one of the most recent writers on this subject:—Plant a frustule; consisting of a unilocular or imperfectly septate cell, invested with a bivalve siliceous epidermis. Gemmiparous increase, by self-division; during which process the cell secretes a more or less siliceous connecting membrane. Reproduction, by conjugation, and the formation of sporangia. (W. Smith.)

The *Diatomaceæ* are endowed with the power of motion; and when this function was supposed to be peculiar to the animal kingdom, it is not to be wondered at that the first observers of these organisms referred them to the animal kingdom. Ehrenberg, in his great work on the 'Infusorial Animalcules,' greatly enlarged our knowledge of this family, and added to the forms that were already known. He regarded them, as well as the *Desmidieæ*, and other beings which are now generally referred to the vegetable kingdom, as animals. The following are the principal points on which he relied for assigning to them this position:—

1st. The *Diatomaceæ* exhibit a peculiar spontaneous movement, which is produced by certain locomotive organs.

2nd. A large number of them have in the middle of the lateral surface an opening about which round corpuscles are situated, which become coloured blue when placed in water containing indigo, just as many of the Polygastic *Infusoria*.

3rd. The shells of the *Diatomaceæ* resemble in structure and conformation those which are seen in the *Mollusca* and other animals.

These arguments are met on the other side by the statement, that spontaneous movement is now known not to be specially animal, as the spores of many *Algæ*, and their entire fronds are known to be actively motile. In the next place the colouring of the interior by indigo also takes place in truly vegetable structures.

The complex structure of the minute siliceous frustules of the *Diatomaceæ* is a fact that has struck many observers. It certainly is without a parallel in the vegetable kingdom. Schleiden in his 'Principles of Scientific Botany,' after giving a minute analysis of the siliceous structure of *Navicula viridis* (*fig.* 6 represents this genus), says, "Such an artificial and complicated structure amongst plants has no explanation and is entirely without significance. In all true plants we find the silica present in a very different form, as minute scales or drops, and distributed through the substance of the cell-wall." Again, in another place he says, "This curious structure is wholly without analogy in the vegetable kingdom, and cannot be derived from the laws of vegetation with which we are at present acquainted."

More recently Professor Meneghini has come forward as an advocate of the animal nature of *Diatomaceæ*. In a very lucid and remarkable essay, published at Venice in 1845, he says:—

"If we suppose them to be plants, we must admit every frustule, every navicula, to be a cell. We must suppose this cell with walls penetrated by silica, developed within another cell of a different nature, at least in every case where there is a distinct peduncle or investing tube. In this siliceous wall we must recognise a complication certainly unequalled in the vegetable kingdom. It would still remain to be proved that the eminently nitrogenous internal substance corresponded with the gonimic substance, and that the oil-globules could take the place of starch. The multiplication would be a simple cellular deduplication (sdoppiamento), but it would remain to be proved that it takes place, as in other vegetable cells, either by the formation of two distinct primitive utricles or by the introflection or constriction of the wall itself. Finally, there would still remain unexplained the external motions and the internal changes, and we must prove Ehrenberg's observations on the exterior organs of motion to be false. But, again, admitting their animal nature, much would remain to be investigated, both in their organic structure and their vital functions; excepting this, so far as we know, we have only one difficulty to overcome, that of the probably ternary non-azotised composition of the external gelatinous substance of the peduncles and investing-tubes. But as the presence of nitrogen is not a positive character of animal nature, so the absence of it is not a proof of vegetable. And in order that the objection should really have some weight, it would be well to demonstrate that this substance is isomeric with starch. For then, supposing all the arguments in favour of the animal nature of *Diatomeæ* were proved by new and more circumstantial observations, this peculiarity, if it deserve the name of objection, might still be regarded as an important discovery. We should then have in the animal as well as in the vegetable kingdom a ternary substance similar to that forming the basis of the vegetable tissue."

Of the chemical composition of the *Diatomaceæ* little satisfactory has at present been made out. Professor Frankland of Manchester, according to the Rev. W. Smith, whose work on the British *Diatomaceæ* is one of the last that has hitherto been published, has found that a large amount of iron exists in the state of a silicate or protoxide in the siliceous frustules, which probably accounts for the brown or yellow colour of these organisms. On the application of tincture of iodine the internal membrane contracts on its contents, and converts these from a golden-yellow to a bright green. On the addition of sulphuric acid they exhibit a deep brown hue.

The fact which is most relied on to support the vegetable nature of the *Diatomaceæ*, by those who advocate this view, does not appear to have been known to Meneghini, and that is the conjugation of the cells of which they are composed in the same manner as in the *Desmidieæ*. [DESMIDIEÆ.] This discovery was made by Mr. Thwaites, and observed in species of *Eunotia* (*fig.* 1), in *Epithemia gibba* and *E. turgida* (*fig.* 19), *Fragilaria pectinalis*, and other species. This process takes place as follows:—Two individuals closely approximated dehisce in the middle of their long diameter, whereupon four protuberances arise, which meet four similar ones in the opposite frustule. These indicate the future channels by which the endochrome of the two frustules becomes united, as well as the spot where subsequently the double sporangium is developed (*figs.* 8, 19). From the sporangium the new individuals are developed. This process is precisely analogous to what takes place in the *Desmidieæ*, so that the frustules of the Diatoms must be regarded as cells of the same individual. "If we duly consider this fact," says Mr. Thwaites, "how much does it exalt the lower tribes of plants in our estimation! since we may contemplate an individual plant of them not as the single phyton—not as the single frond—not as the single cell—but it may be as the aggregate of thousands of these;—view it occupying as much space and exercising as great an influence in the economy of nature as the largest forest-tree!"

The mode by which the cells are multiplied amongst the *Diatomaceæ* appears to be strictly in accordance with what occurs generally in the vegetable kingdom. This process is one of self-division. The first step is the fission or division of the internal cell, "probably by the doubling-in of its membranous wall, and consequently the separation of the endochrome, or cell-contents; the central vesicle or cytoblast also dividing into two parts, which remove to a little distance from each other; these movements being simultaneous with a retrocession of the epidermal valves and the formation of the siliceous connecting-membrane already described. In the centre of the enlarged frustule, in exact apposition to the original valves and closely applied to them, there are now found two new valves, covering the surface of the cell-membranes along the line of fission. The divided portions of the endochrome spread themselves along the membrane which is embraced by the new valves, and there result two half-new frustules bound together by the connecting-membrane, generated during the process we have described.

"During the healthy life of the Diatom the process of self-division is being continually repeated; the two half-new frustules at once proceed to divide again each into two frustules, and thus the process continues. I have been unable to ascertain the time occupied in a single act of self-division, but supposing it to be completed in twenty-four hours, we should have, as the progeny of a single frustule, the amazing number of one thousand millions in a single month; a circumstance which will in some degree explain the sudden or at least rapid appearance of vast numbers of these organisms in localities where they were but a short time previously either unrecognised or only sparingly diffused." (Smith, p. 25.)

From a drawing by Mr. West.

The structure of the siliceous portion of the *Diatomaceæ* is the most remarkable part of their organisation. The following is Meneghini's account of this organ:—

"Every Diatom is formed of a siliceous shield and a soft substance therein contained. According to Kützing, this shield consists of pure silica, or, in some cases, perhaps, of silica combined with alumina. Nägeli further says that the silica is deposited in the outside of an organic membrane, which he believes to be of a vegetable nature. In fact, an organic membrane ought to exist, for the silica could not become solid except by crystallising or depositing itself on some pre-existing substance. On the other hand, we cannot admit, with Nägeli, that it has been deposited externally; for in many genera, and especially in the *Achnanthidia*, the siliceous shield is covered with a very delicate dilatable membrane, itself containing silica, as is proved by its sustaining unchanged the action of fire and acids. Therefore, comparing this shield with other organic formations, whether animal or vegetable, containing in like manner either silica or some other so-called mineral element, we may reasonably consider it to be formed of an organic tissue permeated by silica. This permeation may occur either in the wall of a simple cell, as is seen in the epidermal cells of many plants, or within minute cells, as in various plants and animals. The action of heat or of acid, in these cases, destroying the organic matter and leaving the silica untouched, does not alter the apparent form of the organ, because the skeleton remains unaltered.

"Externally to the shield Kützing observed a thin stratum which he denominated cement, which may be made visible either by desiccation or by calcination; and produces either a simple opacity, or lines, points, and maculæ, sometimes irregularly disposed, sometimes regularly. He supposes it to be a silicate of iron or of alumina. Independently of the chemical materials which it may contain, this outside integument seems to me the more important inasmuch as even without resorting to the means indicated by Kützing, I observe it to be constant, not merely in the species enumerated by him, but also in many others, and I could almost assert that it exists in all. For to me it appears to correspond with that fine membrane of the *Achnanthidia* above mentioned, which, according to Kützing's own observations, is always visible whenever the two new individuals (into which every Diatom is resolved in its multiplication by deduplication) (sdoppiamento) begin to separate. The lines and points supposed to belong to the subjacent shield belong very frequently to this kind of covering.

"The shield itself is formed of at least four pieces, or valves, united together in a four-sided figure—a tetragon. The mode of union is unknown. But the existence of a kind of articulation which permits an opening and closing, like the valves of a shell-fish described by Corda in a species of *Surirella*, has been denied by other observers. Be this as it may, whether spontaneous after death or induced by external means, this separation does take place in a regular manner. Now, if we suppose an organic cell with a wall permeated by silica, and with a four-sided figure, we can easily suppose that all the sides will mechanically support each other. Moreover, we shall meet with numerous facts by a different kind of analogy, namely, that with solid animal tissues belonging either to the internal skeleton or the external tegument.

"The four valves are equal in length, but in many species and genera one pair exceeds the opposite pair in breadth. In order to establish an uniform language it is convenient to term those primary valves or surfaces which exhibit along the middle the line of division in the act of deduplication, which, since it is formed here in a normal manner, runs parallel to the other two surfaces, denominated lateral. Along the primary surfaces we frequently see longitudinal lines, which terminate at the two extremities in small apertures. From their internal surface there project into the cavity linear marks variously formed but always longitudinal: these are termed vittæ.

"The lateral surfaces have frequently a round aperture of greater or smaller size in the centre, and from this a fissure extends towards each extremity. This fissure either loses itself gradually or expands into the regular terminal apertures. When this occurs each of these surfaces is divided into two distinct valves. On these lateral surfaces we observe the striæ, lines, and transverse costæ, no less admirable for their beautiful appearance than for their constant regularity in number, direction, and proportion. When many individuals are united together to form one compound being, like a polyp for instance, it is always by the lateral surfaces that they touch each other; and since all other characters sometimes fail, we can affix to them the denomination 'lateral' from this principal one.

"Besides the vittæ before mentioned, in some genera (*Biddulphia*, *fig.* 15, *Climacosphenia*, *Terpsinoë*) there are other solid substances in their internal cavities: these are variously arranged.

"These essential peculiarities of the shield may perhaps be regarded as indicating a complex structure, very different therefore from what would be prescribed by a simple cellular wall. Ehrenberg deduces from it an argument to compare it with the shell of *Mollusca*. The *Arcellinæ* may be cited among the *Infusoria*. Kützing states, in reply, that among vegetable cells there is found a peculiar conformation of the walls, with prominences, depressions, points, lines, papillæ, and perforations, disposed in a regular manner; he refers to grains of pollen, as an instance. He might have added the more appropriate instance of the *Desmidieæ*, which would be very closely allied to the *Diatomeæ*, if the latter, like the former, could be referred to the vegetable kingdom. If not equal in constancy and regularity, the *Desmideæ* display a greater degree of complication; and we must remember the different nature of their substance, for in the vegetable cell, when lime or silica predominates, the wall becomes uniform and regular (?) (uniforme ed irregolare)."

The siliceous epiderm presents an extraordinary variety of forms, which in every genus and species offer the best possible means of distinction and identification: striæ, or lines frequently moniliform, dots arranged in a radiate or concentric manner, and minute divisions presenting perfectly hexagonal outlines, are amongst the most frequent occurrences. Great difference of opinion exists as to the nature of these. Mr. Smith says, "I am disposed to regard them all as modifications in the arrangement of the silex of the valve, arising from the mode of development peculiar in each case to the membrane with which the silex is combined." He also denies that there are any perforations in the valve, as supposed by Ehrenberg and Kützing. These foramina are also denied by Schleiden. Mr. Smith denies also that the valves are externally covered with any organic membrane.

The delicacy of the markings on many of the *Diatomaceæ* render them objects peculiarly adapted for testing the powers of the object-glasses of the microscope. The following table, drawn up by Messrs. Sollitt and Harrison of Hull, to whom microscopy is indebted for having first pointed out this method of testing the powers of the microscope, was presented by them at the meeting of the British Association at Hull in 1853:—

Focal length of object glass.	Species.	Striæ in inch.	Angle of Aperture.
$\frac{1}{2}$	*Navicula strigilis*	34·000	40°
$\frac{1}{4}$	*N. Hippocampus*	42·000	60°
	N. Spencerii	50·000	70°
	N. liniata	60·000	80°
	N. angulata	60·000	80°
$\frac{1}{8}$	*N. strigosa* (large)	70·000	90°
	N. strigosa (small)	80·000	95°
	Ceratoneis Fasciola	90·000	110°
	Navicula sigmoidea	105·000	120°
$\frac{1}{12}$	*N. arcus*	130·000	150°

The *Diatomaceæ* possess the power of moving. "The cells have no special organs for these movements. But as, in consequence of their nutritive processes, they take in and give out fluid matters, the cells necessarily move when the attraction and the emission of the fluids is unequally distributed on parts of the surface, and is so active as to overcome the resistance of the water. This motion consequently is observed more particularly in those cells which, in consequence of their taper forms, easily pass through the water; these cells moreover move only in the direction of their long axis. If one-half of a spindle-shaped or ellipsoidal cell chiefly or exclusively admits material, the other half, on the contrary, giving it out, the cell moves towards the side where the admission takes place. But, as in these cells both halves are physiologically and morphologically exactly alike, so it is that it is first the one and then the other half which admits or emits, and consequently the cell moves sometimes in one, sometimes in the opposite direction." (Nägeli.)

This is perhaps as satisfactory an explanation of these movements as can be given in the present state of our knowledge. All observers agree that they can find no evidence to support Ehrenberg's notion of a pedal or motile organ projected from the interior of the siliceous shield. The Rev. W. Smith has also detected cyclosis in the *Diatomaceæ*. "A distinct movement," he says, "of the granular particles of the endochrome, closely resembling the circulation of the cell-contents in *Closterium Lunula*, noticed by Mr. Ralfs [DESMIDIEÆ], and which I have frequently detected in the same species, has occasionally fallen under my notice in some of the larger forms of *Diatomaceæ*." He has observed it in *Surirella biseriata*. (*Fig.* 4.) "This circulation," he continues, "has not however the regularity of movement so conspicuous in the *Desmidieæ*, and is of too ambiguous a character to furnish data for any very certain conclusions, save one, namely, that the Diatom must be a single cell, and cannot contain a number of separate organs, such as have been alleged to occupy its interior; since the endochrome moves freely from one portion of the frustule to another, approaching and receding from the central nucleus, unimpeded by any intervening obstacle."

The *Diatomaceæ* are the most abundant and extensively distributed of unicellular organisms. They are found in the ocean, at the mouths of rivers, in brackish waters, in rivers, lakes, ponds, ditches, pools, and cisterns. In fact, wherever a few drops of water are allowed to remain exposed to the air, we may expect to find forms of *Diatomaceæ*. Their forms are not less abundant than their presence. In the first volume of his 'Synopsis of the British Diatomaceæ,' the Rev. W. Smith has described upwards of 220 species, and the second will contain nearly 100, so that the number of species known in Great Britain is considerably above 300. The facility with which their forms are preserved, give to these objects a great advantage, and a handful of sand from the sea or mud from a river in the most remote district of the world may be expected to reward the observer with an abundance of new forms. They occur in great abundance in the river Thames, and its mud affords a large variety of the frustules of those which have ceased to exist. In a report on the 'Microscopical Examination of the Thames and other Water,' by Drs. Lankester and Redfern, upwards of forty species were observed.

The mode of collecting living specimens for observation is simply to allow the water in which they exist to stand for a few hours, when, by carefully decanting the water, a portion remains at the bottom of the vessel more turbid than the rest, and which generally contains in large numbers the objects sought for.

In describing showers of coloured dust which have occurred in various parts of the world, Ehrenberg has demonstrated that various forms of *Diatomaceæ* have been found present. In some seasons these organisms occur in such numbers in the waters of rivers as to give to their banks a peculiar physical aspect. In the autumn of 1841 the stones and pebbles in the nearly dried-up bed of the Annan, in Dumfriesshire, presented an appearance as though they were white-washed. The substance which gave the stones this appearance could be scraped off, and looked like some form of calcareous matter. On submitting this powder to the microscope, Dr. Lankester found that it consisted entirely of the siliceous shields of a species of *Synedra*. (*Fig.* 5.) In the first volume of the new series of the 'Transactions of the Microscopical Society,' Mr. Shadbolt has given an account of the examination of portions of mud given him by Mr. Busk from Port Natal. This mud was recent, and from the nature of the specimens in it, Mr. Shadbolt thinks it probable that it was obtained not far from the mouth of some river. In this mud he made out fifty-five distinct species of *Diatomaceæ*, twenty of which he has described as entirely new species. In the 'Microscopical Journal' for July 1853, Mr. Brightwell of Norwich has described nine new species of one genus—*Triceratium*. Six of these are recent. He says, "We have detected nearly all the recent species described in this memoir in material obtained from the surface of the large sea-shells of the genera *Hippopus* and *Haliotis* before they have been cleaned. Many of them in this state are covered with small zoophytes, minute algæ, and other parasites; and by a careful examination of these, *Triceratia* and other *Diatomaceæ* have been obtained."

One of the most singular positions in which Diatoms are found is in the guano brought from America and Africa. Their history is curious. They must first have been swallowed by fish and subsequently by birds; their shields however have been able to withstand this double process of digestion, and they are found in large numbers in every pure specimen of guano. Some of the forms which have been thus presented to the naturalist are entirely new, and are amongst the most singular of the family. It has been suggested that the silex thus introduced into the guano may contribute to its fertility, as it is well known that this substance is present in the stems of all our cereal grasses, and is necessary to their growth.

If they occur thus abundantly in recent deposits, it would be expected that they should be found in many of the older formations of the earth's surface. This is very extensively the case; although it may be doubted whether, from the fact of their being occasionally found in igneous rocks, that they were amongst the first organisms on the earth's surface. Ehrenberg has been able to detect their presence in some of the earliest rocks of the Palæozoic series. How *Diatomaceæ* may be present in igneous rocks has been suggested by Dr. Hooker. During his voyage with Sir James Ross in the Antarctic Ocean he says, "This order occurred in such countless myriads as to stain the sea every where of a pale ochreous-brown, in some cases causing the surface of the ocean, from the locality of the ships, as far as the eye could reach, to assume a pale-brown colour." This immense mass of organisms perishing are producing a sub-marine deposit, or bank, of vast dimensions, resting on the shores of Victoria Land, and hence on the sub-marine flanks of Mount Erebus, an active volcano upwards of 12,000 feet high. "Knowing as we do that *Infusoria*, *Diatomaceæ*, and other organic constituents, enter into the formation of the pumice and ashes of other volcanoes, and are still recognisable in those minerals, it is perhaps not unreasonable to conjecture that the subterranean and subaqueous forces which kept Mount Erebus in activity, may open a direct communication between this Diatomaceous deposit and its volcanic fires."

Ehrenberg has described a large number of forms of *Diatomaceæ* from the oolite, cretaceous, and other secondary rocks. A formation occurring in Barbadoes, and described by Sir Robert Schomburgk in the 'Reports of the British Association' for 1847, furnished him with an entirely new group of beings apparently related to this family. The following is Sir Robert's account of this discovery:—

"In the white marls and other rocks of Scotland district, Professor Ehrenberg of Berlin discovered a new and great group of siliceous-shielded animalcules, which, in a report read before the Royal Academy of Sciences, he described as *Polycystina*. The regular apertures and articulation of the minute shells which cover these animalcules distinctly bespeak an independent animal structure and development. They possess large apertures at the extremity of the body, which has no analogy among plants, but occur very commonly among animals. These siliceous loricated organic forms from the rocks in Barbadoes differ alike from *Polygastrica* and *Polythalamia*, but develop an important relation to these two groups, which Professor Ehrenberg considers, not upon conjecture but from actual investigation, to form two separate types. They approach most nearly in systematic arrangement to *Polythalamia*, and would occupy a separate group among animals possessed of vessels but without a heart and pulsation, and provided with a simple tubular intestinal canal. The forms developed in the highest degree in that division would be *Holothuriæ* and *Echinoideæ*.

"The minute forms of organic life in the rocks of Barbadoes, as far as investigated by Professor Ehrenberg in February, 1847, consist of the following groups:—

	Species.
Polycystina	282
Polygastrica	18
Phytolitheria	27
Geolithia	27
Polythalamia	7
	361

Of these more than 300 are new forms.

"The great discovery of the *Polycystina*, which might be almost called a new class, since they amount to upwards of 280 species, a larger number of specific forms than is contained in some classes of animals, may guide us to form an idea of the geological age of the rocks in Scotland district, by comparing these forms with similar fossil animalcules from rocks upon the age of which geologists have agreed. Ehrenberg considers that the *Polycystina* from the rocks of Barbadoes resemble more the animalcules from rocks of the secondary period than the tertiary."

Amongst the varieties of quartz rock the mineralogist recognises, under the name of tripoli and polishing powder, certain pulverulent and earthy forms of silex. On placing these substances under the microscope they are found to be entirely composed of the siliceous frustules of *Diatomaceæ*. The polishing powder or slate (polirschiefer) found at Bilin in Bohemia is used for the purpose of producing a polish on fine surfaces. The angularity and hardness of the frustules of the Diatoms well adapt them to this purpose.

Another deposit in which the *Diatomaceæ* have been found in great abundance is the Bergmehl of Sweden. [BERGMEHL.] The Diatoms found by Ehrenberg in this formation are principally species of *Navicula*. (*Fig.* 6.)

Amongst the tertiary deposits, beds of *Diatomaceæ* are very common. They have been observed in Italy, in Germany, and in several of the States of America. "The city of Richmond in Virginia is said to be built upon a stratum of Diatomaceous remains, 18 feet in thickness." (Smith.) Professor Gregory of Edinburgh has recently described, in the 'Transactions of the Microscopical Society,' a Diatomaceous earth, discovered about two years ago by the Duke of Argyll in the Isle of Mull. It constitutes a bed resembling marl in appearance, lying in a rough piece of ground between Loch Baa and the sea. The lake is about 30 feet, the land about 40 feet, above the sea-level. At one part there is a hollow, which in winter used to become a small loch, in summer only a stagnant pool, and in draining this the bed of marl was discovered. The bed rests upon gravel, which appears to belong to the diluvial period, and the Diatomaceous earth is probably of recent origin. Professor Gregory has examined the contents of this earth with great care, and has given a list of upwards of 130 species, which he has been able to make out ('Quarterly Microscopical Journal,' January, 1854). Of these upwards of 20 are altogether new species, or species that are new in a British locality.

From these facts it will be seen that the subject of fossil *Diatomaceæ* promises an almost boundless field for further inquiry. It appears that we may say of these organisms, what we can say of no other family or group of organised beings, that once created they exist for ever. Myriads of species of soft-bodied animals have perished, never to be recognised, but each individual cell of the Diatom leaves its siliceous wall as a record of its existence—a record that the ordinary forces of nature seem to have little or no power in obliterating.

We now turn to the subject of arrangement. It would of course be impossible here to give any account of individual species, and systematic arrangements are being constantly modified by new discoveries. The following is an arrangement of the families or tribes by Kützing:—

Tribe I. STRIATÆ.

Order I. *Astomaticæ*.

Without a central opening on the secondary valve.

* Transverse striæ unbroken.

Family 1. *Eunotieæ*.
Family 2. *Meridieæ*.
Family 3. *Fragilarieæ*.

** Striæ broken (interrupted) in the median line.

Family 4. *Meloseireæ*.
Family 5. *Surirelleæ*.

Order II. *Stomaticæ*.

With the central opening.

α *Monostomaticæ*.

Having a median aperture on only one of the two secondary surfaces.

Family 6. *Cocconeideæ*.
Family 7. *Achnantheæ*.

β *Distomaticæ*.

With a median aperture on each secondary surface.

Family 8. *Cymbelleæ*.
Family 9. *Gomphonemeæ*.
Family 10. *Naviculeæ*.

Tribe II. VITTATÆ.

Order I. *Astomaticæ*.

Without central opening on secondary side.

Family 11. *Licmophoreæ*.
Family 12. *Striatelleæ*.

Order II. *Stomaticæ*.

With a large distinct aperture.

Family 13. *Tabellarieæ*.

Tribe III. AREOLATÆ.

Order I. *Disciformes*.

Family 14. *Coscinodisceæ*.
Family 15. *Anguliferæ*.
Family 16. *Tripodisceæ*.

Order II. *Appendiculata*.

Doubtful forms.

Family 17. *Biddulphieæ*.
Family 18. *Angulatæ*.
Family 19. *Actinisceæ*.

The Rev. W. Smith, in his 'Synopsis of the British Diatomaceæ,' gives the following arrangement of the genera:—

Tribe I. Frustules naked; not imbedded in gelatine nor inclosed in membranaceous tubes.

Sub-Tribe 1. Connecting membrane deciduous; frustules solitary, or during self-division in pairs; rarely in greater numbers, adherent or free, dispersed, or aggregated into a mucous stratum.

22 Genera—

Epithemia (*fig.* 19)	16 species.
Eunotia (*fig.* 1)	7 species.
Cymbella	6 species.
Amphora	8 species.
Cocconeis	6 species.
Coscinodiscus	3 species.
Eupodiscus (*fig.* 2)	5 species.
Actinocyclus	1 species.
Arachnodiscus	1 species.
Triceratium (*fig.* 3)	3 species.
Cyclotella	4 species.
Campylodiscus	7 species.
Surirella (*fig.* 4)	20 species.
Tryblionella	6 species.
Cymatopleura	5 species.
Nitzschia	23 species.
Amphiprora	5 species.
Amphipleura	2 species.
Navicula (*fig.* 6)	36 species.
Pinnularia	24 species.
Stauroneis	10 species.
Pleurosigma (*fig.* 7)	26 species.

Sub-Tribe 2. Connecting membrane subpersistent; frustules after self-division attached by a gelatinous cushion, or dichotomous stripes.

7 genera—

Synedra (*fig.* 5)	24 species.
Doryphora	2 species.
Cocconema (*fig.* 8)	4 species.
Gomphonema (*fig.* 9)	12 species.
Podosphenia	5 species.
Rhipidophora	3 species.
Licmophora	2 species.

Sub-Tribe 3. Connecting membrane evanescent, or obsolete; frustules after self-division united into a compressed filament.

12 Genera—

Meridion (*fig.* 10)	2 species.
Bacillaria (*fig.* 11)	1 species.
Himantidium	7 species.
Odontidium	4 species.
Denticula	4 species.
Fragilaria	3 species.
Eucampia	1 species.
Achnanthes (*fig.* 12)	6 species.
Diadesmis	3 species.
Rhabdonema	2 species.
Striatella (*fig.* 13)	1 species.
Tetracyclus	1 species.

Sub-Tribe 4. Connecting membrane subpersistent; frustules after self-division united into a zigzag chain.

6 Genera—

Diatoma (*fig.* 14)	4 species.
Grammatophora	2 species.
Tabellaria	2 species.
Amphitetras	1 species.
Biddulphia (*fig.* 15)	4 species.
Isthmia	2 species.

Sub-Tribe 5. Connecting membrane subpersistent as a siliceous annulus; frustules after self-division united into a cylindrical filament.

3 Genera—

Podosira	2 species.
Melosira (*fig.* 16)	6 species.
Orthosira	6 species.

Tribe II. Frustules invested with a gelatinous or membranaceous envelope.

Sub-Tribe 6. Frond indefinite; mammillate; frustules scattered.

1 Genera—

Mastogloia	3 species.

Sub-Tribe 7. Frond definite; compressed or globular; frustules scattered.

2 Genera—

Dickieia (*fig.* 17)	3 species.
Berkeleyia	1 species.

Sub-Tribe 8. Frond definite; filamentous; frustules in rows.

3 Genera—

Encyonema	2 species.
Colletonema	4 species.
Schizonema (*fig.* 18)	16 species.

Sub-Tribe 9. Frond definite, filamentous; frustules fasciculated.

1 Genus—

Homœcladia.*	3 species.

(Smith, *Synopsis af British Diatomaceæ*, vols. i. & ii.; Meneghini, *On the Animal Nature of Diatomeæ*, translated by Ray Society; Kützing, *Species Algarum*; Siebold, *On Unicellular Plants and Animals*, translated in *Quarterly Journal of Microscopical Science*, vol. i.; Pritchard, *A History of Infusorial Animalcules, Living and Fossil*; Dujardin, *Histoire Naturelle des Zoophytes Infusoires*; Hassall, *British Fresh-Water Algæ*; Ehrenberg, *Die Infusions-Thierchen*; Hooker, *British Flora*, vol. ii.; Agardh, *Conspectus Criticus Diatomacearum*; Papers in vols. i. & ii. of *Quarterly Journal of Microscopical Science*, by T. Thwaites; *Reports of British Association*; Professor J. W. Bailey in *Smithsonian Contributions to Knowledge*.)

DICÆ'LUS, a genus of Coleopterous Insects. [LICINUS.]

DICÆUM. [CERTHIADÆ; CINNYRIDÆ.]

DI'CERAS, a genus of Fossil Conchiferous *Mollusca*, allied in form to *Chama*. It includes species mostly occurring in the upper part of the Oolitic strata and (*D. Lonsdalii*) the lower part of the Greensand. D'Orbigny ranks the latter species as *Caprotina*. [CHAMACEA.]

DICHELASPIS. [CIRRIPEDIA.]

DICHELESTHIUM. [PŒCILOPODA.]

DICHOBUNE. [ANOPLOTHERIUM; PACHYDERMATA.]

DICHOLOPHUS. [ÇARIAMA.]

DICHO'TOMY, a term in Botany employed to express a mode of branching amongst plants by constant forking. The first stem or vein of a plant divides into two branches, each branch divides into two others, and so on. It is only in the veins of fern leaves, and of those of some of the species of *Coniferæ*, and in the stems of Ferns, that this mode of division exists as a general character. It however does occur elsewhere; for example, the Doom-Palm (*Crucifera Thebaica*) of Thebes is remarkable for its dichotomous branches, and the Screw-Pines (*Pandanus*) have a similar habit.

DICHROITE, a Mineral, also known by the names *Iolite*, *Peliome*, *Steinheilite*, and *Cordierite*. It is an anhydrous silicate of alumina, and occurs massive and crystallised. Its primary form is a right rhombic prism, commonly crystallised in 6 or 12-sided prisms. The cleavage is parallel to the lateral planes. It has a blue colour in the direction of the axis, and yellowish-gray perpendicular to it; sometimes dull yellowish in both directions. The streak is white. Fracture uneven and somewhat conchoidal. Its hardness is 7·0 to 7·8. Lustre vitreous. It is transparent and translucent. Its specific gravity is 2·56. The massive varieties are amorphous. Its structure is indistinctly granular. It is found at Cabo de Gata in Spain, in Greenland, at Bodenmais, in Bavaria, Norway, the United States, &c. The following is an analysis by Stromeyer:—

Silica	50·24
Alumina	33·42
Magnesia	10·84
Protoxide of Iron	4·00
Protoxide of Manganese	0·68
Water	1·66

* For the above illustrations we are indebted to the Rev. W. Smith not only for those published in vol. i. of his 'British Diatomaceæ,' but through Mr. Triffin West, the artist, for several from the unpublished volume of that admirable work. Mr. West has also furnished some original drawings.

DICLIDURUS. [CHEIROPTERA.]

DI'CLINOUS, an obsolete term in Botany, signifying that a plant has its sexes in distinct flowers. It comprehends all the Monœcious and Diœcious plants of Linnæus.

DICOTYLE'DONS, a Natural Class of Plants, deriving their name from the embryo having in general two seed-leaves, or cotyledons; a character to which there are however some exceptions. The genus *Ceratophyllum* has several: *Bertholletia* appears to have none; in *Tropæolum* and many others they are consolidated into one; and *Cuscuta* is certainly destitute of them. Like all others therefore the character derived from the cotyledons, nearly universal as it is, has its exceptions. Hence botanists associate with the character derived from the embryo others derived from the mode of growth, leaves, flowers, &c., and the whole taken together give the real diagnosis of the class to which the name of Dicotyledons is applied.

The stems of Dicotyledous are probably in all cases branched, except when a plant is from its weakness and minuteness unable to reach any development beyond that of the first stage from the plumule. In herbaceous plants that are called stemless, a sort of branching takes place by the formation of small short stems upon the crown of the axis of growth. They have the pith, wood, and bark distinctly separated, and the wood traversed by medullary rays. This wood if more than one year old consists of concentric circles, each of which is formed on the outside of that which immediately preceded it; the consequence of which is that the oldest part of a branch will necessarily consist of the largest number of layers, and will therefore be the thickest: hence the branches of Dicotyledons are always cones, although usually very long ones [EXOGENS], and not cylinders. But to some of these characters the exceptions are not a few. It is difficult to trace any distinction of pith, wood, and bark in the stem of the Water-Lily (*Nymphæa*); there are no concentric circles in the wood of *Aristolochia*, and several other genera; and it is impossible to show by measurement that the stems of many irregular tropical dicotyledonous climbers vary perceptibly in diameter for considerable distances.

The leaves of Dicotyledons are articulated with the stem, so that at a particular time they are thrown off, and leave a clean scar behind them, as in all the trees, whether deciduous or others, which are found in the open air in England. Their veins are repeatedly branched, so as to form a netted apparatus within the parenchyma. But although by far the largest part of Dicotyledons are thus constructed, yet we have contradictions to this also. For instance, in *Dianthus*, and a great many other genera, the leaves have no veins except the midrib, and there are many herbaceous plants whose leaves never drop fairly off the stems.

The number of parts in the flower of dicotyledonous plants is four or five; that is, four or five sepals, four or five petals, and the same number of stamens, present in either a complete or imperfect state; or if the number is greater it is some power of four or five. But in *Ranunculus*, *Ficaria*, most Anonaceous plants, and several more, the parts in the flower are three.

Finally, when the seeds germinate the embryo simply extends the point of its radicle in the form of a root to seek for nourishment in the soil. [EXORHIZÆ.] But although this is, as far as is yet known, a character without exception, nevertheless it has been too little studied for us to assert that it is more free from anomalies than other characters.

Hence it is to be observed that it is neither the two cotyledons, nor the exogenous stem, nor the concentric circles of wood, nor the reticulated disarticulating leaves, nor the quinary or quaternary flowers, nor the exorhizal germinations, which by themselves characterise the class of Dicotyledons, but the combination of those characters; and that the absence of some one of them is immaterial; so that a plant may be essentially a Dicotyledon, although it has any number of cotyledons except two.

The Dicotyledons of Jussieu comprehended the plants now separated under the name of Gymnosperms, and together with Monocotyledons and Acotyledons, constituted the whole vegetable kingdom. They probably consist of at least two-thirds of all known plants: in the state of trees, shrubs, or herbaceous plants, they are found wherever phænogamic vegetation can exist, and they and Gymnosperms together constitute exclusively the arborescent scenery of all cold countries.

DICOTYLES. [SUIDÆ.]

DICRURUS. [LANIADÆ.]

DICTAMNUS, the botanical name of the fragrant herbaceous plant called *Fraxinella* by gardeners. [FRAXINELLA.]

DICTY'OCHA, a genus of organised beings referred by Ehrenberg to the *Naviculaceæ* or *Diatomaceæ*. They are characterised by an areolate spinous shield, and differ so much from the other forms of *Diatomaceæ* that many naturalists have doubted the propriety of placing them there. The species are numerous, the larger number being fossil and found with various forms of *Diatomaceæ*.

DICTYOGENÆ, a class of Plants, proposed by Lindley, and adopted in his 'Vegetable Kingdom.' It embraces a number of orders standing between the larger classes of Exogens and Endogens. They have a monocotyledonous embryo, but they have also a broad net-veined foliage, which usually disarticulates with the stem. The following are the natural orders of *Dictyogenæ* :—

Flowers unisexual. Perianth free. Carpels 00 ; one seeded	*Triuridaceæ.*
Flowers unisexual. Perianth adherent. Carpels consolidated ; several seeded	*Dioscoreaceæ.*
Flowers bisexual. Carpels several, quite consolidated. Placentæ axile. Flowers hexapetaloideous	*Smilaceæ.*
Flowers bisexual. Carpels several, quite consolidated. Placentæ parietal. Flowers 3-6-petaloideous	*Philesiaceæ.*
Flowers bisexual. Carpels several, half consolidated. Placentæ axile. Flowers 3-petaloideous . .	*Trilliaceæ.*
Flowers bisexual. Carpels solitary, simple, many-seeded, with long-stalked anatropal seeds, and a basal placenta	*Roxburghiaceæ.*

DICTYOPHYLLIA. [MADREPHYLLIŒA.]

DICTYOPHY'LLUM, a genus of fossil Plants, proposed by Lindley and Hutton ('Fossil Flora') to include a large specimen (*D. crassinervium*) from the New Red-Sandstone of Liverpool, and a more delicate species (*D. rugosum*) from the Oolitic shales of the Yorkshire coast. The latter is regarded as a fern by later writers. Its nervures are rudely reticulated.

DICTYOTACEÆ. [ALGÆ.]

DICYPELLIUM, a genus of Plants belonging to the natural order *Lauraceæ*. It has diœcious flowers, with a deeply 6-parted spread-out calyx, with equal permanent segments. The staminiferous flowers have 3 rows of sterile stamens; the 3 outer being perfectly petaloid, the 3 next petaloideo-unguiculate, inflexed at the point, with 4 pits below the point; the 3 inner compressed, sessile, truncate, with 2 pits on each side below the point, and 2 glandular protuberances at the back. The fruit is dry, and seated in the enlarged, fleshy, shrivelled calyx, and among the enlarged, hardened, sterile stamens. The inflorescence consists of single few-flowered racemes.

D. caryophyllatum, Bois de Rose, has alternate oblong leaves tapering to a very fine point, which is nevertheless bluntish, acute at the base, papery, and smooth-netted on the under side. It is a tree, and a native of the woods of Brazil and Guyana. It is called Licari Kanali by the Caribs; and is the *Licaria Guianensis* of Aublet. The bark gives out a smell very like cloves, and has a hot, clove-like, peppery taste. It is used as a medicine by the natives in the countries where it grows, and possesses powerful tonic properties.

(Lindley, *Flora Medica*.)

DIDELPHINA, a sub-family of *Marsupiata*. The whole of this sub-family have the inner toe of the hind foot converted into a thumb, destitute however of a claw, and this development is apparent in nearly all the species which have a scaly prehensile tail. Professor Owen remarks that in some of the smaller Opossums the sub-abdominal tegumentary folds are rudimental, or merely serve to conceal the nipples, and are not developed into a pouch; and in these the young adhere to the mother by entwining their little prehensile tails around hers, and clinging to the fur of her back; whence the specific name *dorsigera*, applied to one of the species. He further observes that few facts would be more interesting in the history of the *Marsupialia* than the condition of the new-born young, and their degree and mode of uterine development in these Opossums. Since the Marsupial bones serve not, as is usually described, to support a pouch, but to aid in the function of the mammary glands and testes, they are, he adds, of course present in the skeleton of these small pouchless Opossums, as in the more typical Marsupials. [MARSUPIATA.]

The term Opossums is generally used to designate the *Didelphina*, now confined to the American continents. The former existence of this type in Europe in association with *Palæotherium*, *Anoplotherium*, and other extinct pachydermatous quadrupeds, is proved by the fossil remains in the Paris Basin (Eocene of Lyell). Two species of *Didelphis* have been found fossil in Great Britain. [MARSUPIATA.]

The dentition of these scansorial Marsupials bears more resemblance to that of the Bandicoots (*Perameles*) than to that of the *Dasyuri*, if the structure of the molar teeth be excepted.

The following species of this family are contained in the 'British Museum Catalogue':—

Didelphis Virginiana, the Opossum. North America.
D. Azaræ, Azara's Opossum. Brazil.
Philander nudicaudus, Naked-Tailed Philander. Brazil.
P. Opossum, the Philander. Tropical America.
P. marsupialis, the Crab-Eater. Tropical America.
P. dorsigerus, Menair's Opossum. (See *fig.*).

P. cinereus, Cinereous Opossum. South America.
P. murinus, the Mamose. Tropical America.
Thylanus elegans, Elegant Painted Mamose. Chili, Valparaiso.
(Owen, *On the Classification of the Marsupialia*, *Zool. Trans*, vol. ii.)

Didelphis dorsigera (*Philander dorsigerus*, 'Brit. Mus. Cat.').
From the specimen in the British Museum.

DIDUS. [DODO.]

DIDYMOPRIUM. [DESMIDIEÆ.]

DIDYNA'MIA, the fourteenth class of the Linnæan system of arranging Plants. It is the same as *Tetrandria ;* that is, it has always four stamens, only two of them are a little longer than the other two. Under this class are comprehended a large part of the Lamiaceous, Verbenaceous, Scrophalariaceous, Bignoniaceous, and Acanthaceous Plants of modern botanists. It is divided into two orders, *Gymnospermia* and *Angiospermia*. *Gymnospermia* includes the genera whose ovary is split into four small seed-like lobes, which in the time of Linnæus were taken for naked seeds ; and *Angiospermia*, those which have manifestly the seeds inclosed in a pericarp of some sort.

DIEFFENBA'CHIA, a genus of Plants belonging to the natural order *Araceæ*, to which the *Caladium Seguinum*, Dumb Cane, belongs. [CALADIUM.]

DIERVILLA, a genus of Plants belonging to the natural order *Caprifoliaceæ*, consisting of a single North American species, by Linnæus considered a honeysuckle, and called *Lonicera Diervilla*. It is however obviously not of that genus, because its fruit is a dry capsule with a papery pericarp, with four cells and several seeds.

D. Tourneforti, or, as it is also called, *D. humilis*, *D. lutea*, or *D. Canadensis*, is a common hardy shrub, growing from two to three feet high, in a spreading manner, and having small funnel-shaped irregular 5-cleft yellow flowers, growing in stalked clusters of two or three from the axils of opposite ovate serrated leaves. It is found wild in rocky woods in the United States, from Canada to the Carolinas, flowering in June.

DIFFLUGIA. [INFUSORIA.]

DIGENITE, a native Sulphuret of Copper.

DIGESTION, the process by which the food is converted into nutriment. Taken in its whole extent the process of digestion comprehends the entire series of changes by which the crude aliment is assimilated into arterial blood. These changes are effected by organs which, viewed collectively, comprise a most extensive apparatus commencing at the mouth and ending at the lungs.

The first changes upon the food are effected in the mouth, where it is mixed with mucus and saliva. [SALIVA.] Torn to pieces by the teeth [TEETH] in the operation of mastication, and softened by the secretions of the mouth until it is reduced to a pulp, it is then collected by the tongue [TONGUE], and formed by that organ into a mass called a bolus. The bolus of food thus prepared is carried by the tongue to a muscular membranous bag called the pharynx [PHARYNX], situated at the back part of the throat. The pharynx, as soon as it receives the bolus contracts firmly upon it, and by a proper muscular action delivers it to the œsophagus, a long muscular tube which extends from the pharynx to the stomach. [STOMACH.] The bolus of food does not descend along the œsophagus by its own weight, for a person can swallow while standing on his head, and many animals have obviously to convey their food along the œsophagus against gravity. The food when it enters the œsophagus is transmitted along the tube by a powerful contraction upon it of the strong fasciculi of muscular fibres of which it is composed.

By the œsophagus the food is conveyed into the stomach, where it is converted into a fluid termed Chyme. The chyme when duly prepared in the stomach is transmitted to the small intestines, in the first portion of which it is converted into a new substance called Chyle. In its passage along the second portion of the small intestines the chyle disappears, being taken up by a set of vessels named lacteals, which convey it through a double series of glands, called the Mesenteric Glands, to the Thoracic Duct. By the thoracic duct it is conveyed through the abdomen into the thorax, where it is poured into one of the large veins, the Subclavian, which returns the blood from the upper parts of the body to the right side of the heart, to be, by the heart propelled into the Pulmonary Artery. By the pulmonary artery the chyle, now mingled with venous blood, is conveyed to the lungs, where it undergoes its ultimate change, and is converted into arterial blood. The large intestines meantime carry out of the body that portion of the food which has not been converted into chyle. All solid food undergoes the same process. [FOOD.]

The food torn, as has been stated, into minute fragments by the operation of mastication, softened and brought into the state of a pulp by its admixture with mucus and saliva, and raised nearly to the temperature of the blood by the warmth of the mouth, is received into an extensive chamber, the stomach, where it is constantly maintained at a temperature of 100° of Fahrenheit, and kept in a state of gentle but almost unceasing agitation by a peculiar motion of the stomach, effected by its muscular fibres, and called, from its striking resemblance to the motion of the earthworm, peristaltic. The essential phenomena which take place on the introduction of the food into the stomach are the following :—

The food on entering the stomach is not arranged indifferently in any part of the chamber, but is detained in the great extremity, or that portion of the stomach which is near the entrance of the œsophagus, termed the cardiac extremity. This portion of the stomach during the actual process of digestion appears to be cut off from the rest by a contraction of the circular fibres of the muscular coat, called the hour-glass contraction, by which about a third of the length of the stomach towards its small or pyloric extremity is separated from the great or cardiac extremity. The food received in the cardiac extremity is slowly dissolved ; this solution takes place at the surface ; "in proportion as it proceeds the dissolved part is rolled off the rest by the peristaltic action of the fibres of the stomach, and carried to the pyloric portion," where it accumulates. Thus the undissolved and the dissolved portions of the food are in different parts of the stomach ; the undissolved portion in the cardiac extremity, and the dissolved portion in the pyloric extremity.

A remarkable change takes place on the inner or mucous surface of the stomach the moment a portion of food comes in contact with it. This change has been seen to take place in the stomachs of animals laid open during the process of digestion for the purpose of affording an opportunity to observe the phenomena, and even in the human stomach, which, in more than one instance, has been completely exposed to view in consequence of wounds accidentally inflicted. The mucous coat of the stomach, which is of a pale pink colour when the stomach is empty, becomes of a bright red colour when excited by the contact of food. Over this reddened surface are visible, more especially when it is examined through a magnifying glass, innumerable minute lucid points, from which distils a pure limpid and colourless fluid. This fluid, as it is discharged, is absorbed by the aliment in contact with the surface of the stomach, or collects in small drops and trickles down the sides of the stomach to the more depending parts, and there mingles with the food and dissolves it. This fluid, the true solvent of the food, is termed the Gastric Juice or Acid. It has been ascertained to be the efficient agent in digestion, and its solvent power has been demonstrated by a series of most decisive experiments long ago performed by Spallanzani and others. This distinguished physiologist swallowed a metallic tube perforated with holes and filled with flesh ; he allowed the tube to remain in the stomach four hours, and then contrived to throw it up by exciting vomiting mechanically. The flesh in the tube was found to be thoroughly soaked with the fluid of the stomach ; its surface was in a dissolved state, being soft and gelatinous, and moreover it had wasted from 53 to 38 grains. Subsequently, Dr. Stevens induced a person practised in swallowing pebbles, to swallow a hollow silver sphere containing raw or cooked flesh, or vegetables, and perforated with holes that would admit a crow-quill : the sphere was voided in about forty hours perfectly empty. Next, Mr. Hunter observed that the great extremity of the human stomach is sometimes found after death in a softened state and even in a state of partial solution, the coats of the stomach being dissolved by its own gastric juice, and the edges of the opening appearing pulpy, tender, and ragged, and even the parts adjacent to the stomach, as the spleen, the diaphragm, and the lungs, being in like manner softened.

More recently, Dr. Beaumont, an American physician, has performed a series of experiments on the digestibility of various kinds of food, by introducing food directly into the stomach of a man—Martin St. Ange—who had a fistulous opening into that organ through the parietes of the abdomen. The results of his experiments are interesting, and are given in the following table. It appears that the articles were converted into chyle, that is, digested, in the times indicated :—

	H.	M.		H.	M.
Rice, boiled soft	1	0	Oysters, stewed . .	3	30
Apples, sweet and ripe .	1	30	Eggs, raw	2	3
Sago, boiled	1	45	Eggs, soft boiled . .	3	0
Bread, stale	2	0	Eggs, hard boiled . .	3	30
Milk, boiled	2	0	Beef, roast or boiled .	3	0
Cabbage	2	0	Beef, salted	5	30
Baked Custard . . .	2	45	Mutton, roast or boiled .	3	0
Parsnips, boiled . . .	2	30	Pork, boiled . . .	3	30
Potatoes, roasted . .	2	30	Pork, salt and boiled . .	4	38
Potatoes, boiled . . .	3	30	Pork, roast . . .	5	30
Turnips, boiled . . .	3	30	Veal, roasted . . .	5	30
Carrots, boiled . . .	3	15	Turkey and Goose . .	2	30
Butter and Cheese . .	3	30	Domestic Fowls . . .	4	0
Venison	1	35	Wild Fowls . . .	4	30
Oysters, raw . . .	2	3			

The solution of the food, which takes place during this process, is wholly different from the spontaneous resolution which warmth and moisture tend to produce in it. Exposure of the food to warmth and moisture decomposes it by the process of putrefaction ; but the gastric juice is antiseptic, and stops the putrefying process even after it is considerably advanced. The solution of the food by the gastric juice is a chemical operation, and the gastric juice is a chemical agent, the exact nature of which is not yet clearly ascertained. Spallanzani discovered that the gastric juice is of an acid nature. Some years ago Dr. Prout ascertained that muriatic acid is present. If meat and gastric juice be inclosed in a glass tube, and kept at the temperature of the human body, a product is obtained closely resembling the fluid formed by the solution of the food in the stomach. If meat be inclosed in a glass tube with diluted muriatic acid, and kept at the temperature of the blood, a perfectly similar product is obtained.

From experiments upon the dog it has been ascertained that muriatic acid is not present in the gastric acid of that animal. Its acid reaction is produced by superphosphate of lime. Lactic and acetic acids are also found present in human chyle. So we may state that up to the present time chemistry has not been able to decide whether the acid re-action of the gastric juice depends on free acids, acid salts, or acid organic compounds.

In addition to the acid, the gastric juice contains a substance called Pepsine. The properties of this substance have been principally studied in that form of it obtained from the mucous membrane of the pig, which is very like to that of man. [PEPSINE.] This substance, when combined with muriatic or acetic acid, has a very remarkable power in dissolving albuminous foods. "A liquid which contains only 17-ten-thousandths of acetate of pepsine and six drops of muriatic acid per ounce, possesses solvent power enough to dissolve a thin slice of coagulated albumen in the course of six or eight hours' digestion. With 12 drops of muriatic acid per ounce, the same quantity of white of egg is dissolved in two hours." (Carpenter.) These properties quite explain the action of the gastric juice upon the food.

After the food has undergone the action of the gastric juice, it loses its sensible properties, and is converted into the homogeneous semi-fluid mass which has received the name of chyme. Specific differences are distinguishable in chyme, according as the food from which it is formed has consisted of vegetable or animal matter, and according as it has contained fatty or oily substances, or has been destitute of them. Usually however it consists of a pultaceous mass of a grayish colour ; it has a sweetish taste, and is slightly acid. The character common to it, from whatever kind of food it may have been produced, and therefore distinctive of it, is its acidity.

The state of the food in the chyme has not been clearly made out. Dr. Carpenter gives the following account :—

"The protein compounds, whether derived from animal or vegetable food, are all reduced to the condition of albumen ; a part of which is dissolved, whilst another portion is suspended in a very finely-divided state. Gelatine will be dissolved or not, according to its previous condition; if it exist in a tissue from which it cannot readily be extracted it will pass forth almost unchanged, but when ingested in a state of solution it remains so, and if it have been previously prepared for solution by boiling, its solution is completed in the stomach. The gummy matters of vegetables are dissolved when they exist in a soluble form, as in the case of pure gum, pectine, and dextrine, or starch-gum. The degree in which starch, when its vesicles have not been ruptured by heat, is affected by the gastric fluid, seems to differ in different animals ; the Ruminants and Granivorous Birds apparently possessing the power of crushing or dissolving the envelopes of the starch globules, whilst they pass through the alimentary canal of other *Herbivora* unchanged, and may be detected entire in their excrements. Sugar is unquestionably taken up in solution, as such, in a healthy condition of the system, but it may undergo a previous change in the stomach in disordered states of the digestive process. Oily matters, whether of animal or vegetable origin, are reduced to the condition of an emulsion, being very finely divided, and their particles diffused through the chyme. Most other substances, as resins, woody fibre, horny matter, yellow fibrous tissue, &c., pass unchanged from the stomach, and undergo no subsequent alteration in the intestinal canal; so that they are discharged among the fæces as completely useless."

The chyme upon quitting the stomach passes into the duodenum, where it mingles with the Bile [BILE] and Pancreatic Juice. [PANCREATIC JUICE.] These fluids are not merely excretions, but exercise an influence upon the mass of chyme with which they are mingled. A part of the bile is probably taken up again into the system; and from the experiments of Barnard it would appear that the function of the pancreatic juice is to render the oily matters of the food miscible and fit for absorption.

After mixture with these fluids a spontaneous change takes place in the chyme. It separates into a whitish tenacious fluid termed Chyle, and into a gray pulp; the first is the nutritive part of the food, the second is its excrementitions portion. If fat or oil, whether of vegetable or animal matter, have formed part of the aliment, the chyle is of an opaque white colour, if not, it is of a grayish colour. It differs in its chemical character from chyme; for chyme is acid, chyle on the contrary is alkaline.

The following is the composition of the chyle, according to an analysis by Dr. G. O. Rees:—

Water	90·237
Albuminous Matter (coagulable by heat)	3·516
Fibrinous Matter (spontaneously coagulable)	0·370
Animal Extractive Matter (soluble in water and alcohol)	0·332
Animal Extractive Matter (soluble in water only)	1·233
Fatty Matter	3·601
Salts: Alkaline Chloride, Sulphate, and Carbonate, with traces of Alkaline Phosphate, Oxide of Iron	0·711
	100·000

The chyle, together with the excrementitious portion of the food, is slowly transmitted along the small intestines. The progress of the chyle is rendered slow, partly by its own tenacity, in consequence of which it adheres with some degree of firmness to the villi, and its progress is still farther retarded by the valvulæ conniventes, which act as partial valves. [INTESTINES, SMALL.] In its course through the small intestines the chyle gradually disappears, being absorbed by the lacteal vessels, so called from the milk-like fluid they contain. The lacteals commence on the surface of the villi. [LACTEALS.] Loaded with chyle, the lacteals penetrate the coats of the intestine, pass between the layers of the mesentery [MESENTERY], and enter the first order of mesenteric glands. In the mesenteric glands the lacteals unite freely with each other, and become exceedingly convoluted. On emerging from these glands the lacteals pass, still between the layers of the mesentery, on to the second order of mesenteric glands, which they enter, and in which they present the same convoluted appearance as in the first order. On emerging from the second order of mesenteric glands, the lacteals pass on to the receptacle of the chyle, which forms the commencement of the thoracic duct. [THORACIC DUCT.] In the receptacle of the chyle terminates another system of absorbent vessels, termed lymphatics, from the colourless and pellucid fluid, called lymph, which they contain. [LYMPH.] From the receptacle of the chyle the chyle and lymph commingled flow into the thoracic duct, by which tube they are transmitted through the abdomen and thorax to the left subclavian vein, where they are mixed with venous blood. Together with the blood contained in this great vein, the chyle and lymph are sent by a direct and short course to the lungs.

The result of the successive changes thus wrought upon the food by these progressive steps of the digestive process, is to approximate the crude aliment more and more nearly to the chemical condition of the blood. [BLOOD.] "This is accomplished partly by the gastric and intestinal juices, and partly by matters combined with the food, highly animalised in their own nature, and endowed with assimilative properties, as the salivary secretion mixed with the food during mastication; the pancreatic and biliary secretions mixed with the food during the conversion of chyme into chyle; the mesenteric secretions mixed with the elaborated chyle of the mesenteric glands; and, lastly, organised particles, which have already formed a part of the living structures of the body, mixed with the chyle under the form of lymph in the thoracic duct."

(Valentin, *Text-Book of Physiology*, translated by Brinton; Carpenter, *Manual of Human Physiology;* Müller, *Physiology*, translated by Baly.)

DIGITA'LIS, a genus of Exogenous Plants belonging to the natural order *Scrophulariaceæ*. It is distinguished by its 5-parted leafy calyx, its irregular funnel-shaped inflated corolla with an oblique limb, the upper lip of which is short and 2-lobed, the lower 3-lobed, and its ovate acuminate capsule, splitting into 2 many-seeded valves. The flowers in all the species are arranged in long racemes, are either yellow, purple, or brown, and generally showy; the leaves alternate upon a round herbaceous stem.

D. purpurea, Foxglove, is found all over the west of Europe, especially in England and France. It is a very handsome species, with large purple or white flowers. It is a biennal, with oblong stalked scalloped wrinkled leaves, gray with hairs, and a stem about two feet high, also covered with a close soft nap. The purple or white pendulous flowers are above an inch and a half long, and are arranged in one-sided racemes; in the inside of their corolla, on the lower lip, they are bearded with long hairs, and gaily spotted with blackish-purple specks. There are four didynamous stamens, shorter than the corolla, with large smooth anthers, 2-lobed at the base.

The energetic stimulating acrid narcotic properties of this plant have caused it to be extensively employed medicinally. For its action and properties, see DIGITALIS, in ARTS. AND SC. DIV.

There are about 25 species of this genus; most of them are showy garden flowers. The only one which is truly a British plant is the one described.

DIGITA'RIA, a genus of Grasses belonging to the tribe *Paniceæ*. It has fingered spikes, the spikelets in two rows on one side of a flattened rachis, unarmed, 1-flowered, with an inferior rudiment; the glumes 2, lower very small, upper 3-nerved; the sterile flowers of one 5-7 nerved palea, resembling the upper glume and equalling the flower. This genus has obtained its name from the singular form of its heads of flowers, which look like fingers. Two species are described as natives of Great Britain. *D. sanguinalis* was formerly found in Battersea Fields, near London, but is not a true native. It has the leaves and sheaths hairy, the flowers oblong-lanceolate, glabrous with downy margins. It is a common plant in Germany, and has obtained its specific name from an idle trick which the boys in some parts of Germany have of pricking one another's noses with its spikelets till they bleed. It abounds by the roadsides in Poland and Lithuania, in which countries its seeds are collected, and boiled whole like rice with milk, and is esteemed as a pleasant article of diet. The other species is *D. humifusa*. It has leaves and sheaths glabrous, flowers elliptical and downy, with glabrous nerves. This is a rare plant, and grows in sandy fields. Is is a true native in many parts of England. (Babington, *Manual;* Loudon, *Encyclopædia of Plants.*)

DIGITIGRADES. [CARNIVORA.]

DIGY'NIA, a systematic name given by Linnæus, in his artificial system, to such plants as have two styles, or a single style deeply cleft into two parts.

DILL, the common name of a species of *Anethum.* The genus *Anethum* belongs to the natural order *Umbelliferæ*. It has the following characters:—Calyx obsolete; petals roundish entire, involute, with a squarish retuse lobe; fruit lenticular, flattened from the back, surrounded by a flattened border; half-fruits (mericarps) with equidistant filiform ridges, the 3 dorsal acutely keeled, the 2 lateral more obsolete, losing themselves in the border; vittæ broad, solitary, filling the whole channel, 2 on the commissure. The species are annual plants, with upright smooth stems. Leaves much dissected, with setaceous linear segments. The flowers are of a yellow colour, and there is no involucre.

A. graveolens, the Common Dill, has the fruit rather more than two lines long, oblong, bright shining brown and convex at the back, paler and again convex at the edge, which is separated from the back by a deep hollow; dorsal ridges sharp, filiform, elevated, very distinct but fine; the commissure dull grayish-brown, with the tumid vittæ only indistinctly seen.

The fruit of the Dill, like that of many of the order, is carminative and stimulant. It may be taken with food as a condiment, but is more frequently employed for making a distilled water, for which there is a great demand in the nursery. Whether its popularity as a domestic carminative for children is dependent on any specific power is doubtful, and it is more than probable that other stimulants would act as favourably.

A. Sowa is a species found in the East Indies. It has properties of the same kind, but more powerful than the last, and is employed in Hindustan as an ingredient in curries.

(Lindley, *Flora Medica.*)

DILLENIA, a genus of Plants, the type of the natural order *Dilleniaceæ*. The young calyces of *D. scabrella* and *D. speciosa* have a pleasant taste and are used in curries by the inhabitants of Chittagong and Bengal. Several species of *Dillenia* are large trees, and afford hard durable and valuable timber.

DILLENIA'CEÆ, a natural order of Plants belonging to Polypetalous Albuminous Exogens, and related on the one hand to *Magnoliaceæ*, on the other to *Ranunculaceæ* and to *Anonaceæ*. They are briefly characterised by having 5 sepals in a broken whorl; 5 petals; an indefinite number of stamens; a definite number of ovaries, which are either quite distinct or more or less consolidated; berried or capsular and 2-valved fruits; seeds surrounded by a pulpy aril; and, finally, a minute embryo lying in solid fleshy albumen. Differentially considered, Dilleniaceous Plants are distinguished from *Anonaceæ* by their flowers being arranged upon a quinary, not ternary, type, by their albumen being solid, and not ruminated, and by their want of aromatic properties; from *Magnoliaceæ* by their want of stipules, and the presence of a pulpy aril round the seeds.

The plants of this order are chiefly Asiatic trees or shrubs, and usually yellow-flowered. A few occur in America. The trees are found in the woods of tropical India; the bushes inhabit Australia, especially in the more temperate parts, and in China; the woods of Brazil contain several kinds, usually climbers or having a trailing habit. They appear to possess astringent properties, but nothing further of importance.

The species in cultivation in this country are almost all Australasian, and have something the appearance of yellow-flowered *Cistuses*.

Among these occur species of the curious genus *Pleurandra*, in which the stamens are developed on one side only of the flower, all those on the opposite side being abortive. There are few analogies to this in the vegetable kingdom. *Hibbertia volubilis* is a showy twiner, but its flowers are intolerably offensive in their smell. The Indian species are in almost all cases plants of great beauty. They are remarkable both for the grandeur of their foliage and the magnificence of their flowers. Several species of *Dilleniaceæ* are large trees, and afford valuable timber.

1, a flowering shoot of *Hibbertia volubilis*; 2, the calyx and carpels, with one stamen only remaining; the other stamens cut away to show the carpels in the centre of the flower; 3, the ripe fruit.

DILUVIAL FORMATION. The superficial deposits of gravel, clay, and sand (sometimes containing shells and bones of land *Mammalia*), which lie far from their original sites on hills, and in other situations to which no forces of water now in action could transport them, are thus termed. The explanations proposed by geologists are various, and as yet unsatisfactorily demonstrated. Violent floods passing over the land; streams flowing formerly at levels and in lines now impossible; the littoral action of the sea during the time of the uplifting of the land; glacier movements; and the flotation of icebergs over the surface while yet it was covered by the ocean, have all been strongly proposed for adoption: but the phenomena are very complicated, and seem to require many partial solutions, involving change of level of sea and land as the fundamental condition. [ALLUVIUM.] (Lyell, *Principles of Geology*; Jukes, *Physical Geology*; De la Beche, *How to Observe in Geology*.)

DIMEROCRINITES, a genus of *Crinoidea*, proposed by Phillips ('Sil. System,' t. 17) to include species of *Crinoidea inarticulata* of Miller, with the finger-joints in double rows. From the Wenlock Limestone.

DIMORPHANTHUS, a genus of Plants belonging to the natural order *Araliaceæ*. One of the species, formerly *Aralia edulis*, is eaten in China. [ARALIACEÆ.]

DIMYARIA. [CONCHIFERA.]

DINEMOURA. [PŒCILOPODA.]

DINETUS, a genus of Hymenopterous Insects, of the section *Fossores*. [LARRIDÆ.]

DINGO, or *Australian Dog*. [CANIS.]

DINODES. [CHLÆNIUS.]

DINOPS. [CHEIROPTERA.]

DINORNIS, a genus of Birds probably extinct, the remains of several species of which have been found in New Zealand.

In November, 1839, Professor Owen exhibited, at a meeting of the Zoological Society of London, the fragment of the shaft of a femur, 6 inches in length, and 5½ inches in its smallest circumference, with both extremities broken off. This bone of an unknown struthious bird of large size, presumed to be extinct, was put into the Professor's hands for examination, by Mr. Rule, with the statement that it was found in New Zealand, where the natives have a tradition that it belonged to a bird of the eagle kind, which has become extinct, and to which they give the name Movie or Moa. Similar bones, it was said, were found buried on the banks of the rivers.

After a minute description of the bone, Professor Owen made the following statement:—"There is no bone of similar size which presents a cancellous structure so closely resembling that of the present bone, as does the femur of the ostrich; but this structure is interrupted in the ostrich at the middle of the shaft, where the parietes of the medullary, or rather air-cavity, are smooth and unbroken. From this difference I conclude the struthious bird indicated by the present fragment to have been a heavier and more sluggish species than the ostrich; its femur, and probably its whole leg, was shorter and thicker. It is only in the ostrich's femur that I have observed superficial reticulate impressions similar to those on the fragment in question. The ostrich's femur is subcompressed, while the present is cylindrical, approaching in this respect nearer to the femur of the emeu; but its diameter is one-third greater than that of the largest emeu's femur with which I have compared it. The bones of the extremities of the great *Testudo elephantopus* are solid throughout: those of the crocodile have no cancellous structure like the present bone. The cancellous structure of the mammiferous long bones is of a much finer and more fibrous character than in the fossil. Although I speak of the bone under this term, it must be observed that it does not present the characters of a true fossil; it is by no means mineralised; it has probably been on or in the ground for some time, but still retains most of its animal matter. It weighs 7 ounces 12 drachms avoirdupois.

"The discovery of a relic of a large struthious bird in New Zealand is one of peculiar interest, on account of the remarkable character of the existing Fauna of that island, which still includes one of the most extraordinary and anomalous genera of the struthious order; and because of the close analogy which the event indicated by the present relic offers to the extinction of the Dodo of the island of the Mauritius. So far as judgment can be formed of a single fragment, it seems probable that the extinct bird of New Zealand, if it prove to be extinct, presented proportions more nearly resembling those of the Dodo than of any of the existing *Struthionidæ*. Any opinion however as to its specific form can only be conjectural. The femur of the Stilt-Bird (*Himantopus*) would never have revealed the anomalous development of the other bones of the leg; but so far as my skill in interpreting an osseous fragment may be credited, I am willing to risk the reputation for it on the statement that there has existed, if there does not now exist, in New Zealand, a struthious bird nearly if not quite equal in size to the ostrich."

It was not long before an opportunity occurred of testing this very remarkable statement, and of proving the sagacity of the naturalist who had thus staked his reputation upon his conviction of the truth of the general principles of the science of comparative anatomy. Professor Owen received a communication from the Rev. W. Cotton describing several other remains of animals of the same kind, and in 1843 a collection, comprising vertebræ and bones of the hinder extremities, pelvis, &c., were transmitted by the Rev. W. Williams to the dean of Westminster (Dr. Buckland); and in 1846 many specimens were sent to England by Dr. Mackellar, Mr. Percy Earle, and Colonel Wakefield. These were placed in the hands of Professor Owen, and form the subject of his first and second 'Memoirs on the Dinornis,' in the 'Zoological Transactions,' vol. iii.

In these Memoirs Professor Owen pointed out that the bones which had been thus sent over from New Zealand contained the remains of no less than nine species of a remarkable group of birds, which he at first supposed belonged to the family of *Struthionidæ*. Subsequent examination however has led Professor Owen to the conviction that, although wingless, these birds have as little connection structurally and physiologically with the ostriches as with any other group of recent birds.

From an examination of the various bones thus collected, Professor Owen was enabled to point out that the fragment of bone which he had first received belonged to a species of the genus not only much larger than any of the other species indicated by these remains, but larger than any form of existing bird. To this species he gave the name of *Dinornis giganteus*, and found that the height of this bird must have been from 10 feet to 10 feet 6 inches. The other species described were—*D. ingens*, attaining a height of 9 feet; *D. struthioides*; *D. didiformis*, 4 feet; *D. dromæoides*, 5 feet; *D. struthioides* upwards of 6 feet. In addition to these were described—*D. curtus*, *D. crassus*, *D. otidiformis*, and *D. casuarinus*. Thus these remains showed the existence of a number of birds, varying in size from the almost flightless Bustard to birds of the size of the Dodo, the Emeu, and the Ostrich, and one larger than all.

On a subsequent examination of the bones of *D. ingens* and *D. dromæoides*, Professor Owen discovered a back toe which he had seen nowhere in the other species, and for these he proposed the generic name *Palapteryx*. To these two was afterwards added a third species, *P. geranoides*. Dr. Mantell gives the following account of a further discovery of the remains of birds in New Zealand:—

"In 1846 and 1847 my eldest son, Mr. Walter Mantell, of Wellington, who had resided several years in the colony, explored every known locality of these fossil bones within his reach in the North Island, and went into the interior of the country, and located with the natives, for the purpose of collecting specimens, and of ascertaining whether any of these gigantic birds were still in existence, resolving, if there appeared to be the least chance of success, to penetrate into the unfrequented regions, and obtain a live Moa. The information gathered from the natives offered no encouragement to follow up the pursuit, but tended to confirm the idea that this race of colossal bipeds was extinct, the last individuals having in all probability, like the Dodo, been exterminated by human agency within a comparatively recent period; or that if any of the species, whose bones occur in a fossil state, are still living, they will prove to be of comparatively small types, related to the *Apteryx*, the living diminutive representative of the stupendous ostrich-like birds which once trod the soil of New Zealand. My son succeeded however in forming the most interesting collection of these remains hitherto obtained. It comprised between 700 and 800 bones belonging to birds of various species and genera, and differing considerably in magnitude and age, some belonging to very young individuals, in which the epiphyses of the long bones are distinct from the shaft, while others are those of adult and aged birds." The chief part of this collection is now deposited in the British Museum.

The locality from which these specimens were obtained is thus described by Mr. Mantell:—"Near Waikoriati, 17 miles north of Otago, there is a headland called Island Point, about three-quarters of a mile in length and 150 feet in height; it consists of sandy clay distinctly stratified and traversed by dykes of columnar trap, the columns begin at right angles to the sides of the veins. In a little bight, south of Island Point, on the side of the bar which unites that headland to the mainland at the entrance of the River Waikoriati in front of the native Kaika, named Makuku, is situated the exposed parts of the so-called turbary deposit, whence bones of Moas and other birds of various kinds have been obtained in such number and perfection. This bed is about 3 feet in depth and not more than 100 yards in length, and lies immediately on a stratum of tertiary blue clay; its inland boundary is obscured by vegetation, and appears to be of a very limited extent; the bed is entirely submerged, and only visible when the tide has receded. It consists almost wholly of decayed vegetable matter, and its surface is studded with the undisturbed roots of small trees, which appear to have been burnt to the ground at some remote period. It is a light, sandy, elastic earth, of a blackish-brown colour, and emits a strong fetid odour when first collected; from the large quantity of animal matter it contains I conceive it was originally a swamp or morass, in which the New Zealand Flax (*Phormium tenax*) once grew luxuriantly. It is now covered by a thin layer of sand when exposed at low water. . . Although bones of several species of Moa, especially of the largest kinds, have been collected from this locality in considerable numbers and in great perfection, yet as the bed is rapidly diminishing from the inroads of the sea, there is great reason to fear that it will be entirely washed away, without yielding to the palæontologist all the desired information respecting the extinct animals whose relics it enshrines; for the natives and whalers are well aware of the interest attached to the bones by Europeans, and they seize indiscriminately on any specimen exposed by the receding tide, and if it cannot be readily extracted they break it off, and thus many a valuable relic has been destroyed. Their cupidity and avarice have too been so much excited by the large rewards injudiciously given by casual visiters, that the cost of specimens has increased to an unreasonable amount."

In their general aspect the bones which have been obtained from these spots closely resemble those obtained from the ossiferous caverns in Germany. Professor Owen gives an analysis of their chemical composition, and from this infers that they may have been recently deposited. Mr. Mantell obtained bones also from North Island:—"On the western shore of the North Island, about sixty miles south-west of New Plymouth, there is a stream called Waingougou, which empties itself into the sea at about a mile and a half south of Waimate in the Ngátirúanúi district. Part of the neighbouring country is elevated table-land, with deep tortuous gullies, through which the torrents and streams take their course to the sea. That of Waingougou, which is as tortuous as any of them, takes its rise in the neighbouring volcanic ridge, and has evidently at a former period discharged itself far distant from its present embouchure, as is proved by the existence of a line of cliffs which extends inland, and has manifestly been produced by the corroding action of the river. Driven from its course probably by a change in the relative level of the land and sea, the stream has formed its present channel, which cuts through a bed of loose conglomerate, 100 feet thick, overlying a deposit of finely-laminated sand, which covers a thick stratum of blue clay full of shells. The conglomerate consists of pebbles and large boulders of an infinite variety of volcanic rocks; the clay is the lowermost visible bed; the shells it contains are marine, and resemble species existing in the South Pacific Ocean; but I suspect many will be found specifically distinct from any recent forms. Between the two bluffs near the embouchure of the river there is a sand-flat about 200 yards across, and this on my first visit was strewn with bones of men, moas and other birds, and two species of seals. I had some deep openings made near the foot of the ancient cliff on the top of which is the Pa or native village of Ohawetokoloko, and at the same level as the flat on which I had observed the strewn fragments of bones I came to a regular ossiferous deposit. The bones however though perfect were as soft and plastic as putty, so that if grasped strongly they changed as it were by magic into pipe-clay; and it was necessary to dig them up with great care, and expose them to the air and sun to dry, before they could be packed and removed. . . Unfortunately the natives soon caught sight of my operations, and came down in swarms, men, women, and children, trampling on the bones I had carefully extracted and laid out to dry, and seizing upon every morsel exposed by the spade. My patience was tried to the utmost, and to avoid blows I was obliged to retreat and leave them in the possession of the field; and to work they went in right earnest, and quickly made sad havoc. No sooner was a bone perceived than a dozen natives pounced upon it, and began scratching away the sand, and smashed the specimen at once. It was with great trouble, and by watching the opportunity of working in the absence of the Maoris, that I procured anything worth having."

The remains thus procured by Mr. Mantell were placed at the disposal of Professor Owen by Dr. Gideon Mantell, who was thus enabled to supply many deficiences in his former descriptions of these remarkable birds. They afforded specimens of the bones of *Dinornis curtus*, *D. didiformis*, and *D. casuarinus*; also of *Palapteryx ingens*, variety *robustus*, and of a new species, *P. geranoides*. Notwithstanding the great number of bones that have thus been examined, one fragment only of the wings or humerus has been detected. This indicates the rudimentary condition of the wings in these birds. The humerus found Professor Owen regards as belonging to a species of *Palapteryx*. The following is a summary of the nature of this collection by Professor Owen:—"There are not less than 190 phalanges of the toes referrible to five or six species of *Dinornis*, *Palapteryx*, and *Notornis*, and there are 8 tarso-metatarsals, with the articular surface for a very strong hind toe, and of a conformation more nearly resembling those of the Dodo than of the *Dinornis* and *Palapteryx*, but shorter and thicker in proportion, and appertaining to the same bird as the tibia and fibula described in my Memoir of 1843 under the name of *D. otidiformis*. The proximal articulation of this remarkable form of tarso-metatarsal exactly fits the distal end of the tibia figured, and also that of a corresponding fractured tibia in Mr. Mantell's collection; which also contains the proximal end of another tibia, a fibula, an entire femur, and distal ends of two other femora, of the same species. The large surface for the hind toe; the strong calcaneal process forming a complete bony canal for the flexor tendons at the back part of the proximal end of the tarso-metatarsal; the perforation above the interspace between the outer and middle metatarsals for the tendon of the adductor muscle of the fourth toe, and the more posterior position of the condyle for the inner toe—all concur to indicate the generic distinction of the bird to which it belonged from either *Dinornis* or *Palapteryx*; and I propose to distinguish the new genus by the name of *Aptornis* and the present species *A. otidiformis*." ('Zool. Trans.' iii. p. 347.)

With the remains of the bones found on the banks of the river Waingougou were mixed the fragments of egg-shells. The eggs to which the fragments belonged were supposed to be about the size of a tea-cup. In connection with this subject the recent discovery of a large egg in Madagascar is interesting.

In a report to the French Academie de Sciences, M. Isidore Geoffroy St. Hillaire described three enormous fossil eggs from Madagascar, and some bones belonging to the same bird. The captain of a merchant-vessel trading to Madagascar one day observed a native using for a domestic purpose a vase which much resembled an egg, and upon examination proved to be one. The native stated that many such were to be found in the interior of the island, and eventually procured the eggs and bones exhibited by M. St. Hillaire. The largest of these eggs is equal in bulk to 135 hens' eggs, and will hold two gallons of water. M. St. Hillaire proposes the name of *Epiornis* for the monster biped of which these marvellous eggs and bones are the first evidence brought under the notice of naturalists. Casts of these eggs have been sent to this country, and are to be seen in various museums.

Amongst the bones sent home by Mr. Mantell, the remains of a new genus, *Notornis*, were found. It belongs to the same family as the *Brachypteryx* and the *Rallidæ*, and the interest that attaches to it in this relation is the fact that Mr. Mantell succeeded in obtaining a single living specimen. Many persons had reported the existence of a wingless bird as large as a fowl, and with red beak and legs, with a cry sounding like 'Keo Keo.' The following is Dr. Mantell's account of the discovery of this bird:—"On my son's second visit to the southern part of the Middle Island (as Government Commissioner for the settlement of native claims), he fell in with some sealers who had been pursuing their avocations along the little frequented islets and gullies of Dusky Bay on the south-western shores, and from them obtained the skin of a recent specimen of *Notornis Mantelli*. It appeared that when frequenting the coasts in search of seals and other game, these men observed on the snow, with which the ground was then thickly covered, the foot-tracks of a large and strange bird, and after following the trail for a considerable distance, they caught sight of the object of their search, which ran with great speed and for a long while distanced their dogs, but was at length driven up a gully in Resolution Island, and captured alive. It uttered loud screams, and fought and struggled violently; it was kept alive three or four days on board the schooner and then killed, and the body roasted and eaten by the crew, each partaking of the dainty, which was said to be delicious. The skin, with the skull and bones of the feet and legs, was preserved, and fortunately obtained by my son while in good condition, and thus perhaps the last of the race of Mohos was preserved for the naturalists of Europe. Upon comparing the head of the bird with the fossil crania and mandibles, my son was at once convinced of the specific identity of the recent and fossil specimens; and so delighted was he by the discovery of a living example of one of the supposed extinct contemporaries of the Moa, that he wrote to me and stated that the skull and beaks were alike in both, and that the abbreviated and feeble development of the bones and plumage of the wing were in perfect accordance with the indications afforded by the humerus and sternum found by him at Waingougou and now in the British Museum, as pointed out in the 'Zoological Transactions,' vol. iii. To the natives of the pahs, or villages, my son visited on his homeward route to Wellington, the *Notornis* was a perfect novelty, and excited great interest. No one had seen such a bird, but all agreed that it was the traditional Moho or Takahé, which they had believed was utterly extinct.

"This beautiful bird is about two feet high, and much resembles in its general form the *Porphyrio melanotus*, but it is larger and stouter, and generically distinct; the characters predicated by Professor Owen from the fossil remains being clearly marked in his recent volume. The beaks are short and strong, and as well as the legs were of a bright scarlet in the living animal. The neck and body are of a dark purple colour, the wings and back being shot with green and gold. The wings are short and rounded, and remarkably feeble both in structure and plumage. The tail is scanty and white beneath. The specific identity of the recent and fossil *Notornis* is confirmed by Mr. Gould, who has published a coloured figure the size of the original in a supplementary number of his splendid work on the 'Birds of Australia.'"

In addition to the bones of the animals mentioned, remains of other birds were found in the Mantellian collection. These were of a species of nocturnal Parrot, belonging to the genus *Nestor*, of a probably extinct species of *Apteryx*, of a species of Albatross allied to *Diomedea chlororhynchus*, and also of the Penguin.

For the structure of the *Apteryx* and its relations to other birds, see the article STRUTHIONIDÆ.

In 1851 Professor Owen received from Governor Grey a large collection of specimens from New Zealand of the bones, and more especially the skulls, of several of the species, which he described in a fifth memoir presented to the Zoological Society. An almost perfectly restored skeleton of the *Dinornis giganteus* exists in the Museum of the College of Surgeons. Professor Owen concludes one of the memoirs referred to with the following general remarks:—"The extraordinary number of wingless birds and the vast stature of some of the species peculiar to New Zealand, and which have finally become extinct in that small tract of dry land, suggest it to be the remnant of a larger tract or continent over which this singular Struthious Fauna formerly ranged. One might almost be disposed to regard New Zealand as one end of the mighty wave of the unstable and ever-shifting crust of the earth, of which the opposite end, after having been long submerged, has again risen with its accumulated deposits in North America, showing us in the Connecticut Sandstones of the Permian period the foot-prints of the gigantic birds which trod its surface before it sank; and to surmise that the intermediate body of the land-wave along which the *Dinornis* may have travelled to New Zealand has progressively subsided, and now lies beneath the Pacific Ocean."

(Owen, *Memoirs on the Dinornis*; *Zoological Transactions*, vol. iii.; Owen, *Proceedings of Zoological Society*, in *Annals of Natural History*; Mantell, *Petrifactions and their Teachings*.)

DINOTHE'RIUM, a genus of gigantic extinct Herbivorous Mammifers, established by Professor Kaup. The remains have been found most abundantly at Epplesheim in Hesse Darmstadt, in strata of sand referrible to the second period of the tertiary formations (Miocene of Lyell). Fragments are noticed as occurring also in several parts of France, Bavaria, and Austria, by Cuvier, who, from the resemblance of their molar teeth to those of the Tapirs, at first considered the animals to have been an enormous species of the last-named genus.

We select as an example *Dinotherium giganteum*, the largest species yet discovered, and which is calculated both by Cuvier and Kaup to have attained the length of 18 feet. The bones of the head and the teeth are the principal remains hitherto found. A scapula in form resembling more nearly that of a mole than any other animal, is the principal bone of the body yet found, and this shoulder-blade has been considered as indicating a peculiar adaptation of the fore leg to the purposes of digging. In the autumn of 1836, an entire head of the animal was disinterred at Epplesheim, measuring about 4 feet in length and 3 feet in breadth, of which Professor Kaup and Dr. Klipstein have given figures and a description. ('Beschreibung und Abbildungen von dem in Rheinhessen aufgefundenen colossalen Schedel des Dinotherii gigantei, mit geognostischen Mittheilungen über die knochenführenden Bildungen des mittelrheinischen Tertiärbeckens: von Dr. J. J. Kaup, & Dr. A. Klipstein. 4to., Darmstadt, 1836.')

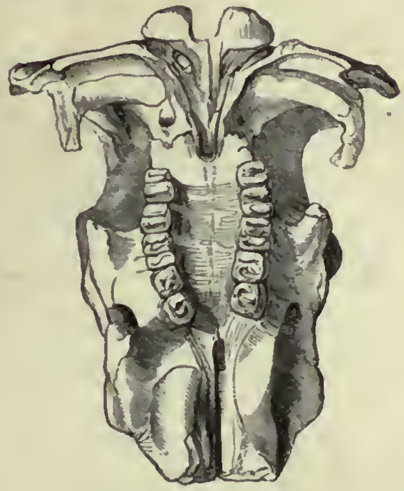
It will be seen from the cuts (which are copied from the works of Dr. Kaup and those of Drs. Kaup and Klipstein), as well as from the casts in the British Museum, that though the form of the molar teeth approximates to that of the tapirs, the tusks placed at the anterior extremity of the lower jaw and curved downwards somewhat after the fashion of those in the upper jaw of the Walrus, exhibit a remarkable deviation from this part of the dental formula in any other known animal, whether living or fossil. With this is combined a form of the lower jaw itself which cannot but arrest the attention of every observer.

Dr. Buckland, in the first edition of his 'Bridgewater Treatise,' published before the appearance of the memoir of Dr. Kaup and Dr. Klipstein, giving figures and a description of the entire head, but after the publication of Dr. Kaup's earlier publication,—when adverting to the *Mammalia* of the Miocene Period of Lyell, observes, that the second, or miocene system of tertiary deposits, contains an admixture of the extinct genera of Lacustrine *Mammalia*, of the first or Eocene series, with the earliest forms of genera which exist at the present time. This admixture, he adds, was first noticed by M. Desnoyers, in the marine formations of the Faluns of Touraine, where the remains of *Palæotherium*, *Anthracotherium*, and *Lophiodon*, which were the prevailing genera in the Eocene Period, are found mixed with bones of the Tapir, Mastodon, Rhinoceros, Hippopotamus, and Horse. These bones are fractured and rolled, and sometimes covered with *Flustræ*, thus giving indication of having been derived from carcasses drifted into an æstuary or sea. Similar admixtures, continues Dr. Buckland, have been found in Bavaria and near Darmstadt, and many of these animals also indicate a lacustrine or swampy condition of the regions they inhabited. One of them (*Dinotherium giganteum*) is stated to have attained 18 feet in length, and to have been the largest of all terrestrial *Mammalia* yet discovered, exceeding even the largest fossil elephant.

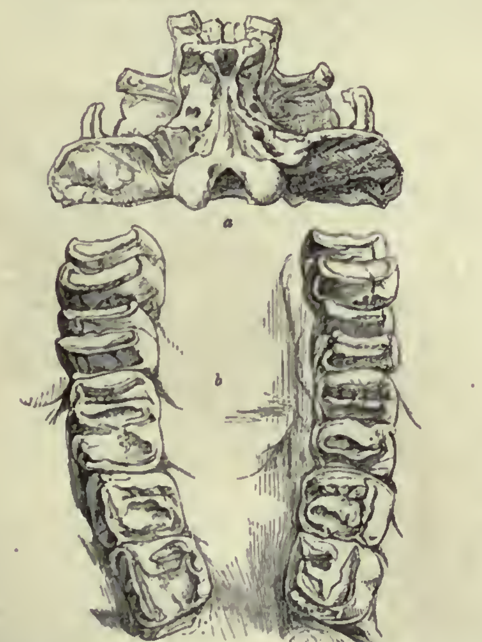
Profile of the skull of *Dinotherium giganteum*. The dotted line shows the edge of the coronoid process of left lower jaw, through the ramus of which the last molar tooth and a portion of the last but one are supposed to be seen. The zygomatic arch is fractured, and the intermediate portion of it lost.

Profile of lower jaw of *Dinotherium giganteum* (another individual), with the coronoid process gone, and only two teeth in sight. The length of this, including the tusk, is nearly four feet.

Skull of *Dinotherium giganteum*, seen from above.



Skull of the same, seen from below.



Portions of the skull of the same; *a*, posterior part of the skull, seen from below, showing the occipital condyle and foramen, &c.; *b*, roof of the mouth and molar teeth; the interval between the rows widening from before backwards.

In this view of the subject it becomes of importance to see what were the remains which were found in the strata of sand at Epplesheim, near Altzey, about 12 leagues south of Mayence, in company with those of the *Dinotherium*.

Dr. Kaup, in his 'Description d'Ossemens Fossiles' (Darmstadt, 1832), gives the following number of species:—*Dinotherium*, 2; *Tapirus*, 2; larger than living species. *Chalicotherium* (allied to Tapirs), 2; *Rhinoceros*, 2; *Tetracaulodon* (allied to Mastodon), 1; *Hippotherium* (allied to Horse), 1; *Sus*, 3; *Felis* (some as large as a Lion), 4; *Machairodus* (allied to Bear, *Ursus cultridens*); *Gulo* (Glutton), 1; *Agnotherium* (allied to Dog, but as large as a Lion), 1.

Dr. Buckland, in the work and in the edition above quoted, after giving a description of the tusks of the *Dinotherium*, thus proceeds:—"I shall confine my present remarks to this peculiarity in the position of the tusks, and endeavour to show how far these organs illustrate the habits of the extinct animals in which they are found. It is mechanically impossible that a lower jaw, nearly four feet long, loaded with such heavy tusks at its extremity, could have been otherwise than cumbrous and inconvenient to a quadruped living on dry land. No such disadvantage would have attended this structure in a large animal destined to live in water; and the aquatic habits of the family of Tapirs, to which the *Dinotherium* was most nearly allied, render it probable that, like them, it was an inhabitant of fresh-water lakes and rivers. To an animal of such habits, the weight of the tusks sustained in water would have been no source of inconvenience; and, if we suppose them to be employed as instruments for raking and grubbing up by the roots large aquatic vegetables from the bottom, they would, under such service, combine the mechanical powers of the pick-axe with those of the horse-harrow of modern husbandry. The weight of the head, placed above these downward tusks, would add to their efficiency for the service here supposed, as the power of the harrow is increased by loading it with weights. The tusks of the *Dinotherium* may also have been applied with mechanical advantage to hook on the head of the animal to the bank, with the nostrils sustained above the water, so as to breathe securely during sleep, whilst the body remained floating at perfect ease beneath the surface: the animal might thus repose, moored to the margin of a lake or river, without the slightest muscular exertion, the weight of the head and body tending to fix and keep the tusks fast anchored in the substance of the bank, as the weight of the body of a sleeping bird keeps the claws clasped firmly around its perch. These tusks might have been further used, like those in the upper jaw of the Walrus, to assist in dragging the body out of the water; and also as formidable instruments of defence. The structure of the scapula already noticed seems to show that the fore leg was adapted to co-operate with the tusks and teeth, in digging and separating large vegetables from the bottom. The great length attributed to the body would have been no way inconvenient to an animal living in the water, but attended with much mechanical disadvantage to so weighty a quadruped upon land. In all these characters of a gigantic, herbivorous, aquatic quadruped, we recognise adaptations to the lacustrine condition of the earth, during that portion of the tertiary periods to which the existence of these seemingly anomalous creatures appears to have been limited."

In his description of the figures of the remains of *Dinotherium* in the same work, Dr. Buckland observes that they were found in a sand-pit containing marine shells at Epplesheim, near Altzey, about 40 miles north-west of Darmstadt, where they are preserved in the museum. He adds, that bones of *Dinotherium* have lately been found in tertiary fresh-water limestone, near Orthes, at the foot of the Pyrenees; and with them remains of a new genus allied to rhinoceros; of several unknown species of deer; and of a dog or wolf, the size of a lion. The following conclusion terminates the note appended to the description in Dr. Buckland's first edition:—"From the near approximation of this animal to the living tapir, we may infer that it was furnished with a proboscis, by means of which it conveyed to its mouth the vegetables it raked from the bottom of lakes and rivers by its tusks and claws. The bifid ungual bone (Kaup, 'Add.,' table 11), discovered with the other remains of *Dinotherium*, having the remarkable bifurcation which is found in no living quadrupeds, except the Pangolins, seems to have borne a claw, like that of these animals, possessing peculiar advantages for the purpose of scraping and digging; and indicating functions concurrent with those of the tusks and scapulæ."

Upon referring to the view of the skull of *Dinotherium giganteum* seen from above, the width of the anterior portion of the cranium and the deep depression there visible, will strike the observer as very remarkable; and we find that Professor Kaup has, in his restoration of the animal, furnished it with a considerable proboscis, and given its general form as a good deal resembling that of the tapir.

Dr. Buckland, in the supplementary notes to his second edition, has the following notice, with a reference to p. 135:—"The *Dinotherium* has been spoken of as the largest of terrestrial *Mammalia*, and as presenting in its lower jaw and tusks a disposition of an extraordinary kind, adapted to the peculiar habits of a gigantic herbivorous aquatic quadruped." The Doctor then alludes to the entire head found in 1836, and thus proceeds:—"Professor Kaup and Dr. Klipstein have recently published a description and figures of this head, in which they state that the very remakable form and dispositions of the hinder part of the skull show it to have been connected with muscles of extraordinary power to give that kind of movement to the head which would admit of the peculiar action of the tusks in digging into and tearing up the earth. They further observe that my conjectures (p. 138) respecting the aquatic habits of this animal are confirmed by approximations in the form of the occipital bone to the occiput of *Cetacea;* the *Dinotherium,* in this structure, affording a new and important link between the *Cetacea* and the *Pachydermata.*" Dr. Buckland, in this second edition, gives a copy of the profile of the entire head and of the restoration.

Restoration of *Dinotherium giganteum.*

This head has been exhibited at Paris, and seems to have excited great interest among the French zoologists; for we find in the 'Journal des Débats' of the 21st of March in the year 1837 that at the sitting of the Académie Royale des Sciences de Paris on the day before M. de Blainville read a note detailing his particular views of the position which the animal held in the animal series—views which, it is there stated, were adopted both by M. Duméril and M. Isidore Geoffroy St. Hillaire. These views were detailed in 'L'Institut' of the 22nd of March; and the subject is so interesting that we here present them to the reader, more especially as they are so much at variance with the restoration, a copy of which is above given.

"M. de Blainville read a note on the fossil head of the *Dinotherium giganteum* recently exhibited at Paris by Messrs. Kaup and Klipstein. According to M. de Blainville the *Dinotherium* constituted a genus of mammifers of the family of the Dugongs and Lamantins, which family makes a part of the order or of the degree of organisation named by the last-mentioned zoologist *Gravigrades,* on account of their heavy progression, and of which the first family is formed by the Elephants. The following were the grounds stated for this opinion:—

"As regards the teeth, the molars, five in number on each side of each jaw, have their crown squared and deeply traversed by two transverse elevations, the same as in the Lamantins. But as this character occurs also in the Tapirs and Kangaroos, and even in the Laphiodons, it would be far from sufficient for deciding the question, if it were not joined with the absence of false molars and canines (a formula which produces a considerable space between the first molar and the incisors), and with the number and form of these last, which entirely resemble small tusks; only they are implanted at the extremity of the lower jaw and are directed downwards. Whether or no there existed a pair of incisors in the upper jaw is an uncertain point, the two extremities of this jaw which have been found being more or less truncated. It may however be inferred, from the enlarged and thick form of a fragment found some years ago, that it is possible that the animal might have had upper incisors, but smaller than those below: perhaps only rudimentary.

"As to the form of the head and its parts it corroborates what the dental system had established. In fact, the occipital condyles are entirely terminal, or in the direction of the longitudinal axis of the head, as in the Lamantins and the Cetaceous *Edentata,* modified for existence in the water. The occipital surface is large, subvertical, and even inclined from before backwards, with a profound mesial depression, for the insertion either of a very strong cervical ligament, or powerful muscles for the elevation of the head, and the basilary part of the skull is narrow in its component parts; while the syncipitofrontal region is on the contrary very flat, very wide, as in the lamantins and dugongs, overplumbing the temporal fossa, which is extremely wide and extremely deep, indicating enormous levator muscles for the lower jaw, not only for the purpose of mastication, but adapted besides for the particular action of that jaw with its rake-like incisor teeth. This disposition of the temporal fossa is perfectly in harmony with the zygomatic arch, which is wide, thick, robust, and complete, as far as may be inferred from the portion which is broken, but which nevertheless offers the articulating surface of the corresponding bone, exactly as in the lamantins; perhaps however without the great enlargement which may be remarked at the jugal apophysis of the temporal bone in the latter. The orbit is, as in the animals last named, very small and lateral, but very largely open in the zygomatic fossa. The auditory aperture is small, narrow, and rather oblique from below upwards. The face is wide and flattened, prolonged and enlarged a little, as in the *Cetacea,* anteriorly. It presents in its middle a very large aperture, the composition of which it has not been possible to study on account of the position of the head, which is upside-down, but which aperture, though evidently wider and greater than that of the dugong, has evidently the greatest analogy to what exists in that animal. The posterior orifice of the nasal cavity is on the contrary very narrow. The sub-orbital hole is very considerable, but even less perhaps than it is in the dugong. With regard to the lower jaw, that again exhibits the greatest analogy to that of the dugong, from the manner in which its branches are curved downwards towards the anterior third part of their length; only, that of the *Dinotherium* being armed at its recurved extremity with a tusk, the ascending ramus offers, in its width and its condyle, which is as transverse as in the *Carnivora,* a concordant disposition; so that the only motions permitted should be those of elevation and depression, as in those animals. The ethmoid surface of the temporal bone also is, as it were, a portion of a hollow transverse cylinder, with an apophysary lamina, having an extremely strong ridge—'une lame apophysaire d'arrêt extrêmement forte.' 'With this element (says M. de Blainville) we may regard it as nearly beyond doubt that the *Dinotherium* was an animal of the family of the Lamantins, or Aquatic *Gravigrades,* its proper position being at the head of the family, preceding the Dugong, and consequently preceded by the *Tetracaulodon,* which ought to terminate the family of the Elephants. In a word, the animal, in our opinion, was a Dugong with Tusk-Incisors. We must then suppose that it had only one pair of anterior limbs, with five toes on each. As to the supposition that the animal was provided with a trunk, which might be presumed from the great nasal opening, the enlarged surfaces which surround it, and the size of the suborbital nerve, as far as may be judged from the size of the suborbital hole, we believe that this is at least doubtful, and that it is more probable that these dispositions bear relation to a considerable development of the upper lip and the necessary modification of the nostrils in an aquatic animal, as is equally the case in the dugong. We think even that the upper lip by its immense development embraced the lower one, and thus hid even the base of the tusks, and that the lower one was sufficiently small, as may be presumed from the chin-holes (trous mentonniers). After this it is easy to perceive that of the two principal opinions which have been broached and discussed concerning this singular animal, we are much further from considering it a great species of *Edentata,* near the sloths, with Dr. Kaup, than from considering it as a tapir, as G. Cuvier did, from an examination of the molar teeth, the only parts then known. In fact, there is, in our opinion, much less distance, in the natural method, between a dugong and a tapir than between a dugong and a sloth.' In this note M. de Blainville has not taken into consideration that the head of the *Dinotherium,* as well as a phalanx which was found in the same locality, are referred by Professor Kaup to the same animal; but M. de Blainville does not believe that this phalanx really belonged to the *Dinotherium.* 'In fact (says he), Mr. Lartet found with these same phalanges a portion of a tooth, which evidently indicates a great pangolin.'

"At the end of the reading, M. Duméril rose to confirm the views of M. de Blainville. He insisted particularly on the transversal form and great extent of the condyle of the lower jaw and of the articular fossa destined to receive it. He much regretted the loss of the zygomatic arch, the bases of which only remain on the jugal and temporal bones. 'The curvatures of this arch,' said he, 'would have given ideas of the volume and force of the masseter and temporal muscles, which must have been considerable. It would be important to know them to compare them with those of the Lamantin on one side, and on the other with the *Megatherium,* whose skeleton is at Madrid. With regard to the phalanges, which are believed to be those of the *Dinotherium,* they are certainly analogous to those of the Sloths: but in the Lamantin, the ungual phalanx, which is in fact a double pulley with a mesial projection at the base, offers at its other extremity a single point with a sort of hood (capuchon) below: that is to say, inverse to that which is found in the great species of Cats (*Felis*), and very different from those of the Sloths and the Ant-Eaters.'"

In this statement there is one position that is rather staggering; and indeed we cannot but think it probable that M. de Blainville has not been quite accurately reported. He is made to observe that the articulation of the lower jaw is such that the only motions permitted should be those of elevation and depression, as in the *Carnivora.* Now, that with true grinding teeth, like those of the *Dinotherium,* the jaws should be limited to the motions of elevation and depression, so admirably fitted for working the cutting edges of the scissor-teeth of the *Carnivora,* is almost inconceivable. Without venturing to give any opinion as to the true position of this interesting genus in the animal series, we may be permitted to observe that the evidence on which M. de Blainville is stated to have rested for the cetaceous character of *Dinotherium*, appears to us to be rather meagre and hardly sufficient to warrant the conclusion. At present the extremities of this creature have not been found. They would undoubtedly throw more light on its true character than the skull alone can do. In the British Museum is the femur of an animal from Epplesheim, supposed to belong to the *Dinotherium*. If this point could be satisfactorily determined it would at once clear up the difficulty, and constitute the *Dinotherium* a terrestrial species.

DIODONTA. [TELLINIDÆ.]

DIŒCIA, the twenty-second class in the artificial method used by Linnæus in arranging plants. It comprehends such genera as have male or stamen-bearing flowers on one plant, and female or pistil-bearing flowers on another, as willows. Hence all plants having the sexes thus distinguished are called diœcious.

DIOMEDEINÆ, a family of Birds to which the Albatrosses belong. The characters of the genus *Diomedea* are given under ALBATROSS. In that article three species of this genus are referred to. We now give a complete list of the species of this important genus :—

Diomedea exulans, Linn. This bird is abundant between 30° and 60° S. lat., and equally numerous in all parts of the ocean bounded by those degrees; its range however extends much farther south, even to within the antarctic circle.

D. melanophrys, Temm. It is the most abundant species of the southern seas; equally numerous in every part between the 30th and 60th degrees.

D. cauta, Gould. This species was procured by Mr. Gould off the south coast of Van Diemen's Land.

D. chlororhynchos, Lath. It occurs between 30° and 60° S. lat., in both the Atlantic and Pacific Oceans.

D. culminata, Gould. This bird is rather abundant both in the Pacific and Atlantic Oceans, between 30° and 50° S. lat.

D. fuliginosa, Gmel. It occurs in all parts of the ocean between 30° and 60° S. lat.; equally common off Van Diemen's Land, Cape Horn, and the Cape of Good Hope.

D. brachyura, Temm. Found in the North Pacific Ocean.

D. gibbosa, Gould. An inhabitant of the North Pacific Ocean.

D. olivaceorhyncha, Gould. China seas (?).

Mr. Gray, in his 'Genera of Birds,' also gives *D. spadicea* as a species. He also makes *D. gibbosa* (Gould) synonymous with *D. nigripes*, Audubon, 'Orn. Biog.,' vol. v. p. 327, and adopts the latter name as having the priority.

DION. [CYCADACEÆ.]

DIONÆA, a most singular genus of herbaceous Plants belonging to the natural order *Droseraceæ*. There is one species, the *D. muscipula*, which is remarkable for the irritability of its leaves, which, when brushed against by an insect, will suddenly close upon it and hold it fast, whence it is often called Venus's Fly-Trap and the Carolina Catchfly Plant. It is botanically related to the *Drosera*, or Sundew, which has also the property of seizing insects by its viscid hairs, but differs so much as to have led some botanists to doubt whether it really belongs to the same natural order. Its flower-branches, for example, are not rolled up before they unfold, but have a straight æstivation; the placentæ of the fruit are stationed at the base of the one-celled capsule; the stigma is a lacerated fringed brush, and there are other differences; but upon the whole it is probably a genuine portion of the Droseraceous Order.

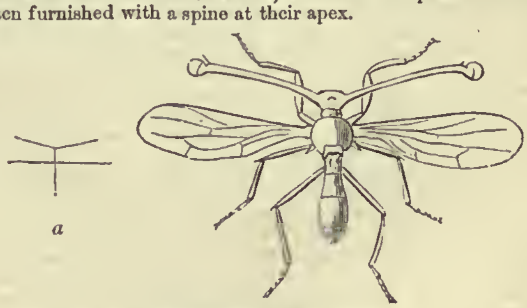
Dionæa has broad stalked leaves, spreading in a circle round the bottom of the flower-stem. Its flower-stem rises straight to the height of 6 or 8 inches, and is terminated by a cyme of small greenish-white flowers, each of which has a calyx of 5 sepals, 5 wedge-shaped notched petals, 10 hypogynous stamens, and an ovary shaped like some of the old German wine-bottles, round at the bottom, and tapering suddenly into a short neck or style. The best modern account of its habits has been given by Mr. M. A. Curtis, who thus speaks of it from his observations upon the plant in its native bogs:—"The *Dionæa muscipula* is found as far north as Newbern, North Carolina, and from the mouth of Cape Fear River to Fayetteville. It is stated moreover to grow along the lower branches of the Santee, in South Carolina; and it is not improbable that it inhabits the savannahs, more or less abundantly, from the latter place to Newbern. It is found in great plenty for many miles around Wilmington in every direction. The leaf, which is the only remarkable part, springs from the root, spreading upon the ground at a little elevation above it. It is composed of a broad stalk, like the leaf of an orange-tree, winged, and from 2 to 4 inches long, which at the end suddenly expands into a thick and somewhat rigid blade, the two sides of which are semicircular, about two-thirds of an inch across, and fringed round their edges with somewhat rigid ciliæ, or long hairs, like eye-lashes. The leaf indeed may be aptly compared to the two upper eyelids, joined at their bases. Each portion of the leaf is a little concave on the inner side, where are placed three delicate hair-like organs, in such an order that an insect can hardly traverse it without interfering with one of them, when the two sides suddenly collapse and inclose their prey, with a force surpassing an insect's attempts to escape. The fringe or hairs of the opposite sides interlace, like the fingers of the two hands clasped together. The sensitiveness resides only in these hair-like processes on the inside, as the leaf may be touched or pressed in any other part without sensible effects. The little prisoner is not crushed and suddenly destroyed, as is sometimes supposed; for I have often liberated captive flies and spiders, which sped away as fast as fear or joy could hasten them. At other times I have found them enveloped in a fluid of mucilaginous consistence, which seems to act as a solvent, the insects being more or less consumed by it. This circumstance has suggested the possibility of the insects being made subservient to the nourishment of the plant, through an apparatus of absorbent vessels in the leaves. But as I have not examined sufficiently to pronounce on the universality of this result, it will require further observation and experiment on the spot to ascertain its nature and importance.

"It is not to be supposed, however, that such food is necessary to the existence of the plant, though, like compost, it may increase its growth and vigour. But however obscure and uncertain may be the final purpose of such a singular organisation, if it were a problem to construct a plant with reference to entrapping insects, I cannot conceive of a form and organisation better adapted to secure that end than are found in the *Dionæa muscipula*. I therefore deem it no credulous inference that its leaves are constructed for that specific object, whether insects subserve the purpose of nourishment to the plant or not. It is no objection to this view that they are subject to blind accident, and sometimes close upon straws, as well as insects. It would be a curious vegetable indeed that had a faculty of distinguishing bodies, and recoiled at the touch of one, while it quietly submitted to violence from another. Such capricious sensitiveness is not a property of the vegetable kingdom. The spider's net is spread to ensnare flies, yet it catches whatever falls upon it; and the ant-lion is roused from his hiding-place by the fall of a pebble; so much are insects also subject to the blindness of accident."

We may add, with reference to the American author's conjecture that the trapped insects may contribute to the nourishment of the leaf of *Dionæa*, that leaves have actually been fed with chopped meat, and have been found to become more healthy and vigorous in consequence of this artificial stimulus; but still no argument can be drawn from this fact in favour of the supposition that the plant catches flies for nutriment, as most plants would be benefited by such treatment.

DIOPSIDE. [AUGITE.]

DIOPSIS, a genus of Dipterous Insects of the family *Sepsidæ*. The insects of this genus are remarkable for the immense prolongation of the sides of the head. The head itself is small, and appears as if it were furnished with two long horns, each having a knob at its apex; these horn-like processes however are not analogous to the parts usually termed antennæ, but are in fact prolongations of the sides of the head, the knob at the apex of each being the eye of the insect. They vary in length according to the species. In some they are almost equal to the whole length of the insect, whereas in others they are only about half that length. The antennæ are situated close to the eyes, and are three-jointed: the basal joint is the smallest and is very short; the terminal joint is the largest, of a globular form (or nearly so), and furnished towards the apex with a simple seta; there is also a short seta on the peduncle or eye-stalk, situated about midway between the base and the apex of that process, and on the anterior part. The thorax is somewhat attenuated anteriorly, but approaches to a spherical form, and is generally furnished with two spines on each side; the scutellum is also furnished with two spines. The body is more or less elongated, sometimes nearly cylindrical, but generally increases in diameter towards the apex. The legs are tolerably long—the anterior femora are generally thick, and furnished beneath with minute denticulations, and the four posterior femora are often furnished with a spine at their apex.



Diopsis Sykesii. G. R. Gray.
a denotes the natural size.

The illustration represents the *Diopsis Sykesii*, one of the largest species of the genus, and which has been selected as possessing the longest eye-stalks; these processes in this insect are of a pitchy red colour, and the body is of the same tint. The head and thorax are black, and the wings are clouded with brown.

But little is known of the habits of these insects. Colonel Sykes, who collected great numbers of the above species during his residence in India, furnished Mr. Westwood with the following notice respecting their habitat and habits:—

"Habitat.—The hill fort of Hurreechunderghur, in the western ghauts of the Deccan, at an elevation of 3900 feet above the level of the sea, 19° 23′ N. lat., 73° 40′ E. long.

"This insect affects chasms or ravines in the lofty woods which encircle the mountain in belts. In various places, where the sunbeams occasionally pierce the woods and fall upon isolated or salient rocks in the above localities, they are seen in myriads, either poising themselves in the rays, or reposing on the spots on which the rays fall."

All the known species are from the tropical parts of the Old World. (Westwood, *Transactions of Linnæan Society*.)

DIOPTASE, a Silicate of Copper. [COPPER.]

DIORITE, a rock consisting of Albite and Hornblende, also called *Greenstone*.

DIOSCO'REA, a genus of Plants which furnish the tropical esculents called Yams. It is the type of the natural order *Dioscoreaceæ*. The genus consists of perennial fleshy-rooted or tuberous diœcious plants, with annual twining stems, broad alternate leaves having a somewhat netted arrangement of their veins, and loose clusters of small green flowers. The corolla and the calyx taken together consist of 6 small equal segments, which, in the females, stand upon the top of the ovary. The male flowers have 6 stamens; the females 3 styles. The seed-vessel is a thin compressed 3-winged capsule, containing one or two membranous seeds.

The best account of the species is that of Dr. Roxburgh, who cultivated seventeen sorts in the Botanic Garden, Calcutta; others are known to botanists, but far from perfectly.

D. alata, the common West India Yam. It is a native of the West Indies, but is met with in the East Indies also, but only in a cultivated state. A figure of it is given in Rheede's 'Hortus Malabaricus,' vol. vii. t. 38, under the name of Katsji-kelengu. Its tubers are oblong, brown externally, white internally, and often of great size, weighing sometimes as much as 30 lbs.; they perish after the first year, if left in the ground, having first produced the young ones that are to replace them. "Besides the tubers the proper roots of all these plants are fibrous, springing from and chiefly about the union of the stems with the tubers, and spreading in every direction." The stems are furnished with four crested leafy wings, and spread to a great extent twining round trees and bushes; they often bear prickles near the ground. The first leaves that appear on the stem are alternate, the succeeding are opposite, seated on long stalks, deeply heart-shaped at the base, sharp-pointed, smooth, with from five to seven ribs. The flowers are small and green, and appear in compound panicles. The remainder of the species are very similar to this in general characters; a few short notes will sufficiently indicate their differences.

D. globosa, cultivated in Bengal under the name of Choo-Pureo-Aloo, is most esteemed of the Indian Yams. Its flowers are highly fragrant; the tubers are white internally; the leaves arrow-headed.

D. rubella, the Guranya-Aloo, is another Indian sort with large tubers stained with red immediately below the cuticle; it is much esteemed; its tubers are sometimes three feet long; its flowers are fragrant.

D. purpurea, called Lal-Guranya-Aloo in Bengal. The tubers are permanently stained purple throughout.

At Malacca is cultivated another purple-rooted sort, the *D. atropurpurea*, whose tubers are large and irregular, and grow so near the surface of the ground as to appear in dry weather through the cracks that they make in the soil by raising the earth over them.

Other eatable sorts are numerous, but are less valuable, and therefore not cultivated. In Otaheite the *D. bulbifera*, which bears small fleshy angular tubers along the stem in the axils of the leaves, is the favourite species.

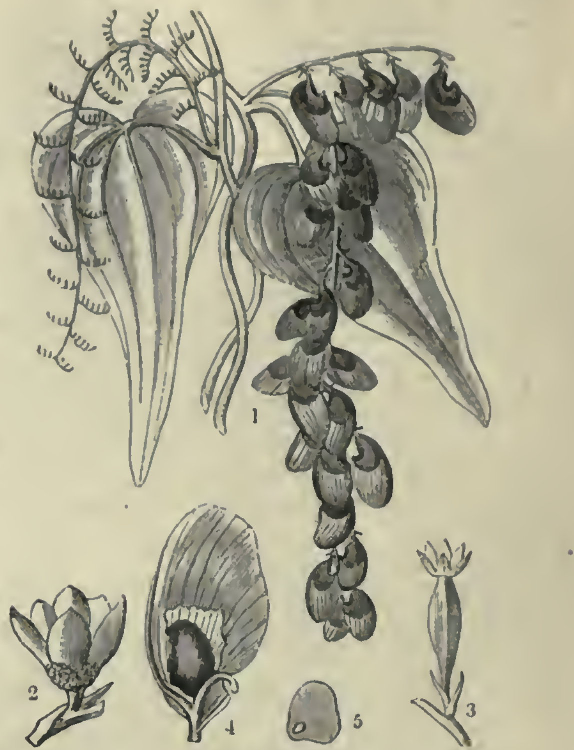
It is not a little remarkable that while so many species are nutritious in this genus, some should be highly dangerous; but such is unquestionably the fact. *D. Dæmonum* and *D. triphylla*, both ternate-leaved species, have very nauseous and dangerous tubers.

DIOSCOREA'CEÆ, *Yams*, the Yam Tribe, a natural order of Plants belonging to the class Dictyogens. They are particularly distinguished by the following characters:—

Flowers diœcious; calyx and corolla superior; stamens 6; ovary 3-celled, with 1 or 2-seeded cells; style deeply trifid; fruit leafy, compressed, occasionally succulent; embryo small, near the hilum, in a large cavity of cartilaginous albumen. The affinities of this order are with *Smilaceæ* and *Aristolochiaceæ*. It contains 6 genera and 100 species.

All the species are twining shrubs, with alternate or spuriously opposite leaves. They consist, with the exception of *Tamus*, Black Bryony, of tropical plants, or at least of such as require a mild frostless climate. Some of them produce eatable farinaceous tubers, or yams, as the various species of *Dioscorea* and *Testudinaria*; but there is a dangerous acrid principle prevalent among them, which renders the order upon the whole suspicious. It exists in a perceptible degree in *Tamus*, and is still more manifest in the 3-leaved *Dioscorea*. [TAMUS; TESTUDINARIA; DIOSCOREA; RAJANIA.]

DIOSMA, a genus of Rutaceous Shrubs inhabiting the Cape of Good Hope. They have alternate simple leaves, strongly marked with dots of transparent oil, and diffusing a powerful odour when bruised. Some of the species are offensive to the European taste, as



Dioscoreaceæ.

1, a shoot of *Rajania cordata*; 2, a male flower; 3, a female flower; 4, a portion of a ripe fruit with the seed exposed; 5, a section of the seed.

the Buckus with which the Hottentots perfume themselves, and which are chiefly yielded by *D. crenata* and *D. serratifolia*. The flowers of most are white; those of a few are red. By most modern botanists the old genus *Diosma* is broken up into eight, namely, *Adenandra*, *Coleonema*, *Diosma* proper, *Euchætis*, *Acmadenia*, *Baryosma*, to which the Buckus belong, *Agathosma*, and *Macrostylis*.

The following are the best known species of the old genus *Diosma*:—

D. serratifolia has linear lanceolate leaves, acuminate, serrulated, smooth, glandular at the edges, and 3-nerved. The flowers are lateral, white, upon short axillary bracteate peduncles. This species is an erect shrub, smooth in every part, and growing a foot or so high; branches tapering, purplish, long, lax; branchlets somewhat whorled, ternate or scattered, angular, purple, twiggy, incurved, loose. Leaves alternate on short stalks, ovate-oblong, blunt, flat, smooth, deep green above, paler beneath, dotted with sunken glands, the midrib somewhat keeled, the margin scolloped, glandular-dotted, and shining. Flowers solitary, white, middle sized. Peduncles filiform, shorter than the leaves.

D. crenulata is an upright shrub between two and three feet high, with twiggy branches of a brownish purple tinge. The leaves are decussate, spreading, about an inch long, oval-lanceolate, on very short petioles, very obtuse, delicately and minutely crenated, quite glabrous, rigid and quite smooth above; the peduncles about as long as the leaf, axillary, and terminal, chiefly from the superior leaves.

D. crenata (Linn.), *D. serratifolia* (Vent.), and *D. crenulata* yield leaves which at the Cape of Good Hope are termed Buchu, or Bucco, and which are sometimes used alone, but more frequently mixed. When bruised they emit a strong peculiar odour resembling rosemary or rue. The taste is aromatic, but not bitter or disagreeable.

Cadet de Gassecourt analysed the leaves, and found no alkaloid, but 6·65 of volatile oil; 21·17 extractive; 2·15 resin; 63 lignin; 1·10 chlorophylle. Brandes considers the extractive to be peculiar, and terms it Diosmin, analogous to Cathartin. The volatile oil and the extractive appear to be the active ingredients. They are usually administered in the form of infusion. [BUCHU, in ARTS AND SC. DIV.]

DIOSPYROS (from διὸς and πυρὸς, which may be translated 'celestial food'), a genus of Plants belonging to the natural order *Ebenaceæ*. They all form large trees, with alternate thick often coriaceous leaves. The flowers are usually single and axillary, the male and female flowers separate or united. Calyx and corolla 4-cleft, rarely 5-cleft. Stamina often 8, but varying in different species. Germ superior, often 8-celled; cells 1-seeded; attachment superior. Styles 3 or 4, rarely 5, or 1, and variously divided. Berry from 1- to 12-seeded, often 8-seeded. Embryo inverse, and furnished with albumen. Male flower frequently with twin anthers. The species are found chiefly in the tropical parts both of Asia and America, as in the Malayan Archipelago and Peninsula, and in almost every part of India. One species extends southward to Australia; one, *D. Lotus*, to Switzerland; and *D. Virginiana* into the United States of America. As some are remarkable for the wood which they afford, and others on account of their fruit, it is necessary only to notice a few of each, though the whole require the labours of a monographist.

D. Ebenus, the True Ebony, and that which is considered to be of the best quality, is a large tree, a native of Mauritius, Ceylon, and apparently also of Madagascar; for *D. lanceolata*, Poir., collected by Commerson in that island, is considered the same. The leaves are very smooth, short, petioled, alternate, bifarious, oblong in shape, the buds very hairy; male flowers sub-racemed, with about twenty anthers, the hermaphrodite solitary, octandrous. Large quantities of the ebony of this species have been sometimes imported into Europe.

Ebony is well known as a hard black-coloured wood brought from the hot parts of the world. The Greek name is ἔβενος, from which the Latin *Ebenus* and our word Ebony have been immediately derived. It is first mentioned by Ezekiel, xxvii. 15, but in the plural, hobnem, where the men of Dedan are described as bringing to Tyre horns of ivory and ebony. The Persian name, abnoos, is that by which it is commonly known all over India; it is probable therefore that the name, like the wood itself, had an eastern origin. From its hardness, durability, susceptibility of a fine polish, and colour, which has almost become another name for blackness, ebony has always been in high estimation, and in the present day is much used for mosaic work and ornamental inlayings, though cheaper woods dyed black are frequently substituted.

Herodotus (iii. 97) mentions ebony as part of the presents brought in considerable quantities to the king of Persia by the people of Ethiopia. Dioscorides describes two kinds—one Ethiopian, which was considered the best; and the other Indian, which was intermixed with whitish stripes and spotted; and hence commentators have disputed whether there were one or two kinds of ebony. But the fact is that several trees yield this kind of wood, and all belong to the genus *Diospyros*. Owing to the known geographical distribution of this genus, the ancients must have derived their ebony either from the peninsula of India and the island of Ceylon, or by the coasting trade from Madagascar; for no species of *Diospyros* has yet been discovered by botanists in the upper parts of Egypt or in Abyssinia, though it is not improbable that some may be found, as the climate is well suited to their existence.

D. Ebenaster. This is also a tree of considerable magnitude, a native of Ceylon, of which the leaves are coriaceous and smooth on both sides, and the buds smooth.

D. reticulata (*Tesselaria*, Poir.) is another elevated tree, a native of Mauritius, of which the heart-wood forms Ebony.

D. melanoxylon, described and figured by Rumph, iii., 'Corom. Plants,' 1 to 46, by Dr. Roxburgh, is the Ebony-Tree of the Coromandel coast. It is found on the mountains of that coast as well as of Malabar and in Ceylon. It grows to be very large, particularly the male tree, of which the wood is also most esteemed. The leaves, which are sub-opposite, oval, oblong, obtuse, and villous, are deciduous in the cold season, the new ones appearing with the flowers in April and May; as in other species, it is only the centre of large trees that is black and valuable, and this varies in quantity according to the age of the tree. The outside wood, which is white and soft, time and insects soon destroy, leaving the black untouched. The ripe fruit is eaten by the natives, though rather astringent, as is also the bark. *D. tomentosa* and *D. Roylei* are other Indian species which yield ebony.

Several species of the genus bear fruit, which, though clammy and sub-astringent, is eaten by the natives of the countries where the trees are indigenous. We need name only the most celebrated, as *D. lotus*, a native of Africa, and now common in the south of Europe, which bears a small yellow sweetish fruit about the size of a cherry, and which has by some been supposed to be the famous Lotus of the Lotophagi; but this is more likely to have been the Jujube, called by botanists *Zizyphus Lotus*.

D. Kaki is celebrated in China and Japan: specimens introduced into the Botanic Garden of Calcutta were found to be identical with others from Nepaul. The fruit is described by Dr. Roxburgh as being tolerably pleasant. It is esteemed in China, where it attains the size of an orange, and is frequently sent to Europe in a dried state, and called the Date-Plum of China, and also Keg-Fig of Japan.

D. discolor of the Philippine Islands also bears a fruit which is esteemed, and called Mabolo.

D. Virginiana, the Persimmon-Tree, is indigenous in North America, especially in the middle and southern parts of the United States, where it attains a height of 60 feet, but it does not flourish beyond 42° N. lat. The fruit while green is excessively astringent, but when ripe, and especially after it has been touched by the frost, it is sweet and palatable. The fleshy part separated from the seeds is made into cakes, which are dried and preserved. A kind of cider has also been made from this fruit, and a spirituous liquor distilled from its fermented infusion.

D. glutinosa also affords a fruit which, though edible, is far from palatable, but more valuable as an article of commerce. The tree is middle-sized, a native of the moist valleys amongst the mountains of the Circars, and all along the foot of the Himalayas to 30° N. lat. Sir William Jones first mentioned what is well known throughout Bengal, that the astringent viscid mucus of the fruit is used for paying the bottoms of boats. The unripe fruit contains a large proportion of tannin, and its infusion is employed to steep fishing-nets in to make them more durable.

DIOTIS (double-eared, from δίς, double, and οὖς, ὠτός, an ear), a genus of Plants belonging to the natural order *Compositæ*, the tribe *Senecionidæ*, and the section *Anthemideæ*. It has homogamous discoïdal heads; florets hermaphrodite, tubular, the tube compressed, with two auricles at the base; the receptacle convex with concave downy-topped scales; the involucre bell-shaped, imbricated; the fruit is compressed, and is crowned with the persistent auricled tube of the corolla.

D. maritima is the only British species. The whole plant is densely cottony and white; the stem is about a foot high, recumbent below, densely leafy and corymbose above; the leaves sessile, oblong, obtuse, flat, crenate, persistent; the heads in terminal corymbose tufts; the flowers are yellow. It is found on sandy sea-shores, but is a rare plant. *Diotis* is adopted by some botanists as the name of a genus of plants belonging to the *Chenopodiaceæ*, the *Axyris ceratoides* of Linnæus. It is a shrub of no great beauty, and is found wild in Siberia, and some parts of Austria. It thrives well in a light soil, and is easily increased by layers or cuttings under a hand-glass.

(Babington, *Manual*; Koch, *Flora Germanica*.)

DIOXYLITE, a native Sulphato-Carbonate of Lead. [LEAD.]

DIPHANITE. [PREHNITE.]

DIPHUCE'PHALA, a genus of Coleopterous Insects belonging to the *Lamellicornes*, section *Phyllophagi*.

This genus appears to be confined to Australia, and the species of which it is composed are distinguished from those of allied genera chiefly by their having the clypeus deeply emarginated; they are of an oblong form; the thorax is attenuated anteriorly, the elytra are somewhat depressed, and the abdomen is very convex. The antennæ are 8-jointed, and the club is composed of 3 joints; the anterior tibiæ are generally dentated externally; the anterior tarsi of the males have the four basal joints dilated, and furnished with a velvet-like substance beneath, and all the claws are bifid.

A rich golden-green appears to be the prevailing colour of these insects, and we understand that they are found on flowers.

D. sericea (Kirby) is nearly half an inch in length, of a golden-green hue, and has a silk-like gloss on the upper parts; the legs are red; the anterior tibiæ have an obtuse tooth-like process on the outer side, near the apex; the head and thorax are very thickly and delicately punctured; the elytra are covered with confluent punctures, which are arranged in longitudinal rows, and each elytron has two smooth elevated striæ; the under parts of the body are covered with white scale-like hairs. This is the largest species known; there are however many which are nearly equal to it in size.

(*Transactions of the Entomological Society of London*, vol. i.)

DIPHYDÆ. [ACALEPHÆ.]

DIPHYDES. [ACALEPHÆ.]

DIPHYES. [ACALEPHÆ.]

DIPHYLLIDIA. [INFEROBRANCHIATA.]

DIPHYSA. [ACALEPHÆ.]

DIPLACA'NTHUS, a genus of Fossil Placoid Fishes, from the Old Red-Sandstone of Scotland. Agassiz admits four species. (*Reports of British Association for* 1842.)

DIPLAZIUM, a genus of Ferns. The rhizomas of one species, *D. esculentum*, are eaten.

DIPLEU'RA, a genus of *Trilobites*, proposed by Green.

DIPLOCLUNUM, a genus of Plants belonging to the natural order *Begoniaceæ*.

DIPLOCTE'NIUM, a fossil genus of Lamelliferous Corals, allied to *Turbinolia*, from Mæstricht. [MADREPHYLLIÆA.]

DIPLODA'CTYLUS, a genus of Lizards established by Dr. J. E. Gray, and regarded by him as forming a new genus in the family of *Geckos*.

Generic Character.—Scales sub-conformable, minute, smooth; the abdominal scales rather large; the caudal scales annulate and larger; the labial scales moderate, distinct, the three anterior ones on each side much the largest; no gular scales. Tail cylindrical, ventricose. Toes 5, 5, simple, subequal, subcylindrical, the points subdilated, bifid beneath, with two oval oblique smooth fleshy discs; claws 5, 5, small, very retractile. No femoral pores. (Gray.)

This genus differs from *Phyllodactylus* of the same zoologist in having the under sides of the tips of the toes furnished with two rather large oblong tubercles, truncated at the tip, and forming two oval discs placed obliquely, one on each side of the claw, instead of having, as in *Phyllodactylus*, two membranaceous scales. The scales of *Diplodactylus* are moreover uniform, whilst in *Phyllodactylus* there is a row of larger scales, extending along the back.

D. vittatus, the Yellow-Crowned Diplodactyle. Brown, with a broad longitudinal dorsal fillet; limbs and tail margined with rows of yellow spots.

There are two rows of rather distant small spots on each side of the body; the spots become larger on the upper surface of the tail, and are scattered on the limbs. Length of head and body two inches; that of the tail an inch and a quarter. It is an inhabitant of Australia, whence it was brought to England by Mr. Cunningham.

The Yellow-Crowned Diplodactyle (*Diplodactylus vittatus.*)

The remaining species of this genus in the 'British Museum Catalogue' are—*D. ornatus*, *D. ocellatus*, a native of Australia, *D. marmoratus*, from Australia, *D. bilineatus*, and *D. lineatus*, Cape of Good Hope.

DI'PLODON, Spix's name for a genus of Fresh-Water Conchifers, *Naiades* of Lea. [NAÏADES.]

DIPLODONTA. [LUCINIDÆ.]

DI'PLODUS, a genus of Fossil Placoid Fishes, from the Coal Formation and Mountain Limestone. (Agassiz.)

DIPLOLEPIS, a genus of Insects proposed by Geoffroy for some of the species which produce Galls. [GALLS.]

DIPLOPTERA, a division of stinging Hymenopterous Insects, including the various species of Wasps, and distinguished by having the upper wings folded longitudinally when at rest.

DIPLO'PTERUS, a genus of Fossil Placoid Fishes, from the Old Red-Sandstone of Scotland, three species; and from the coal shale of Leeds, one species. (Agassiz, *Report to British Association*, 1842.)

DIPLOTAXIS (from διπλοῦς, double, and τάξις, an arrangement, on account of the double rows of seeds in each cell), a genus of Plants belonging to the natural order *Cruciferæ*, and the tribe *Brassiceæ*. It has a compressed pod and subconvex valves, with one straight nerve, and the seeds oval or oblong, in two rows. The species are herbaceous plants, natives of Europe and the temperate parts of Asia and Africa. There are two British species: *D. tenuifolia*, with a leafy branched glabrous stem, shrubby below; and *D. muralis*, with an herbaceous simple hispid stem. The former is a fetid plant with large yellow flowers, and grows on old walls, and is not an uncommon plant in England and Scotland; the latter is a rare plant. (Babington, *Manual*; Loudon, *Encyclopædia*.)

DIPPER. [MERULIDÆ.]

DIPSACA'CEÆ, *Teazleworts*, the Teazle Tribe, a small natural order of Exogenous Plants, with monopetalous flowers, nearly allied to *Compositæ*, from which it differs in the ovule being pendulous instead of erect, in the embryo being inverted, in the anthers being distinct, not syngenesious, and in the corolla having an imbricated, not valvate æstivation. In habit the species are similar to *Compositæ*, having their flowers constantly arranged in heads. It embraces 6 genera and about 150 species. None of the species are of any importance except the Fuller's Teazle (*Dipsacus Fullonum*), whose prickly flower-heads are extensively employed in carding wool. Many of the species have handsome flowers, especially the Scabioses, and are cultivated in the gardens of the curious. Purple and Starry Scabioses are common hardy annuals. [DIPSACUS; KNAUTIA; SCABIOSA.]

DIPSACUS, a genus of Plants, the type of the natural order *Dipsacaceæ*. It has the following characters:—The calyx is cup-shaped, the involucel forming a thickened margin to the ovary; the corolla 4-fid; the receptacle with spinous scales shorter than the involucre; the fruit with four sides and eight little depressions. The species are erect prickly or pilose biennial herbs. The leaves are opposite; the heads of flowers are terminal, and the corollas lilac-coloured, yellow, or white.

D. sylvestris, the Wild Teazle, has opposite undivided leaves; the scales of the receptacle straight, at the end longer than the flowers, involucre curved upwards; the stem is five or six feet high, prickly, leafy, branched. It is a native of Great Britain, and common in hedges and by road-sides. The water which collects in the connated leaves has a reputation for curing warts, and also as a cosmetic amongst the country people; hence Ray conjectures it has one of its names, *Labrum Veneris*.

D. Fullonum, the Fuller's Teazle, has the scales of the receptacle hooked at the end as long as the flowers; involucres reflexed. This plant is extensively cultivated in Great Britain, especially in the north and west of England, on account of the use of its hard recurved spiny scales in the preparation of woollen cloth. In this way it has been probably introduced. The most useful kinds are grown on the continent of Europe, where it is an undoubted native. [TEAZLE, in ARTS AND SC. DIV.]

D. pilosus has the leaves stalked, with a leaflet at the base on each side. The heads of the flowers are small. It grows in moist shady places, and is a native of England and the whole of Europe.

There are many other species of *Dipsacus*, but they are of little importance.

A portion of the upper part of *Dipsacus Fullonum.*

1, a flower with the hard spiny bract from which it springs; 2, a corolla with two of the stamens, and the ovary containing a pendulous ovule much magnified; 3, a longitudinal section of a fruit, with the pendulous seed and the inverted embryo.

DIPSAS (Laurenti), *Bungarus* (Oppel), a genus of Serpents, placed by Cuvier under the great genus *Coluber*. Body compressed, much less than the head; scales of the spinal row of the back larger than the others.

D. Indica, Cuvier; *Coluber Bucephalus*, Shaw. Black, annulated with white.

The cut in the next page, from Guerin ('Iconog.') will illustrate the form.

The term *Dipsas* is also used by Dr. Leach to distinguish a genus of Fresh-Water Conchifers; and he states that its systematic situation is between *Unio* and *Anodonta* (Anodon); *Unio* of Sowerby; *Naïades* of Lea. [NAÏADES.]

DIPSASTRÆA. [MADREPHYLLIÆA.]

DI'PTERA, one of the orders into which Insects are divided. This name was first applied by Aristotle, and has subsequently been adopted by almost all entomologists to designate those insects the most striking characteristic of which is the possession of two wings only.

The common House-Fly and Blue-Bottle-Fly afford familiar examples of this order. Some Dipterous Insects however are destitute of wings (such as the species of the genera *Melophagus*, *Nycterobia*, &c.); hence it is necessary that we should here notice other peculiarities observable in these insects.

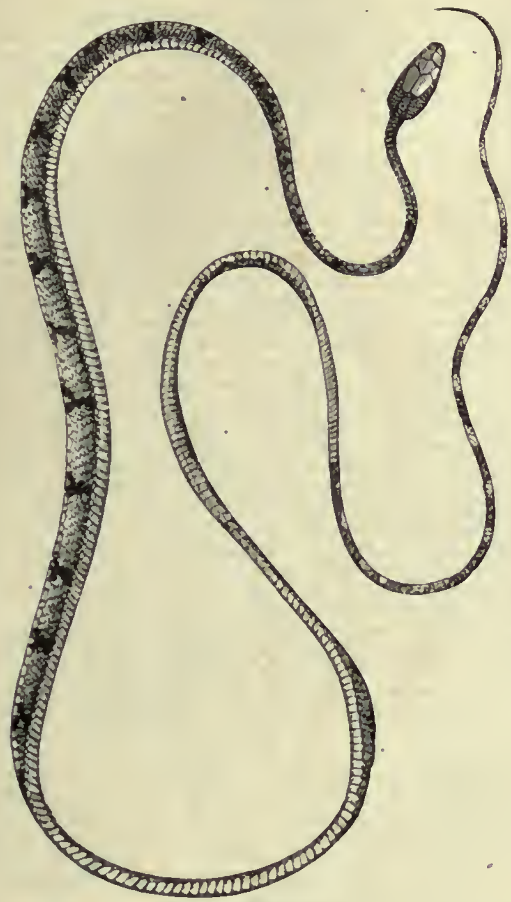
The *Diptera* have 6 legs furnished with 5-jointed tarsi, a proboscis, 2 palpi, 2 antennæ, 3 ocelli, and 2 halteres, or poisers.

The wings are generally horizontal in their position and transparent; their nervures are not very numerous, and are for the most part longitudinally disposed, a character in which the wings of Dipterous Insects differ from those of the orders *Neuroptera* and *Hymenoptera*.

The proboscis, situated on the under part of the head, is generally short and membranous, and consists of a sheath (or part analogous to the under lip or labium in mandibulate insects), which serves to keep in situ other parts of the mouth, which when they are all present represent the mandibles, maxillæ, tongue, and labium.

There are however considerable modifications in the structure of the proboscis: in some it is long, slender, and corneous; and the number of inclosed pieces, which are generally very slender and sharp, varies from two to six.

It is evident that this structure of mouth is adapted only to the



Dipsas cyanodon (Iconog.)

extraction and transmission of fluids; and when these fluids are contained within any moderately tough substance, the parts inclosed by tho sheath of the proboscis are used as lancets in wounding and penetrating so as to allow the escape of the fluid, which by their pressure is forced to ascend and enter the œsophagus.

The palpi are situated at the base of the proboscis. The antennæ are placed on the fore part of the head, and approximate at their base; they are generally small and 3-jointed; tho last joint however is often furnished with an appendage called the stylet, which is considerably diversified not only in form but in its position.

In some of the insects of this order, the *Tipulidæ* [TIPULIDÆ] for instance, the antennæ are long and composed of numerous joints; and iu tho *Culicides* [CULICIDES] they resemble little plumes.

The eyes in Dipterous Insects are generally large, especially in the male sex, where they often occupy nearly the whole of the head.

The Halteres, or Poisers, are two small organs of a slender form, and furnished with a knob at their apex, situated at the base of the thorax on each side, and immediately behind the attachment of the wings. Theso organs have been considered by many as analogous to the under wings of four-winged insects. Latreille and others however have come to a different opinion, from the circumstance of their not being attached to the same part of the thorax. The use of these organs is not yet ascertained; it is however supposed by some that tho little knob which we mentioned is capable of being inflated with air, and that they serve to balance the insect during flight, at which time these organs are observed to be in rapid motion.

As regards the thorax, it is only necessary here to observe that the chief part of that which is visible from above consists of the meso-thorax; the prothorax and metathorax being comparatively small.

The scutellum varies considerably iu form, and is sometimes armed with spines; we find it developed in an extraordinary manner in tho genus *Celyphus* (Dalman), where it is very convex, and covers the whole abdomen.

The abdomen seldom presents moro than seven distiuct segments; its form is very variable.

Dipterous Insects undergo what is termed a complete transformation. Their larvæ are devoid of feet, and have a head of the same soft substance as the body, and without determinate form. The parts of the mouth exhibit two scaly pointed plates. Tho stigmata are nearly all placed on tho terminal segment of the body. When about to assume the pupa state, they do not cast their skin (as is tho case with the larvæ of most insects), but this becomes gradually hardened, and after a time the animal assumes the pupa state within, so that the skin of the larva forms as it were a cocoon.

There are however exceptions to this rule, for many change their skin before they assume the pupa state, and some spin cocoons.

We may here observe, that in some of the species of the genus *Sarcophaga* the eggs are hatched within the body of the mother, whence the insect first makes its appearanco in the larva state; and in the *Pupipara* not ouly are the eggs hatched within the body of the pareut, but the larvæ continue to reside there until their transformation into pupæ.

As regards the habits of Dipterous Insects, they will be found under the heads of the several families and genera; we shall therefore conclude by noticing the two great sectious into which this order is divided by Macquart. These are the *Nemocera* and the *Brachocera*.

The species of these two sections are distinguished chiefly by the number of joints of the antennæ and palpi. Their characters are as follows:—

Section 1. *Nemocera.*—Antennæ filiform or setaceous, often as long as the head and thorax together, and composed of at least six joints; palpi composed of four or five joints; body generally slender and elongated; head small; proboscis sometimes long and sleuder, and inclosing six lancets; sometimes short and thick, haviug but two lancets; thorax large and very convex; legs loug; wings long, aud with elongated basal cells.

Section 2. *Brachocera.*—Antennæ short, composed of three joints, the third joint generally furnished with a stylet; palpi composed of one or two joints; head usually hemispherical, and as broad as tho thorax; proboscis either long, slender, coriaceous, and protruded, or short, thick, and retracted, aud containing either six, four, or two lancets; thorax moderately convex; legs usually of moderate length; wings with the basal cells rather short.

(Wiedemann, *Diptera Exotica*, 8vo, 1821; Meigen, *Systematische Beschreibung der bekannten Europäischen zweiflügelingen Insekten*, 6 vols. 8vo, with figures; Macquart, in the *Suites à Buffon, Histoire des Insectes*, 'Diptères,' 2 vols. 8vo.; Kirby and Spence, *Introduction to Entomology;* Walker, *British Museum Catalogue*, 'Diptera' in *Insecta Britannica.*)

DIPTERA'CEÆ, or DIPTEROCARPEÆ, *Dipterads*, an importaut order of East Iudiau Exogenous Polypetalous Trees. They have a tubular unequal permauent calyx, with five lobes, which after flowering become leafy and very much enlarged, surmounting the fruit without adhering to it. There are five petals, with a contorted æstivation, an indefinite uumber of awl-pointed narrow anthers, and a few-celled superior ovary, with two pendulous ovules in each cell; of these all

Dipterocarpus gracilis.

1, two of the stamens; 2, a ripe fruit surrounded by the calyx whose segments have become large and leafy, and very unequal.

are eventually abortive, except one, which forms the interior of a hard dry leathery pericarp. The seed is solitary, contains no albumen, and has an embryo with two large twisted and crumpled cotyledons, and a superior radicle. The leaves are long, broad, alternate, rolled inwards before they unfold, with strong straight veins running obliquely from the midrib to the margin, and oblong deciduous stipules rolled up like those of a *Magnolia*. The affinities of this order are with *Tiliaceæ* and *Corylaceæ* on the one side, and *Clusiaceæ* and *Ternstromiaceæ* on the other.

The different species produce a number of resinous, oily, and other substances; one a sort of camphor [DRYOBALANOPS]; another a fragrant resin used in temples; a third, Gum Animl; while some of the commonest pitches and varnishes of India are procured from others. Rhal, or Dhoona, a resin burned in the temples of India, is produced by *Shorea robusta*. Saul, the best timber in India, is furnished by the same tree. It contains 7 genera and 47 species. [DIPTEROCARPUS; DRYOBALANOPS; VATERIA.]

DIPTERIX. [COUMAROUNA.]

DIPTEROCARPUS, a genus of East Indian, and chiefly insular Trees, the type of the natural order *Dipteraceæ*. Blume gives the following essential characters:—"Calyx irregularly 5-lobed at the mouth; the two opposite segments very long and ligulate; petals five, convolute when unexpanded; stamens numerous; anthers long, linear, terminating in an awl-shaped point; nut rather woody, and 1-celled and 1-seeded by abortion, inclosed in the enlarged calyx." The species are described as enormous trees, abounding in resinous juice, with erect trunks, an ash-coloured bark, strong spreading limbs, and oval leathery entire leaves, with pinnated veins. The flowers are large, white or pink, and deliciously fragrant. The pubescence is always stellate when present. The resinous juice of *D. trinervis*, a tree from 150 to 200 feet high, inhabiting the forests of Java, is made into plaisters for ulcers and foul sores; and when dissolved in spirit of wine, or formed into an emulsion with white of egg, acts upon the mucous membranes in the same way as balsam of copaiva. *Dryobalanops Camphora*, the Camphor-Tree of Sumatra, is usually referred to this genus; but, according to Blume, is really a distinct genus. [DRYOBALANOPS.]

DI'PTERUS, a genus of Fossil Fishes, from the Old Red-Sandstone of Caithness and Herefordshire. (Valenciennes and Pentland, *Geol. Trans.*, 2nd series, vol. iii.)

DIPUS. [MURIDÆ.]

DIPYRE, a variety of Scapolite. It occurs with talc in the Pyrenees, and contains—

Silica	55·5
Alumina	24·8
Lime	9·6
Soda	9·4

It has a specific gravity of 2·65.

DIRCA, a genus of Plants belonging to the natural order *Thymeleaceæ*. It has a campanulate calyx, with an obsolete unequal limb; eight capillary projecting filaments inserted into the middle of the tube, alternately longer; the style incurved at the apex. This is an American genus, with a single species, the *D. palustris*. It is remarkable for growing in watery places, and is called Bois de Plomb by the French. It is found in the low woods of North America, bearing the severest cold, and the greatest heat of the various parts of the United States. It is an irregular shrub, with a tendency to a horizontal direction in its branches. The flowers are yellow, and appear before the leaves, and when young they are inclosed within a small hairy bud, occupying a sheath or cavity in the end of each flowering branch. The fruit is a small, oval, acute, red, 1-seeded berry. This plant is in all its parts very tough, and the twigs are used for making rods, the bark for ropes, baskets, &c. The bark is acrid, and in doses of six or eight grains it produces heat in the stomach, and brings on vomiting. It also acts as a vesicatory when applied to the skin, and in small doses as a cathartic. The fruit possesses narcotic properties, and produces effects upon the system similar to those of *Stramonium*. Snails are observed to be very fond of this plant, when it is cultivated. In its cultivation, layers require two years before they produce roots. It cannot be propagated in this country either by cuttings or seeds. (Loudon, *Encyclopædia of Plants*; Lindley, *Flora Medica*.)

DISA'STER, a subdivision of *Echinodermata*, including *Spatangus ovalis* of Phillips. From the Oolite. (Agassiz.)

DISCARIA, a genus of Plants belonging to the natural order *Rhamnaceæ*. One species, *D. febrifuga*, yields the Quina of Brazil, which is employed as a febrifuge and a tonic.

DISCO'BOLI, the third family of the Malacopterygious Osseous Fishes in the arrangement of Cuvier. The distinguishing character is the presence, on the under surface of the body, of a disc composed of the united ventral fins. The fishes of this family are popularly known as Sucking-Fishes. The most common and most remarkable species inhabiting the British seas is the Lump-Sucker (*Cyclopterus Lumpus*). It is a large-bodied small-finned fish, bearing on its back an elevated crest or ridge, and having a powerful sucker under its throat, formed of the combined pectorals and ventrals. Before the spawning season it is of a brilliant crimson colour mingled with orange, purple, and blue, but afterwards changes to a dull blue or lead colour. When full grown it is rough with tubercles, but when very young is smooth and beautiful, marked with brilliant stripes of various hues. In the seas of the Orkneys, in June, numbers of the young fish, half an inch in length, are seen swimming around floating sea-weeds. For a long time they were supposed to belong not only to a different species, but even to a different genus. In the old fish the sucker is so powerful that a pail of water, containing some gallons, has been lifted up by a person holding the tail of a *Cyclopterus* adhering to the bottom. It lives on young fish. It is brought to market, but oftener as a curiosity than as an article of food. The *Cyclopterus Lumpus* ranges from the shores of Greenland to those of the south of England, and westward as far as the coast of North America. Another genus of this family is *Lepadogaster*, consisting of a number of small fishes which have two discs on the under surface of their bodies, the one formed by the pectoral fins and the other by the ventrals. They adhere to stones, rocks, and shells by these discs. They have wedge-shaped defenceless bodies, smooth and without scales, often painted with the most brilliant and defined colours. The Sea-Snail, or *Liparis*, is a third genus of this family, the species of which resemble gobies in form. They are found under stones at low-water mark, and are not so brilliantly coloured as others of the tribe. They are furnished with a single sucker formed by the united ventrals and pectorals.

DISCOI'DEA, a genus of *Echinodermata*, in which are ranked, by Gray and Agassiz, several species generally referred to in works on organic remains under the title of *Galerites*. They belong to the Chalk, Greensand, and Oolite.

DISK, or DISC, a term in Botany signifying any ring or whorl of glands, scales, or other bodies that surround the base of an ovary, intervening between it and the stamens. In its most common state it is a fleshy wax-like ring as in the orange; it frequently forms a yellowish lining to the calyx, as in the plum and cherry; and not unfrequently rises up like a cup around the ovary, as in the tree pæony. The latter renders it probable that the disk is nothing but an inner whorl of rudimentary stamens. Previously to the expansion of the flower the disk contains fæcula, and is dry and brittle; but after the blossom unfolds, it perspires a sweet honey-like fluid, and becomes tough, absorbing oxygen and parting with carbonic acid.

DISSEPIMENTS, the partitions in the inside of a fruit which are formed by the union of the sides of its constituent carpels. Dissepiments are therefore necessarily alternate with the stigma. When partitions which do not bear this relation to the stigma occur in the inside of a fruit, they are called Phragmata, or spurious dissepiments, as in the *Cathartocarpus fistula*, where they are horizontal, and in *Verbena*, where they are vertical.

DISTHENE, a name for *Kyanite*. [KYANITE.]

DI'STICHOUS, a term in Botany, signifies 'arranged in two rows,' as the grains in an ear of barley, and the florets in a spikelet of quaking-grass.

DISTOMA. [BOTRYLLIDÆ.]

DITHYROCA'RIS, a fossil genus of Crustaceans, so named by Dr. Scouler. It occurs in Tyrone and Derry. *D. Colei* and *D. orbicularis* are described in Portlock's 'Geological Report' on those counties.

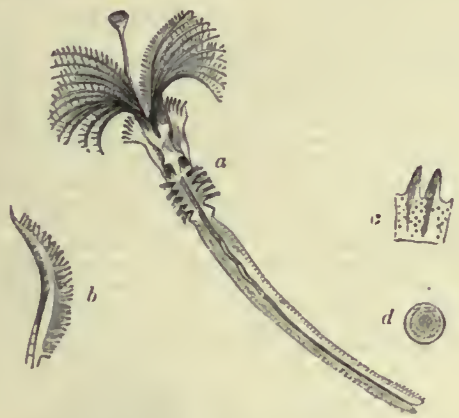
DITRU'PA, a genus of *Annelida*, founded by the Rev. M. J. Berkeley, and which, from its having been previously confounded with the species of an entirely distinct genus (*Dentalium*), and some circumstances respecting its capture in a living state, requires particular notice. It has the following characters:—

Shell free, tubular, open at both ends. Operculum fixed to a conical pedicellated cartilaginous body, thin, testaceous, concentrically striate. Branchiæ twenty-two, in two sets, not rolled up spirally, flat, broadest at the base, feathered with a single row of cilia. Mantle rounded behind, slightly crisped, denticulated in front, strongly puckered on either side. Fascicles of bristles, six on each side. (Berkeley.)

Mr. Berkeley states that a few of the specimens of sand, gravel, &c., from different parts of the great bank running parallel with the north-west coast of Ireland, obtained by Captain A. Vidal, R.N., during the extensive soundings made by that officer in the summer of 1830, whilst in search of Aitkin's Rock, were placed in his hands, when he found among them several specimens of the shell of a testaceous animal, which proved to be the *Dentalium subulatum* of Deshayes, and identical with the Madeira specimens; the only points of difference being a paler hue, and an almost total absence of the constriction near the orifice, the former being, as Mr. Berkeley observes, exactly such as might be expected from the occurrence of the species in a higher latitude, and the latter so variable as not to throw any doubt on its specific identity. Having previously been convinced, from Mr. Lowe's specimen, that the animal was not a *Dentalium*, but an Annelide, Mr. Berkeley requested Captain Vidal to preserve in spirit during the following summer, when operations on the bank were to be resumed, whatever animals he should procure alive in sounding, and, if possible, specimens of the so-called *Dentalium*, at the same time noting the depth at which they were taken. The result was the capture of the shell with the included animal, which enabled Mr. Berkeley to establish the genus named at the head of this article. The animals of the Madeira and British specimens proved to be perfectly identical.

It appears from Mr. Berkeley's paper, that the shells first handed to him by Captain Vidal occurred in fine sand, at various distances from the coast, in lat. 55°, at great depths—from 60 to 120 fathoms. After speaking of the animals preserved in spirit, and stating that Captain Vidal noted the depth at which each specimen was taken, Mr. Berkeley remarks that the so-called *Dentalium* did not occur at any less depth than 63½ fathoms, and twice (on one occasion off St. Kilda) it occurred at 171 fathoms. Nothing could be concluded as to habit, from the manner in which the shells were imbedded in the tallow (with which the lead was armed); but this was of the less consequence, says Mr. Berkeley, because it had appeared, from Mr. Lowe's information, that the animals are found in great numbers together, in masses of a conglomerate (if it may be so called) of mud and various marine substances, the broader end only appearing above the surface. Mr. Berkeley infers, from the great difference in the diameter, that the narrow or posterior end is gradually absorbed in the course of growth.

Mr. Berkeley is of opinion that, notwithstanding the resemblance of the shell to that of true *Dentalia*, it is most nearly allied to *Serpula;* but evidently distinct, in having an unattached shell (for there is no evidence to lead to a suspicion that it is attached, even in infancy), and especially in possessing a posterior as well as anterior aperture. He thinks that other species of so-called *Dentalia* may be found to belong to the genus *Ditrupa*. One at least, he observes, does so belong, namely, *Dentalium Gadus*, Mont. (*D. coarctatum*, Lam.). He thinks it highly probable that other minute British *Dentalia* will prove to possess an animal of like structure, though possibly, even in that case, it would be requisite to place them in a distinct genus.



Ditrupa subulata, magnified.

a, the animal; *b*, one of the branchiæ; *c*, a portion of the anterior part of the mantle; *d*, operculum. ('Zool. Journ.' vol. v.)

DITTANY OF CRETE, the common name of the woolly labiate Plant called *Origanum Dictamnus* or *Amaracus Dictamnus.*

DIURIS, a genus of curious Orchidaceous Plants, from Australia.

DIVERS. [COLYMBIDÆ.]

DIVI DIVI. [CÆSALPINIA.]

DIVI LADNER, the Forbidden Fruit of the Ceylonese. It is produced by a species of *Tabernæmontana.*

DOCK, the common name of many perennial tap-rooted species of the genus *Rumex.* They do not multiply by division of the root, but their seeds are dispersed in such abundance that they become a serious nuisance in cultivated land if they are not extirpated. The only two methods of doing this are either by tearing or digging them up, which is so slow as scarcely to be adopted in practical husbandry, or by constantly hoeing up their young shoots; by the latter means they usually may be destroyed in a single summer. [RUMEX.]

DOCLEA. [MAIADÆ.]

DODDER. [CUSCUTACEÆ.]

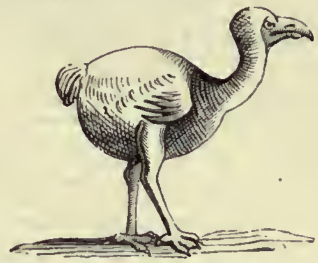
DODECAGY'NIA, the name of any order in the Linnæan classification of plants wherein the number of styles is twelve.

DODECA'NDRIA, the twelfth class in the Linnæan classification of plants. It contains species having twelve or about twelve stamens, provided they do not adhere by their filaments.

DODO (*Didus*), a genus of extinct Birds, of whose existence in the 16th and 17th centuries there is abundant evidence. As this is one of the few instances in which any history has been left of the extinction of a race of animals, we proceed to draw attention to the more prominent facts.

It appears that Vasco do Gama, after having doubled the Cape of Good Hope (Cabo Tormentoso, or Capo of Storms) in 1497, discovered at 60 leagues beyond it a bay, Angra de San Blaz, near an isle, where he saw a very great number of birds of the form of a goose, but with wings like those of the bats, which the sailors called Solitaries. On their return in 1499, the Portuguese touched again at San Blaz, where they took a great number of these birds, and comparing them to swans, called the island Ilha des Cisnes (Isle of Swans). In the voyage to the East Indies in 1598 by Jacob van Neck and Wybrand van Warwijk (small 4to., Amsterdam, 1648), there is a description of the Walgh-Vögels in the island of Cerne, now called Mauritius, as being as large as our swans, with large heads, and a kind of hood thereon; no wings, but in place of them three or four black little pens (pennekens), and their tails consisting of four or five curled plumelets (pluymkens) of a grayish colour. The breast is spoken of as very good, but it is stated that the voyagers preferred some turtle-doves that they found there. The bird appears with a tortoise near it in a small engraving, one of six which form the prefixed plate.

In the frontispiece to De Bry ('Quinta Pars Indiæ Orientalis,' &c., M.DCI), surmounting the architectural design of the title-page, will be found, we believe, the earliest engravings of the Dodo. A pair of these birds stand on the cornice on each side, and the following cut is taken from the figure on the left hand.



Dodo (*Gallus gallinaceus peregrinus.*)

In De Bry's 'Descriptio Insulæ de Cerne a nobis Mauritius dicta' is the following account:—"Cærulean parrots also are there in great numbers, as well as other birds; besides which there is another larger kind, greater than our swans, with vast heads, and one half covered with a skin, as it were, hooded. These birds are without wings, in the place of which are three or four rather black feathers (quarum loco tres quatuorve pennæ nigriores prodeunt). A few curved delicate ash-coloured feathers constitute the tail. These birds we called Walck-Vögel, because the longer they were cooked the more unfit for food they became (quod quo longius seu diutius elixarentur, plus lentescerent et esui ineptiores fierent). Their bellies and breasts were nevertheless of a pleasant flavour (saporis jucundi) and easy of mastication. Another cause for the appellation we gave them was the preferable abundance of turtle-doves which were of a far sweeter and more grateful flavour." It will be observed that the bill in De Bry's figure is comparatively small.

Clusius in his 'Exotica' (1605) gives a figure, here copied, which, he says, he takes from a rough sketch in a journal of a Dutch voyager who had seen the bird in a voyage to the Moluccas in the year 1598.

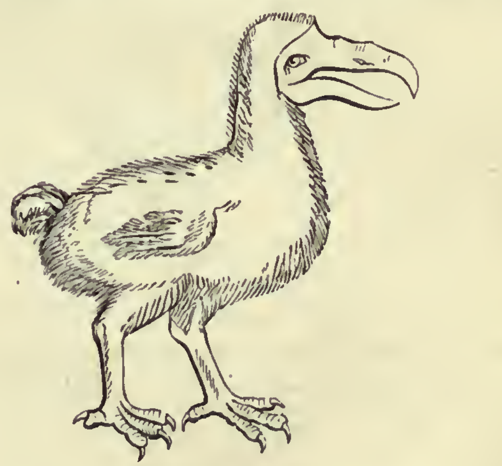


Figure from Clusius.

The following is Willughby's translation of Clusius, and the section is thus headed: "The Dodo, called by Clusius *Gallus gallinaceus peregrinus*, by Nieremberg *Cygnus cucullatus*, by Bontius *Dronte*":—"This exotic bird, found by the Hollanders in the island called Cygnæa or Cerne (that is the Swan Island) by the Portuguese, Mauritius Island by the Low Dutch, of 30 miles compass, famous especially for black ebony, did equal or exceed a swan in bigness, but was of a far different shape; for its head was great, covered as it were with a certain membrane resembling a hood: beside, its bill was not flat and broad, but thick and long; of a yellowish colour next the head, the point being black. The upper chap was hooked; in the nether had a bluish spot in the middle between the yellow and black part. They reported that it is covered with thin and short feathers, and wants wings, instead whereof it hath only four or five long black feathers; that the hinder part of the body is very fat and fleshy, wherein for the tail were four or five small curled feathers, twirled up together, of an ash-colour. Its legs are thick rather than long, whose upper part as far as the knee is covered with black feathers; the lower part together with the feet of a yellowish colour: its feet divided into four toes, three (and those the longer) standing forward, the fourth and shortest backward: all furnished with black claws. After I had composed and writ down the history of this bird with as much diligence and faithfulness as I could, I happened to see in the house of Peter Pauwius, primary professor of physic in the university of Leyden, a leg thereof cut off at the knee, lately brought over out of Mauritius his island. It was not very long, from the knee to the bending of the foot, being but little more than four inches, but of a great thickness, so that it was almost four inches in compass, and covered with thick-set scales, on the upper side broader, and of a yellowish colour, on the under (or backside of the leg) lesser and dusky. The upper side of the toes was also covered with broad scales, the under side wholly callous. The toes were short for so thick a leg: for the length of the greatest or middlemost toe to the nail did not much exceed two inches, that of the other toe next to it scarce came up to two inches: the back toe fell something short of an inch and a half; but the claws of all were thick, hard, black, less than an inch long; but that of the back toe longer than the rest, exceeding an inch.* The mariners in their dialect gave this bird the name Walgh-Vögel, that is, a nauseous or yellowish† bird; partly because after long boiling its flesh became not tender, but continued hard and of a difficult concoction, excepting the breast and gizzard, which they found to be of no bad relish, partly because they could easily get many turtle-doves, which were much more delicate and pleasant to the palate. Wherefore it was no wonder that in comparison of those they despised this, and said they could be well content without it. Moreover they said that they found certain stones in its gizzard, and no wonder, for all other birds as well as these swallow stones, to assist them in grinding their meat." Thus far Clusius.

In the 'Voyage of Jacob Heemskerk and Wolfert Harmansz to the East Indies' in 1601, 1602, 1603 (small 4to., Amsterdam, 1648), folio 19, the Dod-aarsen (Dodos) are enumerated among the birds of the Island of 'Cerne, now Mauritius;' and in the 'Journal of the East Indian Voyage of Willem Ysbrantsz Bontekoe van Hoorn, comprising many wonderful and perilous things that happened to him'—from 1618 to 1625 (small 4to., Utrecht, 1649)—under the head of the 'Island of Mauritius or Maskarinas,' mention is made (page 6) of the Dod-eersen, which had small wings, but could not fly, and were so fat that they scarcely could go.

Herbert, in his 'Travels' (1634), gives a figure or rather figures of a bird that he calls 'Dodo,' and the following account:—"The Dodo

Herbert's figure.

comes first to our description, here, and in Dygarrois (and no where else, that ever I could see or heare of, is generated the Dodo). (A Portuguize name it is, and has reference to her simplenes), a bird which for shape and rarenesse might be called a Phœnix (wer't in Arabia); her body is round and extreame fat, her slow pace begets that corpulencie; few of them weigh lesse than fifty pound: better to the eye than the stomack: greasie appetites may perhaps commend them, but to the indifferently curious nourishment, but prove offensive. Let's take her picture: her visage darts forth melancholy, as sensible of nature's injurie in framing so great and massie a body to be directed by such small and complementall wings, as are unable to hoise her from the ground, serving only to prove her a bird; which otherwise might be doubted of: her head is variously drest, the one halfe hooded with downy blackish feathers; the other perfectly naked; of a whitish hue, as if a transparent lawne had covered it: her bill is very howked and bends downwards, the thrill or breathing place is in the midst of it: from which part to the end, the colour is a light greene mixt with a pale yellow; her eyes be round and small, and bright as diamonds; her cloathing is of finest downe, such as you see in goslins; her trayne is (like a China beard) of three or foure short feathers; her legs thick, and black, and strong; her tallons or pounces sharp; her stomack fiery hot, so as stones and iron are easily digested in it; in that and shape, not a little resembling the Africk oestriches; but so much, as for their more certain difference I dare to give thee (with two others) her representation."—(4th ed., 1677.)

Nieremberg's description (1655) may be considered a copy of that of Clusius, and indeed his whole work is a mere compilation. As we have seen above, he names the bird *Cygnus cucullatus*.

In Tradescant's Catalogue ('Musæum Tradescantianum; or, a Collection of Rarities preserved at South Lambeth, near London, by John Tradescant,' London, 1656, 12mo.), we find among the 'Whole Birds'—"Dodar, from the island Mauritius; it is not able to flie being so big." That this was a Dodo there can be no doubt; for we have the testimony of an eye-witness, whose ornithological competency cannot be doubted, in the affirmative. Willughby at the end of his section on 'The Dodo,' and immediately beneath his translation of Bontius, has the following words:—"We have seen this bird dried, or its skin stuffed in Tradescant's cabinet." We shall hereafter trace this specimen to Oxford.

Jonston (1657) repeats the figure of Clusius, and refers to his description and that of Herbert.

Bontius, edited by Piso (1658), writes as follows: "De Dronte, aliis Dod-aers." After stating that among the islands of the East Indies is that which is called Cerne by some, but Mauritius 'a nostratibus,' especially celebrated for its ebony, and that in the said island a bird 'miræ conformationis' called Dronte abounds, he proceeds to tell us—we take Willugbby's translation—that it is "for bigness of mean size between an ostrich and a turkey, from which it partly differs in shape and partly agrees with them, especially with the African ostriches, if you consider the rump, quills, and feathers: so that it was like a pigmy among them, if you regard the shortness of its legs. It hath a great ill-favoured head, covered with a kind of membrane resembling a hood; great black eyes; a bending, prominent fat neck; an extraordinary long, strong, bluish-white bill, only the ends of each mandible are of a different colour, that of the upper black, that of the nether yellowish, both sharp-pointed and crooked.

Dronte. Figure from Bontius (wood-cut).
There is also a figure of the bird in the frontispiece, a copper-plate engraving.

It gapes huge wide as being naturally very voracious. Its body is fat, round, covered with soft gray feathers, after the manner of an ostriches: in each side instead of hard wing-feathers or quills, it is furnished with small soft-feathered wings, of a yellowish-ash colour; and behind, the rump, instead of a tail, is adorned with five small curled feathers of the same colour. It hath yellow legs, thick, but very short; four toes in each foot, solid, long, as it were scaly, armed with strong black claws. It is a slow-paced and stupid bird, and which easily becomes a prey to the fowlers. The flesh, especially of the breast, is fat, esculent, and so copious, that three or four Dodos will sometimes suffice to fill an hundred seamen's bellies. If they be old, or not well boiled, they are of difficult concoction, and are salted and stored up for provision of victual. There are found in

* We are indebted to Dr. J. E. Gray for the following measurement of the foot in the British Museum:—Knee to ancle 4½ inches; circumference 4 inches; middle toe 3 inches; back toe 1½ inch; front claws, which are much worn, 8 lines; back claw, also much worn, shorter. Dr. Gray observes that the leg mentioned by Clusius is probably, from the similarity of the measurement, the specimen which was afterwards noticed by Grew, and finally came to the British Museum.

† So in Willughby, but the print is somewhat indistinct, and there may be error. In the original the words are "Walgh-Vogel, hoc est, nauseam movens avis, partim quod," &c.: the word therefore is an interpolation.

their stomachs stones of an ash colour, of divers figures and magnitudes; yet not bred there, as the common people and seamen fancy, but swallowed by the bird; as though by this mark also nature would manifest that these fowl are of the ostrich kind, in that they swallow any hard things, though they do not digest them."

It appears from Adam Olearius ('Die Gottorfische Kunst Kammer,' 1666), that there was a head to be seen in the Gottorf Museum; but the figure (tab. xiii. f. 5) is very like that of Clusius. It is mentioned as the head of the Walch-Vogel, and Clusius is referred to. In the plate the head is shaded, and has a more finished appearance; the rest of the bird is in outline.

Grew ('Musæum Regalis Societatis; or a Catalogue and Description of the Natural and Artificial Rarities belonging to the Royal Society,' London, folio, 1681), at p. 68, thus describes the bird which is the subject of our inquiry:—"The leg of a Dodo, called *Cygnus cucullatus* by Nicrembergius; by Clusius, *Gallus gallinaceus peregrinus;* by Bontius called *Dronte*, who saith that by some it is called (in Dutch) Dod-aers, largely described in Mr. Willughby's 'Ornithol.' out of Clusius and others. He is more especially distinguished from other birds by the membranous hood on his head, the greatness and strength of his bill, the littleness of his wings, his bunchy tail, and the shortness of his legs. Abating his head and legs, he seems to be much like an ostrich, to which also he comes near as to the bigness of his body. He breeds in Mauris's Island. The leg here preserved is covered with a reddish-yellow scale; not much above four inches long, yet above five inches in thickness, or round about the joints, wherein, though it be inferior to that of an Ostrich or Cassowary, yet, joined with its shortness, may render it of almost equal strength." At p. 73 there is the following notice:—"The head of the Man of War, called also Albitrosse; supposed by some to be the head of a Dodo, but it seems doubtful. That there is a bird called the Man of War is commonly known to our seamen; and several of them who have seen the head here preserved do affirm it to be the head of that bird, which they describe to be a very great one, the wings whereof are eight feet over. And Ligon ('Hist. of Barbad.' p. 61), speaking of him, saith, that he will commonly fly out to sea to see what ships are coming to land, and so return. Whereas the Dodo is hardly a volatile bird, having little or no wings, except such as those of the Cassowary and the Ostrich. Besides, although the upper beak of this bill doth much resemble that of the Dodo, yet the nether is of a quite different shape; so that this either is not the head of a Dodo, or else we have nowhere a true figure of it." Grew then gives a very lengthened description of the skull which is figured by him (tab. 6), and intituled "Head of the Albitros," as it doubtless was. The leg above mentioned is that now preserved in the British Museum, where it was deposited with the other specimens described by Grew, when the Royal Society gave their 'rarities' to that national establishment. Grew was a well-qualified observer, and much of this description implies observation and comparison; indeed, though he does not refer to it, there is no reason for supposing that Grew was not familiar with Tradescaut's specimen.

Charleton also ('Onomasticon,' 1688) speaks of the *Dodo Lusitanorum*, *Cygnus cucullatus*, Willughby and Ray, and asserts that the Museum of the Royal Society of London contained a leg of the Dodo. This was evidently the leg above alluded to.

We now proceed to trace the specimen which was in the Musæum Tradescantianum. There were, it seems, three Tradescants—grandfather, father, and son. [TRADESCANT, in LIT. AND BIOG. DIV.] The two former are said to have been gardeners to Queen Elizabeth, and the latter to Charles I. There are two portraits to the 'Musæum,' one of 'Joannes Tradescantus pater' and the other of 'Joannes Tradescantus filius,' by Hollar. These two appear to have been the collectors: for John Tradescant, the son, writes in his address "to the ingenious reader" that he "was resolved to take a catalogue of those varieties and curiosities which my father had sceduloucly collected, and my selfe with continued diligence have augmented, and hitherto preserved together." This John Tradescant, the son, must have been the Tradescant with whom Elias Ashmole boarded for a summer when Ashmole agreed to purchase the collection, which was said to have been conveyed to Ashmole by deed of gift from Tradescant and his wife. Tradescant died soon after, and Ashmole in 1662 filed a bill in Chancery for a delivery of the curiosities. The cause is stated to have come to a hearing in 1664; and in 1674 Mrs. Tradescant delivered up the collection pursuant to a decree in Chancery, and afterwards (April, 1678, some say) was found drowned in her own pond. Ashmole added to the collection, and presented it to the University of Oxford, where it became the foundation of the Ashmolean Museum. That the entire 'Dodar' went to Oxford with the rest of Tradescant's curiosities there can be no doubt. Hyde ('Religionis Veterum Persarum, &c., Historia,' 1700) makes particular mention of it as existing in the Museum at Oxford. There, according to Mr. Duncan, it was destroyed in 1755 by order of the visitors, and he thus gives the evidence of its destruction:—

In the 'Ashmolean Catalogue, made by Ed. Llhwyd, Musæi Procustos,' 1684 (Plott being the keeper), the entry of the bird is "No. 29. Gallus gallinaceus peregrinus Clusii," &c. In a Catalogue made subsequently to 1755, it is stated that "The numbers from 5 to 46 being decayed, were ordered to be removed at a meeting of the majority of the visitors, Jan. 8, 1755." Among these of course was included the Dodo, its number being 29. This is further shown by a new Catalogue, completed in 1756, in which the order of the visitors is recorded as follows: "Illa quibus nullus in margine assignatur numerus a Musæo subducta sunt cimelia, annuentibus Vice-Cancellario aliisque Curatoribus ad ea lustranda convocatis, die Januarii 8vo., A.D. 1755." The Dodo is one of those which are here without the number. (Duncan, 'On the Dodo;' 'Zool. Journ.,' vol. iii. p. 559.)

Upon this solemn sentence, which left to the Museum nothing but a foot and a head, Sir C. Lyell makes the following observation: "Some have complained that inscriptions on tomb-stones convey no general information, except that individuals were born and died, accidents which must happen alike to all men. But the death of a species is so remarkable an event in natural history that it deserves commemoration; and it is with no small interest that we learn from the archives of the University of Oxford, the exact day and year, when the remains of the last specimen of the Dodo, which had been permitted to rot in the Ashmolean Museum, were cast away:" and the author concludes by giving the fatal record at length with becoming gravity. The head and foot which now constitute the greatest treasure of the Museum at Oxford were preserved by the curator, who seems to have had a larger amount of natural history knowledge than the majority of visitors.

We now come to the celebrated painting in the British Museum, a copy of which, by the kind assistance of the officers of the zoological department, who have given us every assistance in prosecuting this inquiry, and who had it taken down for the purpose, we present to our readers.

It has been stated that the painting came into the possession of Sir Hans Sloane, president of the Royal Society, and that it was bought at his sale by Edwards, who, after publishing a plate from it in his 'Gleanings,' presented it to the Royal Society, whence it passed, as well as the foot, into the British Museum. But Dr. Gray informs us that the foot only came with the museum of the Royal Society described by Grew; and that the picture was an especial gift from Edwards. Edwards's copy seems to have been made in 1760, and he himself says, "The original picture was drawn in Holland from the living bird brought from St. Maurice's Island in the East Indies in the early times of the discovery of the Indies by the way of the Cape of Good Hope. It was the property of the late Sir Hans Sloane to the time of his death; and afterwards becoming my property I deposited it in the British Museum as a great curiosity. The above history of the picture I had from Sir Hans Sloane and the late Dr. Mortimer, secretary to the Royal Society."

M. Morel, Ecrivain Principal des Hôpitaux au Port-Louis de l'Isle de France, writes as follows in his paper 'Sur les Oiseaux Monstrueux nommés Dronte, Dodo, Cygne Capuchonné, Solitaire, et Oiseau de Nazare, et sur la petite Isle de Sable à 50 lieues environ de Madagascar:' "These birds, so well described in the second volume of the 'History of Birds,' by M. le Comte de Buffon, and of which M. de Borame has also spoken in his 'Dictionary of Natural History,' under the names of Droute, Dodo, Hooded Swan (Cygne Capuchonné), Solitary or Wild Turkey (Dinde Sauvage) of Madagascar, have never been seen in the Isles of France, Bourbon, Rodriguez, or even the Seychelles lately discovered, during more than 60 years since when these places have been inhabited and visited by French colonists. The oldest inhabitants assure every one that these monstrous birds have been always unknown to them." After some remarks that the Portuguese and Dutch who first overran these islands may have seen some very large birds, such as Emeus or Cassowaries, &c., and described them each after his own manner of observing, M. Morel thus proceeds:—"However this may be, it is certain that for nearly an age (depuis près un siècle) no one has here seen an animal of this species. But it is very probable that before the islands were inhabited, people might have been able to find some species of very large birds, heavy and incapable of flight, and that the first mariners who sojourned there soon destroyed them from the facility with which they were caught. This was what made the Dutch sailors call the bird 'Oiseau de Dégoût' (Walck-Voegel), because they were surfeited with the flesh of it. . . . But among all the species of birds which are found on this isle of sand, and on all the other islets and rocks which are in the neighbourhood of the Isle of France, modern navigators have never found anything approaching to the birds above named, and which may be referred to the number of species which may have existed, but which have been destroyed by the too great facility with which they are taken, and which are no longer found excepting upon islands or coasts entirely uninhabited. At Madagascar, where there are many species of birds unknown in these islands, none have been met with resembling the description above alluded to." ('Observations sur la Physique, pour l'An 1778,' tom. xii. p. 154. Notes.)

Mr. Duncan thus concludes his paper above alluded to:—"Having applied, through the medium of a friend, to C. Telfair, Esq., of Port Louis, in the Mauritius, a naturalist of great research, for any information he could furnish or procure relating to the former existence of the Dodo in that island, I obtained only the following partly negative statement:—

"'That there is a very general impression among the inhabitants that the Dodo did exist at Rodriguez, as well as in the Mauritius itself; but that the oldest inhabitants have never seen it, nor has the bird or any part of it been preserved in any museum or collection formed in those islands, although some distinguished amateurs in natural history have passed their lives on them, and formed extensive collections. And with regard to the supposed existence of the Dodo in Madagascar, although Mr. Telfair had not received, at the time of his writing to Europe, a reply to a letter on the subject which he had addressed to a gentleman resident on that island, yet he stated that he had not any great expectations from that quarter; as the Dodo was not mentioned in any of his voluminous manuscripts respecting that island, which contained the travels of persons who had traversed Madagascar in all directions, many of them having no other object in view than that of extending the bounds of natural history.'"

We close this part of the case with the evidence of one evidently well qualified to judge, and whose veracity there is no reason to doubt. If this evidence be, as we believe it to be, unimpeachable, it is clear, not only that the Dodo existed, but that it was publicly exhibited in London. The lacunæ in the print represent the spaces occasioned by a hole burnt in the manuscript.

In Sloane Manuscript (No. 1839, 5, p. 108, Brit. Mus.) is the following interesting account by L'Estrange, in his observations on Sir Thomas Browne's 'Vulgar Errors.' It is worthy of note that the paragraph immediately follows one on the 'Estridge' (Ostrich):—

"About 1638, as I walked London streets I saw the picture of a strange fowl hong out upon a cloth vas and myselfe with one or two more Gen. in company went in to see it. It was kept in a chamber, and was a great fowle somewhat bigger than the largest Turkey Cock and so legged and footed but stouter and thicker and of a more erect shape, coloured before like the breast of a yong Cock Fesan (pheasant), and on the back of dunn or deare coulour. The keeper called it a Dodo and in the ende of a chimney in the chamber there lay an heap of large pebble stones whereof hee gave it many in our sight, some as bigg as nutmegs, and the keeper told us shee eats them conducing to digestion, and though I remember not how farre the keeper was questioned therein yet I am confident that afterwards shee cast them all agayne." *

Since the foregoing history was recorded in the 'Penny Cyclopædia,' the late Mr. Hugh Edwin Strickland, whose early loss by a melancholy accident the world of science has to deplore, has published a work on the Dodo and its kindred, in which he has most diligently retraced the ground previously gone over by Mr. Broderip. With regard to the statement of L'Estrange, Mr. Strickland says:—"I have endeavoured to find some confirmation from contemporary authorities of this very interesting statement, but hitherto without success. The middle of the 17th century was most prolific in pamphlets, newspapers, broadsides, 'rows of dumpy quartos,' and literary 'rubbish mountains,' as Mr. Carlyle designates them; but the political storms of that period rendered men blind to the beauties and deaf to the harmonies of nature, and its literature is very barren in physical research."

In addition to the works quoted in which reference is made to the Dodo, Mr. Strickland gives the following:—

Cornelius Matelief, a Dutch admiral, arrived in the Mauritius in 1606, and in a journal published in Dutch, and translated into French, gives an account of the Dodo, which he calls Dod-aersen, or Drouten.

Dodo, from the picture in the British Museum.

In 1607 two ships, under the command of Van der Haagen, stayed some weeks in the Mauritius. A journal was published in Dutch of this voyage, and translated in the 'Recueil des Voyages de la Compagnie des Indes Orientales,' Rouen, 1725.

Admiral Peter Wilhelm Verhuffen touched at Mauritius in 1611, and in 1613 an account of this voyage was published at Frankfurt, entitled 'Eylffter Schiffart ander Theil,' &c., in which reference is made to the Dodo, and especially to the fact that it attacked its aggressors, and wounded them severely if they were not careful.

In a journal by Peter van der Broecke, in which allusion is made to a visit to the Mauritius in 1617, Mr. Strickland discovered the sketch of a Dodo, but found no reference to it in the letter-press.

In a work published by François Cauche at Paris in 1651, entitled 'Relations veritables et curieuses de l'Isle de Madagascar,' he describes birds called Oiseaux de Nazaret, which answer to the Dodo. He says they lay but one egg the size of a halfpenny roll. How he came to

* This curious statement is extracted in the modern edition of Sir Thomas Browne's works by Wilkins: published by Pickering.

call the Dodo by this name, and what the size of a halfpenny roll was in 1651 are difficulties.

There is a tract in the Ashmolean Museum of which there are two editions, the first without a date, the second printed in London 1665. It is a catalogue of rarities to be seen at 'the musique house at the west end of Paules,' by R. H. alias Forges, Gentleman. Here at p. 11 we find "A Dodo's Leg; it is a bird that cannot fly." This is probably the specimen that passed into the possession of the Royal Society, and was described by Grew.

The last of Mr. Strickland's additions is a manuscript, entitled 'A coppey of Mr. Benj. Harry's Journall when he was chief mate of the Shippe Berkley Castle, Captn. Wm. Talbot then Commander on a voyage to the Coste and Bay, 1679, which voyage they wintered at the Maurisshes.' He speaks of the "Dodos, whose flesh is very hard."

This seems to be the last notice of the Dodo. "That the destruction of the Dodos," says Mr. Strickland, "was completed by 1693 may be inferred from the narrative of Leguat, who in that year remained several months in Mauritius, and enumerates its animal productions at some length, but makes no mention whatever of Dodos."

M. de Blainville says that at a public dinner at the Mauritius in 1816 several persons were present from 70 to 90 years old, who had no knowledge of such a bird from recollection or tradition. Mr. J. V. Thompson also, who resided for some years in Mauritius and Madagascar previous to 1816, states that no more traces of the existence of the Dodo could then be found than of the truth of the tale of Paul and Virginia, although a very general idea prevailed as to the reality of both.

Since the publication of the 'Penny Cyclopædia' the pictorial evidence of the existence and characters of this bird has also increased. In the royal collection of the Hague is a painting by Roland Savery, which is regarded as one of that master's chef d'œuvres. It represents Orpheus charming the animal creation with his music, and among innumerable birds and beasts the clumsy Dodo is represented as spell-bound by the lyric bard. This bird was discovered in this picture by Professor Owen in 1838.

"Whilst at the Hague," writes the professor to Mr. Broderip, "in the summer of 1838, I was much struck with the minuteness and accuracy with which the exotic species of animals had been painted by Savery and Breughel in such subjects as Paradise, Orpheus charming the Beasts, &c., in which scope was allowed for grouping together a great variety of animals. Understanding that the celebrated menagerie of Prince Maurice had afforded the living models to these artists, I sat down one day before Savery's Orpheus and the Beasts, to make a list of the species which the picture sufficiently evinced that the artist had had the opportunity to study alive. Judge of my surprise and pleasure in detecting in a dark corner of the picture (which is badly hung between two windows) the Dodo, beautifully finished, showing for example, though but three inches long, the auricular circle of feathers, the scutation of the tarsi, and the loose structure of the caudal plumes. In the number and proportions of the toes, and in general form, it accords with Edwards's oil painting in the British Museum; and I conclude that the miniature must have been copied from the study of a living bird, which it is most probable formed part of the Mauritian menagerie.

"The bird is standing in profile, with a lizard at its feet. Not any of the Dutch naturalists to whom I applied for information respecting the picture, the artist, and his subjects, seemed to be aware of the existence of this evidence of the Dodo in the Hague collection.

"I think I told you that my friend Professor Eschricht of Copenhagen had written to inform me that the skull of a Dodo had been lately discovered in the museum at Copenhagen: it had before formed part of the museum of the Duke of Gottorp."

In 1845 Mr. Strickland was examining Roland Savery's paintings at Berlin. "Among them," he says, "I found one which represents numerous animals in Paradise, one of which is a Dodo of about the same size and in nearly the same attitude as the one last mentioned. This picture was painted in 1626. Another picture of the Dodo, also by Roland Savery, date 1628, exists in the imperial collection of the Bellvedere at Vienna. The attitude is very different from that in the other pictures, giving the impression that Savery must have studied this bird from living specimens, and probably the one exhibited in London sat to Savery for his portraits."

The only existing recent remains attributed to the Dodo are—a leg in the British Museum, and a head (a cast of which is in Brit. Mus.), and a leg in the Ashmolean Museum at Oxford, the relics of Tradesoant's bird, and the head referred to by Professor Owen. Whether the leg formerly in the museum of Pauw be that at present in the British Museum may be perhaps doubtful, though we think with Dr. Gray that they are probably identical; but that the specimen in the British Museum did not belong to Tradeccant's specimen is clear, for it existed in the collection belonging to the Royal Society when Tradescant's 'Dodar' was complete. In the 'Annales des Sciences' (tom. xxi. p. 103, Sept. 1830) will be found an account of an assemblage of fossil bones, then recently discovered under a bed of lava in the Isle of France (Mauritius), and sent to the Paris Museum. They almost all belonged to a large living species of land-tortoise, called *Testudo Indica*, but amongst them were the head, sternum, and humerus of the Dodo. "M. Cuvier," adds Sir Charles Lyell in his 'Principles of Geology,' "showed me these valuable remains at Paris, and assured me that they left no doubt in his mind that the huge bird was one of the gallinaceous tribe."

Head of Dodo (from cast of Oxford specimen).

Foot of Dodo (specimen in the British Museum).

"Let us now endeavour," says Mr. Strickland, "to combine into one view the results of the historical, pictorial, and anatomical data which we possess respecting the Dodo.

"We must figure it to ourselves as a massive clumsy bird, ungraceful in its form, and with a slow waddling motion. We cannot form a better idea of it than by imagining a young duck or gosling enlarged to the dimensions of a swan. It affords one of those cases, of which we have many examples in zoology, where a species, or a part of the organs in a species, remains permanently undeveloped or in an infantine state. Such a condition has reference to peculiarities in the mode of life of the animal, which render certain organs unnecessary; and they therefore are retained through life in an imperfect state, instead of attaining that fully-developed condition which marks the mature age of the generality of animals. The Greenland Whale, for instance, may be called a permanent suckling; having no occasion for teeth the teeth never penetrate the gums, though in youth they are distinctly traceable in the dental groove of the jaws. The Proteus again is a permanent tadpole, destined to inhabit the waters which fill subterranean caverns; the gills which in other batrachian reptiles are cast off as the animal approaches maturity are here retained through life, while the eyes are mere subcutaneous specks, incapable of contributing to the sense of vision. And, lastly (not to multiply examples), the Dodo is (or rather was) a permanent nestling, clothed with down instead of feathers, and with the wings and tail so short and feeble as to be utterly unsubservient to flight. It may appear at first sight difficult to account for the presence of organs which are practically useless. Why, it may be asked, does the whale possess the germs of teeth which are never used for mastication? Why has the proteus eyes, when he is especially created to dwell in darkness? and why was the dodo endowed with wings at all, when those wings were useless for locomotion? This question is too wide and too deep to plunge into at present. I will merely observe that these apparently anomalous facts are really the indications of laws which the Creator has been pleased to follow in the construction of organised beings. They are inscriptions in an unknown hieroglyphic, which we are quite sure mean something, but of which we have scarcely begun to master the alphabet. There appear however reasonable grounds for believing that the Creator has assigned to each class of animals a definite type, or structure, from which he has never departed, even in the most exceptional or eccentric modifications of form. Thus if we suppose, for instance, that the abstract idea of a mammal implied the presence of wings, we may then comprehend why in the whale, the proteus, and the dodo, these organs are merely suppressed, and not wholly annihilated. And let us beware of attributing anything like imperfection to these anomalous organisms, however deficient they may be in those complicated structures which we so much admire in other creatures. Each animal and plant has received its peculiar organisation for the purpose, not of exciting the admiration of other beings, but of sustaining its own existence. Its perfection therefore consists, not in the number or complication of its organs, but in the adaptation of its whole structure to the external circumstances in which it is destined to live, and in this point of view we shall find that every department of the organic creation is equally perfect; the humblest animalcule, or the simplest *Conferva*, being as completely organised with reference to its appropriate habitat and its destined functions as man himself, who claims to be lord of all. Such a view of the creation is surely more philosophical than the crude and profane idea entertained by Buffon and his disciples, one of whom calls the dodo 'un oiseau bizarre, dont toutes les parties portaient le caractère d'une conception manquée.' He fancies that this imperfection was the result of the youthful impatience of the newly-formed volcanic islands which gave birth to the dodo, and implies that a steady old continent would have produced a much better article."

We now pass to the consideration of the place this apparently anomalous bird ought to occupy in the systems of classification of zoologists.

Piso, in his edition of Bontius, places the Dodo immediately before the Cassowary; and here we may observe that the figure of Bontius does not appear to be identical with the picture which now hangs in the British Museum. Though there is a general resemblance there are particular differences which go far to show, at all events, that the figure of Bontius and that in the picture are different portraits.

Willughby's eighth chapter treats of 'The greatest land-birds, of a peculiar kind by themselves, which by reason of the bulk of their bodies and the smallness of their wings cannot fly, but only walk.' The Ostrich occupies the first section of this chapter, and the Dodo the fourth and last, being immediately preceded by the Cassowary or Emeu. Ray's section 'Aves rostris rectioribus nimiusque hamatis maximæ, singulares et sui generis, ob corporum molem et alarum brevitatem volandi impotes' contains the same birds as Willughby's eighth chapter, namely, the Ostrich, the American Ostrich, the Emeu, Eme, or Cassowary, and lastly the Dodo.

Moehring, and after him Brisson, gives the bird under the name of *Raphus* a position next to the Ostriches also.

Buffon places it independently.

Linnæus, in his last edition of the 'Systema Naturæ' (the 12th, 1766), places the bird at the head of his *Gallinæ*, the order immediately succeeding the *Grallæ*, under the name of *Didus ineptus*, and immediately before the genus *Pavo* (Peacocks). The genus *Struthio* is the last of his *Grallæ*, and *Rhea* (American Ostrich) the last species of *Struthio*, so that *Didus ineptus* stands between *Struthio Rhea*, Linn., and *Pavo cristatus* (the Peacock). In a former edition Linnæus had noticed the bird under the name *Struthio cucullatus*.

Latham in his synopsis (1782) followed Linnæus, but gave three species: namely, the Hooded Dodo, the Solitary Dodo, and the Nazarene Dodo.

Gmelin, in his edition of the 'Systema Naturæ' (1789), makes *Psophia* (Trumpeter) the last genus of the Linnæan *Grallæ*, and *Otis* (Bustard) the first genus of the Linnæan *Gallinæ*, under which last-mentioned order he arranges the genus *Didus*, placing it between the genera *Struthio* and *Pavo*, which are both included by Gmelin in the order *Gallinæ*. He also gives three species—1st, *Didus ineptus*, which he describes as "black, clouded with white, with tetradactyle feet." The following are his synonyms:—*Didus*, 'Syst. Nat.' xii. 1, p. 267, n. 1; *Struthio cucullatus*, 'Syst. Nat.' x. p. 155; *Raphus*, Briss. 'Av.' 5, p. 14, n. 1; *Cygnus cucullatus*, Nieremb. 'Nat.' 231; *Gallus gallinaceus peregrinus*, Clus. 'Exot.' 99, t. 10; Olear. 'Mus.' 23, t. 13, f. 5; Dronte, Bont. 'Jav.' 70; Buff. 'Hist. Nat. des Ois.' i. p. 480; Dod-aersen, or Valgh-Vogel, Herbert, it. p. 382, t. 383; Dodo, Raj. 'Av.' p. 37, n. 8; Will. 'Orn.' p. 153, t. 27; Edw. 'Glean.' t. 294; Hooded Dodo, Lath. 'Syn.' iii. 1, p. 1, t. 70. 2nd, *Didus solitarius*, Solitaire, Buff. 'Hist. Nat. des Ois.' i. p. 485; Leguat, it. i. p. 98; Solitary Dodo, Lath. 'Syn.' iii. 1, p. 3, n. 2. This species is described by Gmelin as "varied with gray and brown, with tetradactyle feet." 3rd, *Didus Nazarenus*, Oiseau de Nazareth, et Oiseau de Nausée, Buff. 'Hist. Nat. des Ois.' i. p. 485; Cauche, 'Madag.' p. 130; Nazarene Dodo, Lath. 'Syn.' iii. 1, p. 4, n. 3. Gmelin describes this species as "black, with tetradactyle feet."

Blumenbach followed Linnæus; and Duméril and Vieillot followed Latham.

Temminck instituted in his 'Analyse du Système Général d'Ornithologie' the order *Inertes* for the Dodo and the *Apteryx*; two birds, as Mr. Yarrell in his paper on the *Apteryx* ('Trans. Zool. Soc.' vol. i. p. 71) observes, differing decidedly from each other in their beaks; but in reference to their imperfect wings, as also in the nature of their external covering, having obvious relation to the species included in his order *Cursores*. "But," adds Mr. Yarrell, "the situation chosen for this order *Inertes*, at the extreme end of his systematic arrangement, leads me to infer that M. Temminck considered as imaginary the subjects for which it was formed."

Illiger, in his 'Prodromus' (1811), instituted the order *Inepti* for the reception of the Dodo alone, *Apteryx* not being then known, and he placed it immediately preceding his *Cursores*, containing the Struthious Birds.

Cuvier, in the first edition of his 'Règne Animal,' at the end of his notice on his family *Brevipennes* (Les Autruches, *Struthio*, Linn.), has the following note appended to his description of the last species, *Rhea*.—"I cannot place in this table species but badly known, or, more, so little authentic as those which compose the genus *Didus*. The first, or the Dronte (*Didus ineptus*), is only known from a description given by the first Dutch navigators, and preserved by Clusius, 'Exot.' p. 99, and by an oil-painting of the same epoch copied by Edwards, pl. 294; for the description of Herbert is puerile, and all the others are copied from Clusius and Edwards. It would seem that the species has entirely disappeared, and we now possess no more of it at the present day than a foot preserved in the British Museum (Shaw, 'Nat. Miscell.' pl. 143), and a head in bad condition in the Ashmolean Museum at Oxford. The bill does not seem to be without some relation to that of the Auks (Pingouins), and the foot would bear considerable resemblance to that of the Penguins (Manchots) if it were palmated. The second species, or the Solitaire (*Didus solitarius*), rests only on the testimony of Leguat, 'Voy.' i. p. 98, a man who has disfigured the best known animals, such as the Hippopotamus and Lamantin. Finally, the third species, or L'Oiseau de Nazare (*Didus Nazarenus*), is only known through François Cauche, who regards it as the same as the Dronte, and yet only gives it three toes, while all other authors give four to the Dronte. No one has been able to see any of these birds since these voyagers." Cuvier's opinions subsequently underwent considerable modification. When he was in this country he had an opportunity of seeing the head preserved in the Ashmolean Museum, and the foot in the British Museum, and he doubted the identity of this species with that of which the painting is preserved in the national collection. Lyell mentions these doubts, and we must here recall to the reader the geologist's statement above alluded to, that Cuvier showed him the valuable remains in Paris, and that he assured him that they left no doubt on his mind that the huge bird was one of the Gallinaceous tribe. ('Sur quelques Ossemens,' &c., 'Ann. des Sci.' tome xxi. p. 103, Sept. 1830.)

Shaw, as appears indeed from Cuvier's note, made mention of the Dodo in his 'Naturalist's Miscellany' (plates 142 and 143), giving a figure of the head preserved in the Ashmolean Museum, and in his 'Zoological Lectures.'

Mr. Vigors in his paper 'On the Natural Affinities that connect the Orders and Families of Birds' ('Linn. Trans.' vol. xiv.) thus writes on the subject of the Dodo:—"The bird in question, from every account which we have of its economy, and from the appearance of its head and foot, is decidedly gallinaceous; and, from the insufficiency of its wings for the purposes of flight, it may with equal certainty be pronounced to be of the Struthious structure, and referable to the present family. But the foot has a strong hind toe, and, with the exception of its being more robust, in which character it still adheres to the *Struthionidæ*, it corresponds exactly with the foot of the Linnæan genus *Crax*, that commences the succeeding family."

M. Lesson, in his 'Manual' (1828), after giving a description of the Dodo (genus *Dronte*, *Didus*, Linn., *Raphus*, Moehring, Brisson), says that the genus includes but one species which may be considered as at all authenticated, and which exists no longer; this is the Dronte, *Didus ineptus*, described by Clusius, ex. p. 99, figured by Edwards, pl. 294. "They possess," he adds, "a foot and head of it at London, figured in Shaw's 'Miscell.' pl. 143 and 166." Then comes the following statement:—"M. Temminck has adopted, after Shaw, the genus *Apteryx*, which he thus describes." M. Lesson, after giving the description and noticing the only known species, *Apteryx Australis*, proceeds to make the following queries: "May not the Dronte be the Cassowary of the East Indies, to which has been added the bill of an Albatross? It is said that it was once very common in the Isles of France and of Bourbon, and that the former received the name of the Isle of Cerne from those birds. May not the *Apteryx* of M. Temminck be founded on the fragments of the Dronte preserved in the Museum of London?" To make the confusion complete, M. Lesson places immediately before the genus *Dronte* the *Emou Kirikiri*, *Dromiceius Novæ Zelandiæ*, Less., which is no other than the *Apteryx Australis* of Shaw, and which has been so well described and figured by Mr. Yarrell in the first volume of the 'Transactions of the Zoological Society of London.'

M. de Blainville, in a memoir on the 'Didus ineptus,' read before the Academy of Sciences, on the 30th of August, 1830, and published in the 'Nouvelles Annales du Muséum d'Histoire Naturelle' (tome iv. p. 1, 4to., Paris, 1835), enters at large into the history of the bird. After giving the different points on which the claim of the Dodo to be considered a gallinaceous bird rests, and the reasons for and against it, he thus proceeds:—"Among the orders of birds which include the largest species, there only remain the birds of prey with which the Dodo can be compared; and it seems to us that it is to them that the bird bears the greatest resemblance." In proof of this it is necessary to attend to the following observations:—

1. The eyes are situated in the same part of the bill as in *Cathartes*.
2. The nostrils are oval, situated very forward, and without a superior scale, as in those birds.
3. The form of the skull, its great width in the interorbitary space, and its flatness at the sinciput, are also nearly the same as in those vultures.
4. Even the colour of the bill, and the two caruncular folds of the origin of the curved part, are nearly the same as in those birds.
5. The species of hood which the skin forms at the root of the bill, and which have earned for the Dodo the name of *Cygnus cucullatus*, has a very similar disposition in *Cathartes*.
6. The almost entire nudity of the neck, as well as its greenish colour seen through the few downy feathers which cover it, are also characteristic of the vulture.

7. The form, the number, and the disposition of the toes, as well as the force and curvature of the clawe, indicate a hird of that family at least as much as a Gallinaceoue Bird.

8. The ecaly eystem of the tarsi and of the toes more resembles also what ie found in *Cathartes* than what is observed in the Gallinaceous Birds.

9. The kind of Jabot at the root of the neck, and even the muscular etomach, are found in one order as well as in the other.

10. Lastly, M. de Blainville noticee the absence of the spur (l'ergot), which he remarks is nearly characteristic of the Gallinaceoue Birds.

M. de Blainville, after expressing a hope that both the Aye-Aye (*Cheiromys*, which has not been eeen a second time since the days of Sonnerat) and the Dodo may be yet recovered in the interior of Madagascar, thus concludes his memoir :—

"1. There exist in the English collectious traces of at least three individuals of a large species of walking bird (oiseau marcheur), to which has been given the name of Dodo, Dronte, *Didus ineptus*.

"2. These tracee exist in Europe eince the epoch when the Dutch began to take part in the diecovery of the passage to the East Indies by the Cape of Good Hope, that ie to say, about 1594.

"3. The name of Dodo is employed for the first time hy Herbert, that of Dronte by Piso, hut without its heing possible to arrive at the origin and etymology of these denominations.

"4. The country of this bird is the Isle of France; there being nothing to prove positively that it has been found either at Bourbon or at Fernandez, as has been thought, owing to the confusion, no douht, between the Dodo and Solitaire of Leguat.

"5. The Dronte should be approximated to or even placed in the order of Rapacious Birds, near the vultures, rather than in that of the Gallinaceous Birds; and, for stronger reasons, rather than among the *Grallatores* (Echassiers), or near the Penguine (Manchots).

"6. It is by no means certain that thie bird has disappeared from the number of living animals. If thie is possihle in the case of the Iele of France, it is not probahle in the case of Madagascar, the productions of which are so little known, and which helongs, up to a certain point, to the same archipelago.

"There remains another question to discuss, namely, whether the incrusted bonee which have been lately sent to M. Cuvier from the Isle of France really belonged to the Dodo, as M. Cuvier was led to believe. It is a question which would be most easily eolved by the immediate comparisou of these hones with the pieces preserved in England. If thie was so, which the difference of height in the tarsal boue does not permit us to helieve, it would be at the same time proved that the Dodo existed also at Rodriguez, for these bonee have becu found in this isle in a cave (grotte), as M. Quoy, who saw them on his passage to the Isle of France, has assured me; and not at the Isle of France under bede of lava, as M. Cuvier has stated from erroneous information in his note read lately to the academy. Then there would be nearly a certainty that the Dodo was a Gallinaceous Bird; hut in making the observation that these bones come from the Isle of Fernandez, and that the descriptiou of the Solitaire of Leguat accords sufficiently well with a bird of this order, or at least with a Gallino-Gralle, it might he that the hones actually in the hands of M. Cuvier were no other than those of the Solitary Bird properly so called, and not those of the true Dronte."

The memoir is illustrated with four plates. The first is a coloured copy of the head of the Dodo from the Museum portrait, of the size of the original. In the painting, the author observee, the head is at least a foot long from the occiput to the extremity of the bill; but the head at Oxford is only eight inches and a half, or about two-thirds. The bill, he adds, makes out nearly three-fourthe of the wholo length. The eecond plate gives a profile of the Oxford head from a sketch taken from the original, and a view of the same seen from above, and skulls of the *Urubu* and *Vultur Papa*. The third plate gives two views of the foot preserved in the British Museum, and the remains of the foot at Oxford; a foot of the Heath-Cock (Coq de Bruyère), a foot of a Penguin, and a foot of *Vultur Papa*. The fourth plate gives a profile of the cast of the head at Oxford, aud a view of the same seen from below.

In the British Museum (1837), in cases 65-68 (Room xiii.), are the Ostrich; Bustards "which in many respects are allied to the Gallinaceous Birds;" the foot and cast of the head of the Dodo above alluded to; the Courser and Pratincole; and at page 99 of tho 'Synopsis' (1832) we have the following observations :—"Over the door adjoiuing the twelfth room is an original paiuting of the Dodo, preseuted to the Museum by George Edwards, Esq., the celebrated ornithological artist, and copied in hie worke, plate No. 294, who says it was 'drawn in Holland from a living bird hrought from St. Maurice'e Island in the East Indies.' The only remains of this bird at preeent known are a foot (case 65) in this collection (preeented hy the Royal Society), and a head and foot said to havo belonged to a epecimen which was formerly in Tradescant's Museum, hut ie now in the Ashmolean Museum at Oxford. The cast of the head above meutioned (in the same case) was presented hy P. Duncan, Esq. The bird in the shortness of the wings resemhlce the ostrich, but its foot in general rather resembles that of the common fowl, and the heak from the position of its nostrils is most nearly allied to tho vultures; so that its true place in the series of birds, if indeed such a hird ever really existed, is not as yet eatisfactorily determined."

Mr. Swaiuson ('Natural History aud Claseification of Birds,' 1836), speaking of the birds of prey, says (p. 285) :—"The third and last type of this family appears to us to be the Secretary Vulture of Africa, forming the genus *Gypogeranus*. At least we canuot assign it to any other known division of the *Raptores* without separating it much more widely from its congeners thau our present state of knowledge will sanction. It hae been thought indeed that this remarkable bird represented one of the primary divisions of the whole order, in which case it would etand between the owls and the Dodo; but its similarity to the vulturee and the falcons in our opiniou is too great to favour this supposition; while, on the other hand, it will subsequently appear that the circle of the *Falconidæ* is sufficiently complete to show that it does not enter into that family." After some other observations Mr. Swainson concludee his remarks on the Secretary thus :—"It must be rememhered also that the very same objections occur agaiust placing this hird (the Secretary) hetween the *Strigidæ* (Owls) and the *Didide* (Dodos) as those we have intimated against considering it as the grallatorial type of the *Vulturidæ*."

That a hird or birds called by the name of Dodo and the other appellations which we need not here repeat once existed, we think the evidence above given eufficiently provee. We have indeed heard doubte expressed whether the Museum portrait was taken "from a living hird," and have also heard it euggested that the picture may represeut a epecimen made up of the hody of an ostrich to which the bill and legs of other hirds have been attached; and here it is that the destruction of Tradescant'e specimen hecomes a source of the greatest regret. Whatever was the condition of that specimen, as long as the skin was preserved there existed the means of ascertaining whether it was real or a made-up monster; and when the vice-chancellor and the other curators, in making their lustratiou, gave the fatal nod of approbation they destroyed that evidence. With regard to the picture, we have endeavoured to place it before tho reader as well as our limited meaue will permit, in order that he may have an opportunity of judging from the internal evidence as to the probability of the portrait being taken from a living bird, and with this view we have given the accessories as they appear in the painting as well ae the principal figure.

Dr. J. E. Gray, among others, still inclines, we believe, to the opinion that the bird represented was made up hy joining the head of a bird of prey approaching the Vultures, if not belouging to that family, to the lege of a Gallinaceous Bird; and his opiniou, from his attainmente and experience, is worthy of all reepect. Hie reasous for conеidering the Dodo as helonging to the *Raptores* chiefly rest ou the following facts, premising, as he does, that it ie to bo horne in mind that in the Raptorial Birds the form of the bill is their chief ordinal character, which is not the caso with the *Grallatores* or the *Natatores*, where the form of the feet and lege are the chief character of the order :—

"1. The base of the bill is enveloped in a cere, as may be eeen in the cast, where the folds of tho cere are distinctly exhibited, especially over the back of the nostrils. The cere is ouly found in the Raptorial Birds.

"2. The nostrile are placed exactly in frout of the cere, as they are iu the other *Raptores*; they are oval, and nearly erect, as they are in the True Vultures, and in that genus alone; and uot longitudinal as they are in the *Cathartes*, all the Gallinaceous Birds, *Grallatores*, aud *Natatores*; aud they are uaked, and covered with an arched scale, as ie the case in all the *Gallinaceæ*.

"3. In Edwards's picture the bill is represented as much hooked (like the *Raptores*) at the tip; a character which unfortunately cannot be verified ou the Oxford head, as that speciuicu is destitute of the horny sheath of the hill, and only showe tho form of the bony core.

"With regard to the eize of the bill, it is to be ohserved that this part variee greatly in the different species of Vultures; indeed so much so, that there is no reasou to helieve that the hird of the Oxford head wae much larger than some of the known Vultures.

"With regard to the foot," adds Dr. Gray, "it has all the characters of that of the Galliuaceous Birds, and differe from all tho Vultures in the shortness of the middle toe, the form of the scalee on tho leg, and the bluntness of the clawe."

But if we grant Dr. Gray's poeition, see what we have to deal with. We have theu two species, which are either extinct or have escaped the researches of all zoologists, to account for: one, a hird of prey, to judge from its bill, larger than the condor; the other a Galliuaceous Bird, whose pillar-like legs must have supported au enormoue body. As to the stories of the disgusting quality of the flesh of the bird found and eaten by the Dutch, that will weigh but little in the scale when we take the expression to be, what it really was, indicative of a comparative preference for the turtle-doves there found after feeding on Dodos 'usque et nauseam.' "Always partridges" has become almost proverbial, and we find from Lawson how a repetition of the most delicious food palls. "We cooked our supper," eays that traveller, "but having neither bread nor salt our fat turkeys began to be loathsome to us; although we were never wantiug of a good appetite, yet a coutinuance of one diet mado us weary;" and again: "By the way our guide killed more turkeys, and two pole-cats, which he eat, esteeming them before fat turkeys."

With regard to the form of the bill, we must be careful how we lay too much stress on that. Who would have expected to find a bill "long, slender, smooth, and polished, in form resembling that of an Ibis, but rather more straight and depressed at the base," on an Emeu-like body with rasorial legs and feet? Yet such is the form of *Apteryx*. As to the argument arising from the absence of the spur, it is worth but little at best; and it may be said in favour of those who would place the Dodo between the Struthious and Gallinacious Birds, that its absence in such an osculant bird would be expected.

If the picture in the British Museum and the cut in Bontius be faithful representations of a creature then living, to make such a bird a bird of prey—a Vulture, in the ordinary acceptation of the term—would be to set all the usual laws of adaptation at defiance. A Vulture without wings! How was it to be fed? And not only without wings, but necessarily slow and heavy in progression on its clumsy feet. The *Vulturidæ* are, as we know, among the most active agents for removing the rapidly decomposing animal remains in tropical and intertropical climates, and they are provided with a prodigal development of wing to waft them speedily to the spot tainted by the corrupt incumbrance. But no such powers of wing would be required by a bird appointed to clear away the decaying and decomposing masses of a luxuriant tropical vegetation—a kind of Vulture for vegetable impurities, so to speak—and such an office would not be by any means inconsistent with comparative slowness of pedestrian motion.

Nevertheless we have the following expression of opinion from Professor Owen, who in 1845 published a paper on the subject of the Dodo in the 'Transactions of the Zoological Society.' He concludes his paper thus: "Upon the whole then the Raptorial character prevails most in the structure of the foot as in the general form of the beak of the Dodo, and the present limited amount of our anatomical knowlege of the extinct terrestrial bird of the Mauritius supports the conclusion that it is an extremely modified form of the Raptorial order. Devoid of the power of flight, it could have had small chance of obtaining food by preying upon the members of its own class; and if it did not exclusively subsist on dead and decaying organised matter, it most probably restricted its attacks to the class of reptiles and to the littoral fishes, *Crustacea*, &c., which its well developed back toe and claw would enable it to seize and hold with a firm gripe."

Mr. Strickland, who is the last writer upon the affinities of the Dodo, and has produced a work quite exhaustive of the subject, refers the Dodo to the *Columbidæ*.

"The extensive group of *Columbidæ*, or Pigeons," says Mr. Strickland, "is very isolated in character, and though probably intermediate between the Insessorial and Gallinaceous orders, can with difficulty be referred to either. In this group we find some genera that live wholly in trees, others which are entirely terrestrial, while the majority, of which the common Wood-Pigeon is an instance, combine both these modes of life. But the main characteristic of all is their diet, composed almost exclusively of the seeds of various plants and trees. We accordingly find much diversity in the forms of their beaks, according to the size and mechanical structure of the seeds on which each genus is destined to live. Those which feed on cereal grains and the seeds of small grasses and other plants, like the Common Pigeon and Turtle-Dove, have the beak considerably elongated, feeble, and slender. But in tropical countries there are several groups of Pigeons called Nutmeg-Eaters and Trerons, which feed on the large fruits and berries of various kinds of palms, fig, nutmeg, and other trees. These birds, and especially those of the genus *Treron* (*Vinago* of Cuvier) have the beak much stouter than other pigeons, the corneous portion being strongly arched and compressed, so as greatly to resemble the structure of certain Rapacious Birds, especially of the Vulturine family. This Raptorial form of beak is carried to the greatest extent in the genus *Didunculus*, a very singular bird of the Samoan Islands in the Pacific Ocean. Very little is yet known of its habits, but Mr. Stair, a missionary recently returned from those islands, has reported that the bird feeds on bulbous roots. Its first discoverer, Mr. Titian Peale, an American naturalist (whose account is I believe still unpublished) saw something in its form or habits that reminded him of the Dodo, and hence its generic name. Sir W. Jardine, who first described the bird, under the name of *Gnathodon strigirostris* in the 'Annals of Natural History,' vol. xvi. p. 175, referred it conjecturally to the *Megapodidæ*, though he recognised in it several dove-like characters. And Mr. Gould, who has given two figures of it in his 'Birds of Australia,' part 22, pronounces that the bird approaches nearest to the Pigeons. We shall soon see that the Didine and Columbine hypotheses, though apparently incongruous, resolve themselves (as often happens) into one truth.

"Although certain genera of *Columbidæ* are thus seen to assume a form of beak resembling that of the *Raptores*, yet no two groups in the same class can be more opposed in habits and affinities than the 'feroces Aquilæ' and 'imbelles Columbæ.' It is interesting however to observe that mechanical strength, whether for the devouring of animal or vegetable substances, is obtained in both cases by a similarity of structure.

"If now we regard the Dodo as an extreme modification, not of the vultures, but of these vulture-like frugivorous pigeons, we shall, I think, class it in a group whose characters are far more consistent with what we know of its structure and habits. There is no à priori reason why a pigeon should not be so modified in conformity with external circumstances as to be incapable of flight, just as we see a Grallatorial Bird modified into an Ostrich, and a Diver into a Penguin. Now, we are told that Mauritius, an island forty miles in length and about one hundred miles from the nearest land, was when discovered clothed with dense forests of palms and various other trees. A bird adapted to feed on the fruits produced by these forests would in that equable climate have no occasion to migrate to distant lands; it would revel in the perpetual luxuriance of tropical vegetation, and would have but little need of locomotion. Why then should it have the means of flying? Such a bird might wander from tree to tree, tearing with its powerful beak the fruits which strewed the ground, and digesting their strong kernels with its powerful gizzard, enjoying tranquillity and abundance, until the arrival of man destroyed the balance of animal life, and put a term to its existence. Such in my opinion was the Dodo, a colossal brevipennate frugivorous pigeon."

The first idea of referring the Dodo to the Pigeons seems to have occurred to Professor Reinhardt of Copenhagen. To Mr. Strickland however must be given the credit of laboriously working out this idea. We can here only refer to his volume, 'The Dodo and its Kindred,' for further information. In working out the anatomical details he was assisted by Dr. Melville, now Professor of Natural History, Queen's College, Galway, Ireland. This part of the work is remarkable for the detailed manner in which the subject is gone into, and the beautiful illustrations which accompany the text.

We have now to draw attention to another part of this subject. In speaking of the Dodo several references have been made to a bird called the Solitaire, and many of the writers quoted have confounded it with the Dodo, or made it a second species. This bird was first described by Leguat, who was for many years the commander of a party of French Protestant refugees who settled upon the island of Rodriguez in the year 1691. In his description * of the isle, which is called either Diego-Rodrigo, or Diego-Ruys, or Rodrigo, he gives the following account:—"We had also another creek on the other side of our cabins, and full of oysters sticking to the rock. We went often to breakfast there, and brought some home, with which we made an excellent ragout with palm-tree cabbages and turtle's fat. Of all the birds in the island the most remarkable is that which goes by the name of the Solitary (le Solitaire), because it is very seldom seen in company, though there are abundance of them. The feathers of the males are of a brown-gray colour; the feet and beak are like a turkey's, but a little more crooked. They have scarce any tail, but their hind part, covered with feathers, is roundish like the crupper of a horse. They are taller than turkeys. Their neck is straight, and a little longer in proportion than a turkey's, when it lifts up its head. Its eye is black and lively, and its head without comb or cop. They never fly; their wings are too little to support the weight of their bodies; they serve only to beat themselves and flutter when they call one another. They will whirl about for twenty or thirty times together on the same side during the space of four or five minutes; the motion of their wings makes then a noise very like that of a rattle, and one may hear it two hundred paces off. The bone of their wing grows greater towards the extremity, and forms a little round mass under the feathers as big as a musket-ball: that and its beak are the chief defence of this bird. 'Tis very hard to catch it in the woods, but easy in open places, because we run faster than they, and sometimes we approach them without much trouble. From March to September they are extremely fat, and taste admirably well, especially while they are young. Some of the males weigh forty-five pound.

"The females are wonderfully beautiful, some fair, some brown: I call them fair because they are of the colour of fair hair. They have a sort of peak, like a widow's, upon their breasts, which is of a dun colour. No one feather is straggling from the other all over their bodies, being very careful to adjust themselves and make them all even with their beaks. The feathers on their thighs are round like shells at the end, and being there very thick, have an agreeable effect; they have two risings on their craws, and the feathers are whiter there than the rest, which livelily represent the fine neck of a beautiful woman. They walk with so much stateliness and good grace, that one cannot help admiring them and loving them, by which means their fine mien often saves their lives.

"Though these birds will sometimes very familiarly come up near enough to one when we do not run after them, yet they will never grow tame; as soon as they are caught they shed tears without crying, and refuse all manner of sustenance till they die. We find in the gizzards of both male and female a brown stone, of the bigness of a hen's egg; it is somewhat rough, flat on one side, and round on the other, heavy and hard. We believe this stone was there when they were hatched, for let them be never so young you meet with it always. They have never but one of them; and besides, the passage from the craw to the gizzard is so narrow that a like mass of half the bigness could not pass. It served to whet our knives better than any other stone whatsoever. When these birds build their nests they choose a clean place, gather together some palm-leaves for that purpose, and

* 'A new Voyage to the East Indies by Francis Leguat and his Companions, containing their Adventures in two Desert Islands,' &c., 8vo., London, 1708.

heap them up a foot and a half high from the ground, on which they sit. They never lay but one egg, which is much bigger than that of a goose. The male and female both cover it in their turns, and the young is not hatched till at seven weeks' end. All the while they are sitting upon it, or are bringing up their young one, which is not able to provide for itself in several months, they will not suffer any other bird of their species to come within two hundred yards round of the place; but what is very singular is, the males will never drive away the females, only when he perceives one he makes a noise with his wings to call the female, and she drives the unwelcome stranger away, not leaving it till it is without her bounds. The female does the same as to the males, whom she leaves to the male, and he drives them away. We have observed this several times, and I affirm it to be true. The combats between them on this occasion last sometimes pretty long, because the stranger only turns about, and does not fly directly from the nest; however the others do not forsake it till they have quite driven it out of their limits. After these birds have raised their young one, and left it to itself, they are always together, which the other birds are not; and though they happen to mingle with other birds of the same species, these two companions never disunite. We have often remarked, that some days after the young one leaves the nest, a company of thirty or forty brings another young one to it, and the new-fledged bird, with its father and mother joining with the band, march to some bye-place. We frequently followed them, and found that afterwards the old ones went each their way alone, or in couples, and left the two young ones together, which we called a marriage. This particularity has something in it which looks a little fabulous; nevertheless, what I say is sincere truth, and what I have more than once observed with care and pleasure." The worthy narrator then indulges in some reflections on marriages in general, and early marriages in particular. It is worthy of note, with reference to the alleged juxtaposition of the bones of a large land-turtle and those of the Dodo, to which we shall have occasion to allude, that the same author, in the description of the same island, speaks of the multitude of land-turtles; of which he says, "I have seen one that weighed one hundred pound, and had flesh enough about it to feed a good number of men."

Solitary Bird of Leguat.

The preceding cut is copied from Leguat's figure of 'the Solitary Bird.'

In the frontispiece is represented one in a sort of landscape, and also land-turtles; and in 'a plan of the settlement' in the island of Rodrigo, many, some in pairs, are placed about. This plan shows the situation of the houses, &c. of Leguat and his companions; there are also land-turtles and other animals.

Although Rodriguez is now a British colony we have no further testimony about living Solitaries. Persons resident on the spot have inquired with the same results as have attended inquiries after the Dodo in Mauritius. Bones, probably of this bird, have however been found.

In a letter addressed to the Secretary of the Zoological Society by Charles Telfair, Esq., Corr. Memb. Zool. Soc., dated Port Louis (Mauritius), November 8, 1832, and read before a meeting of the society on the 12th March 1833, it appeared that Mr. Telfair had recently had opportunities of making some researches about the buried bones of the Dronte or Dodo found in the Island of Rodriguez. The result of these researches he communicated, and inclosed letters addressed to him by Colonel Dawkins, military secretary to the Governor of the Mauritius, and by M. Eudes, resident at Rodriguez.

Colonel Dawkins, it was stated, in a recent visit to Rodriguez, conversed with every person whom he met respecting the Dodo, and became convinced that the bird does not exist there. The general statement was that no bird is to be found there except the Guinea-Fowl and Parrot. From one person however he learned the existence of another bird, which was called Oiseau-Bœuf, a name derived from its voice, which resembles that of a cow. From the description given of it by his informant, Colonel Dawkins at first believed that this bird was really the Dodo; but on obtaining a specimen of it, it proved to be a Gannet (apparently referrible to the Lesser Gannet of Dr. Latham, the *Sula candida* of Brisson, and the *Pelecanus Piscator* of Linnæus). It is found only in the most secluded parts of the island. Colonel Dawkins visited the caverns in which bones have been dug up, and dug in several places, but found only small pieces of bone. A beautiful rich soil forms the ground-work of them, which is from six to eight feet deep, and contains no pebbles. No animal of any description inhabits these caves, not even bats.

M. Eudes succeeded in digging up in the large cavern various bones, including some of a large kind of bird, which no longer exists in the island: these he forwarded to Mr. Telfair, by whom they were presented to the Zoological Society. The only part of the cavern in which they were found was at the entrance, where the darkness begins; the little attention usually paid to this part by visiters may be the reason why they have not been previously found. Those near the surface were the least injured, and they occur to the depth of three feet, but no where in considerable quantity; whence M. Eudes conjectured that the bird was at all times rare, or at least uncommon. A bird of so large a size as that indicated by the bones had never been seen by M. Gory, who had resided forty years on the island. M. Eudes added that the Dutch who first landed at Rodriguez left cats there to destroy the rats which annoyed them: these cats have since become very numerous, and prove highly destructive to poultry; and he suggested the probability that they may have destroyed the large kind of bird to which the bones belonged, by devouring the young ones as soon as they were hatched—a destruction which may have been completed long before the island was inhabited.

The bones procured by M. Eudes for Mr. Telfair were presented by that gentleman to the Zoological Society. At the reading of the letter, &c., they were laid on the table, and consisted of numerous bones of the extremities of one or more large species of Tortoise, several bones of the hinder extremity of a large bird, and the head of a humerus. With reference to the metatarsal bone of the bird, which was long and strong, Dr. Grant pointed out that it possessed articulating surfaces for four toes, three directed forwards and one backwards, as in the foot of the Dodo preserved in the British Museum, to which it was also proportioned in its magnitude and form. ('Zool. Proc.' 1833, Part 1.)

The bones belonging to the birds here spoken of, Mr. Strickland believes were those of the Solitaire. They were lost before he began to investigate the subject. He however had an opportunity of examining the bones before alluded to as preserved in the Museum in Paris, and also a collection of bones made by Mr. Telfair in Rodriguez, and now in the Andersonian Museum at Glasgow. The bones from Paris and Glasgow were found to agree, and were referrible to a bird having the characters of the Solitaire as described by Leguat. They however differed from those of the Dodo, but were found to present affinities to the *Columbidæ* equally as strong as those of the Dodo.

From occasional notices amongst early travellers, Mr. Strickland comes to the conclusion that also in the island of Bourbon there formerly existed a brevipennate bird or birds, homologous with the Dodo and Solitaire, that are now extinct. He refers also to a notice by Flacourt of a large brevipennate bird as an inhabitant of Madagascar. He thus concludes this part of his work:—"On a review of the various historical and osteological evidences which I have now brought together, it seems sufficiently clear that the three oceanic islands, Mauritius, Rodriguez, and Bourbon, which, though somewhat remote from each other, may be considered as forming one geographical group, were inhabited until the time of their human colonisation by at least four distinct but probably allied species of brevipennate birds. This result at once reminds us of the analagous case of the New Zealand group of islands, where the scientific zeal of Messrs. Cotton, Williams, Colenso, Mantell, and others has brought to light a mine of osteological treasures, from which the consummate sagacity of Professor Owen has reconstructed two new genera of brevipennate birds. Seven species of *Dinornis* and two of *Palapteryx* have been clearly established and elaborately described by Professor Owen; while in the still surviving genus *Apteryx*, of which Mr. Gould has very recently described a second species, we see an almost expiring member of the same zoological group. The extraordinary success of the naturalists of New Zealand in procuring from recent alluvial deposits a series of osseous remains which have more than doubled the number of struthoid birds previously known, should encourage the scientific residents in the islands of the Indo-African Sea to make similar researches. I feel confident that if an active naturalist would make a series of excavations in the alluvial deposits in the beds of streams and amid the ruins of old habitations in the Mauritius, Bourbon, and Rodriguez, he would speedily discover remains of the Dodo, the two Solitaires, or the Oiseau Bleu. But I would especially direct the attention to the caves with which those volcanic islands abound. The chief agents in the destruction of the brevipennate birds were probably the runaway negroes who for many years infested the primæval forests of those islands, and inhabited the caverns, where they would doubtless leave the scattered bones of the animals on which they fed. Here then may we more especially hope to find the osseous remains of these remarkable animals. Should any copies of this work find their way to Mauritius or Bourbon they may perhaps incite the lovers of knowledge in those islands to investigate further the subject, which has been diligently but imperfectly pursued in this volume; and I shall feel rewarded for the trouble it has cost, if my researches into the history and organisation of these birds, aided by the anatomical investigations which Dr. Melville has introduced into the second part of the work, shall have rescued these anomalous creatures from the domain of fiction, and established their true rank in the scheme of creation."

DOG. [CANIS.]

DOGBANE. [APOCYNACEÆ.]

DOG-FISH. [SQUALIDÆ.]

DOG-ROSE. [ROSA.]

DOG'S-TAIL-GRASS. [CYNOSURUS.]

DOG'S-TOOTH-SPAR. [CALCAREOUS SPAR.]

DOG-WOOD. [CORNUS.]

DOLABELLA. [TECTIBRANCHIATA.]

DOLABRIFORM, a term applied in Botany to certain fleshy leaves, which are straight at the front, taper at the base, compressed, dilated, rounded, and thinned away at the upper end at the back, so as to bear some resemblance to an old-fashioned axe-head.

DOLERITE, a form of Basalt consisting of *Labradorite* and *Augite*.

DOLICHONYX. [BOB-O-LINK.]

DO'LICHOS. Under this name Linnæus included the greater part of those tropical twining Leguminous Plants which bear eatable fruit like the kidney-beans cultivated in Europe. A large number of species, ill distinguished from each other, and differing materially in the structure of their fructification, were for so long a time collected under this name that, although they are now broken up into several genera, we shall briefly notice the more remarkable in this place.

Dolichos itself is confined to the species with a compressed linear pod, having incomplete cellular dissepiments, and ovate seeds with a small oval hilum. Of these *D. Catjang*, the pulse of which is called Boberloo in India, is an annual, and has somewhat deltoid leaves, angular at the back, few-flowered peduncles, and erect pods. It is cultivated in the fields in many parts of India during the dry season, and its seeds are extensively consumed by the poorer natives. *D. lignosus*, a perennial, with long racemes of flowers, broad heart-shaped leaflets, and linear sharp-pointed pods, is extremely common all over India, where it is cultivated "during the cold season in gardens and about the doors of the natives, forming not only cool shady harbours, but furnishing them with an excellent pulse for their curries," &c. There are several varieties of it constituting the commonest kidney-beans of India. *D. biflorus*, an annual, with oblong pointed leaflets and scimitar-shaped hairy pods, furnishes the pulse called in India Horse-Gram; and *D. sphærospermus* produces the Calavana or Black-Eyed Peas of Jamaica.

Lablab has a compressed scimitar-shaped pod, rough, with tubercles at the sutures, and furnished with transverse imperfect cellular partitions, and ovate seeds with a fungous callous linear scar. *Lablab vulgaris*, the old *Dolichos Lablab*, is a common plant in the hedges in many parts of India, whence it has travelled into the tropical parts of America. It is a smooth perennial with showy white or purple flowers, and large horizontal pods, containing from three to four seeds. It has a heavy disagreeable bug-like smell, prefers a rich black soil that cannot be flooded by rains, and produces a coarse but wholesome pulse, much eaten by the lower classes in India.

Pachyrhizus has a long compressed pod, with kidney-shaped seeds and no dissepiments, and is remarkable for its principal species, *P. angulatus* (formerly *Dolichos bulbosus*), producing a root of the size and substance of a turnip. It is reported to have been carried to the Philippines from South America, and thence to have been introduced into the west of Asia. The side leaflets are nearly triangular, that in the middle lozenge-shaped, slightly toothed, and shaggy on both sides. The flowers are very beautiful, of a violet-blue colour, and arranged in axillary nearly erect racemes, from one to two feet long. Its root is a common article of food in the Malay Archipelago, but no other part of the plant is eaten.

In *Psophocarpus* the pods are oblong, and have four longitudinal wings; the seeds are roundish. It comprehends the *Dolichos tetragonolobus*, a twining annual, the pods or tuberous roots of which are a common Indian esculent.

Canavalia, with long straightish compressed pods, having three short wings at the lower suture, cellular dissepiments, and oblong seeds with a narrow hilum, comprehends the South American Lima Beans and the Sword Beans of India. The species have a handsomer and firmer foliage than the other genera, and the flowers are usually large and showy. *C. gladiata*, the common cultivated species, has often pods two feet long, and varies with red, gray, and white seeds.

Finally, the genus *Mucuna*, known by its oblong puckered compressed hispid pods, includes all the species from which Cowage is obtained. [COWITCH or COWAGE.]

DOLIOLUM. [ACALEPHÆ.]

DOLIUM. [ENTOMOSTOMATA.]

DOLOMITE, a variety of Magnesian Limestone, first noticed by Dolomieu. It occurs mostly massive, and in mountain masses; it is usually white, sometimes grayish or yellowish; its structure is sometimes slaty; it is frequently translucent on the edges. It is softer than common limestone. Sometimes it is met with in veins accompanied by quartz, carbonate of lime, &c. The Dolomite of the Apennines consists of 59 carbonate of lime and 40 carbonate of magnesia: it contains a variable quantity of oxide of iron.

Compact Dolomite or Gurhoffian is snow-white, and very compact. The surface, when newly broken, is scarcely shining, and the fragments, which are sharp, are translucent on the edges; the fracture is flat chonchoidal, and its hardness is considerable. It occurs in veins traversing serpentine between Gurhoff (whence its name) and Aggsbach, in Lower Austria. According to Klaproth, it consists of carbonate of lime 70·50, and carbonate of magnesia 29·50.

This rock, having the aspect and general geological history of limestone, but composed of carbonate of magnesia united to carbonate of lime, usually atom to atom, occurs as a part of the Oolitic system of the Alps and Apennines, and of the German Jurakalk; and it is perhaps proper to call by the same name the crystallised Magnesian Limestone of Nottinghamshire, Derbyshire, Yorkshire, and Durham. The best example of this English Dolomite is at Bolsover, in Derbyshire, from whence the stone is taken to build the new Houses of Parliament. From the manner in which this rock occurs along the Lake of Lugano, and other parts on the south side of the Alps, in direct contact or more frequently in a peculiar relation of propinquity to augitic traps, Von Buch inferred that Dolomite was a metamorphic limestone, altered by absorption of magnesian vapours yielded by volcanic action. There is much to recommend this inference. In England we frequently find the mountain limestone dolomitised, along lines of fracture and along the sides of mineral veins; and these cases appear to enter into Von Buch's explanation. But the broad Magnesian Limestones of the North of England are certainly due to original crystallisation together of the two carbonates already named. Dolomite is usually very deficient in organic remains. In the Alps and in Franconia its aspect is very picturesque.

The Magnesian Limestone belongs to a system of rocks called by modern geologists Permian, which includes the Zechstein Kupferschiefer and Roth-todte-ligende of German geologists. [PERMIAN SYSTEM.]

DOLPHIN. [CETACEA.]

DO'MBEYA, a genus of Plants belonging to the natural order *Byttneriaceæ*, inhabiting the East Indies and the isles of France, Bourbon, and Madagascar. They have a 5-parted persistent calyx, surrounded by a 3-leaved unilateral involucel. The petals are 5. The stamens are from 15 to 20, scarcely monadelphous, five of them being sterile, with from 2 to 3 fertile ones between each sterile stamen. The name *Dombeya* was also applied to the plant now called *Araucaria excelsa*. The bark of *D. spectabilis* is made into ropes in Madagascar.

DONAX. [ARUNDO.]

DONAX. [CONCHACEA.]

DOOM, or DOUM, a remarkable Palm-Tree exclusively inhabiting Upper Egypt, especially the neighbourhood of Thebes, whence it is named *Cucifera Thebaica*. Its stem, instead of growing without branches like other palms, forks two or three times, thus assuming the appearance of a Pandanus. Clumps of it occur near Thebes. The fruit is about the size of an orange, angular, irregularly formed, of a reddish colour, and has a spongy, tasteless, but nutritious rind. The albumen of the seed is hard and semitransparent, and is turned into beads and other little ornaments. Gærtner described it under the name of *Hyphæne coriacea*. It is known in Egypt as the Gingerbread-Tree, because of the resemblance of its brown mealy rind to that cake.

DORE'MA, a genus of Plants belonging to the natural order *Umbelliferæ*. It has an epigynous cup-shaped disc; the fruit slightly compressed from the back, and edged; 3 distinct filiform primary ridges near the middle, and alternating with them 4 obtuse secondary ridges, the whole enveloped in wool; vittæ 1 to each secondary ridge, 1 to each primary marginal ridge, and 4 to the commissure, of which 2 are very small.

D. ammoniacum is a glaucous green plant with a perennial root, large leaves 2 feet long, somewhat bipinnate, the pinnæ in three pairs, the leaflets inciso-pinnatifid, with oblong mucronulate entire or slightly-lobed segments from 1 to 5 inches long and half an inch to 2 inches broad; the petiole very large, downy, and sheathing at the base; the teeth of the calyx acute, membranous, minute; the petals ovate, reflexed at the point; the fruit elliptical, compressed, surrounded by a broad flat edge. This plant is a native of Persia, in the plains of Yerdekahst and Kumisha in the province of Irak; and near the town of Jezud Khāst in very dry plains and gravelly soil, exposed to an ardent sun. This plant is one of those which yields gum ammoniacum, but it is probable that there are several species of plants which yield this as well as the other gum-resins of the order *Umbelliferæ*.

(Lindley, *Flora Medica*.)

DORIPPE (Fabricius), a genus of Brachyurous Decapod *Crustacea* belonging to the sub-division which have the feet of the fourth and fifth pairs elevated on the back and not terminated with paddles, and the eyes supported upon simple peduncles (*Notopoda*). The genus is adopted by Latreille, Lamarck, Leach, Bosc, and Risso: it is the *Notogastropus* of Vosmaer, and was comprehended under the general term *Cancer* by Linnæus, Herbst, Aldrovandus, and Plancus. It has the following characters:—External antennæ rather long, setaceous, inserted above the intermediate ones, which are folded (pliées), but not entirely lodged in the cavities where they take their insertion; third joint of the external jaw-feet (pieds-mâchoires) straight, elongated, terminated in a point; buccal opening triangular; claws (chelæ) small, short, equal; the other feet very long and compressed, the third pair being the greatest; the last two pair elevated upon the back, and terminated by a small hooked nail, which is folded back upon the next joint. Carapace slightly depressed (the sides wider posteriorly than they are anteriorly), truncated, and spinous before; truncated, sinuous, and bordered behind; the surface marked with small humps or tubercles, which correspond exactly to the regions proper to the soft parts beneath. Two great oblique openings, ciliated on their edges, communicating with the branchial cavity and situated below the head, one at the right, the other at the left of the mouth. Inferior and posterior part of the body truncated into a kind of gutter to receive the reflected abdomen, the pieces of which are nodulous or tuberculous. Eyes small, lateral, supported on rather long peduncles, placed near the angles of the head, and protected by its angular projections, which form the edges of their orbits. (Desmarest.)

The Mediterranean and Adriatic seas, and Manilla, are among the localities in which the species have been found. They haunt great depths in the sea, nor has it yet been proved whether they make use of the feet elevated on the back to cover themselves like the *Dromiæ* with foreign bodies. It is however very probable that such is their use.

D. lanata, Latreille, Lamarck; *D. Facchino*, Risso; *Cancer lanatus*, Linnæus; *C. hirsutus alius*, Aldrovandus.

It has four dentations in the front and a very strong lateral point, forming at the same time the angle of the head and the external border of the orbit. A short point on the middle of each side of the carapace. Anterior border of the thighs of the second and third pair of feet without spines. Fingers of the chelæ compressed and arched within, having their internal edge armed with a series of dentilations, which are rather strong, oblique, equal, and white. Body often covered with reddish down.

Dorippe lanata.
a, external left jaw-foot.

It inhabits the Mediterranean and the Adriatic seas. The inhabitants of Rimini call it Facchino. (Desmarest.)

Fossil Dorippe.

Desmarest ('Histoire Naturelle des Crustacés Fossiles,' 1822) describes a species, *D. Rissoana*, which has some resemblance to the species above figured and described, and still more to the crab figured by Herbst under the name of *Cancer Frascone*; and above all to a species brought from Australia by Péron, and named *D. nodosa*. Desmarest observes that he is the more inclined to consider it as approaching very near to this last, inasmuch as he had thought that the specimen which he had described might not be in reality fossil. In fact, he adds, that though brown and shining, like the fossil crabs which come from the East Indies, it is much lighter, more friable, and not so much imbedded in the clay as they are. In his 'Considérations Générales sur la Classe des Crustacés' (1825) he describes the Dorippe à Quatre Dents with the synonyms *D. quadridens*, Fabr. Latr.; *D. nodosa*, Coll. du Mus.; *Cancer Frascone*, Herbst. "This *Dorippe* from the East Indies," he adds, "has lately been brought from Manilla by M. Marion de Procé. It so much resembles a species which I have described with doubt as fossil, that I know not how precisely to point out the difference. This species belongs to M. Defrance, who has stated its characters in the article 'Dorippe' (fossil) of the 'Dict. des Sciences Naturelles.'"

DORIS. [NUDIBRANCHIATA.]

DORO'NICUM, a genus of Plants belonging to the natural order *Compositæ*, to the sub-order *Corymbiferæ*, the tribe *Senecionidæ*, and the section *Senecioneæ*. It has the florets of the ray ligulate and pistiliferous; those of the disc tubular, with both stamens and pistils; the involucre hemispherical, of 2 or 3 rows of equal scales; the pappus pilose, wanting in the ray. The species are deciduous herbaceous plants. Two are natives of Great Britain.

D. pardalianches, with cordate denticulate leaves. It has a stem from 2 to 3 feet in height, erect, solitary, hollow, and hairy. It is a rare plant, and found in damp and hilly woods and pastures. It has its specific name from πάρδαλις, a tiger, and ἄγχειν, to strangle, on account of the use said formerly to have been made of the plant for the purpose of destroying wild animals. With the species of *Arnica* and other plants of the order it has the common name of Leopard's Bane.

D. plantaginerum, the second British species, has ovate leaves, and the stem-leaves clasping. It attains about the same height as the last, and its flowers are also yellow. *D. scorpioides*, *D. Caucasicum*, *D. Austriacum*, and *D. pardalianches* are natives of the continent of Europe.

(Koch, *Flora Germanica*; Babington, *Manual of Botany*.)

DORR-HAWK. [GOATSUCKERS.]

DORSATI. [AMMONITES.]

DORSIBRANCHIA'TA, Cuvier's appellation for the second order of Annelides, which have their organs, and especially their branchiæ, distributed nearly equally along the whole of their body, or at least a part. *Chloeia* (Savigny) and *Cirratulus* (Lamarck), with many other genera, belong to this order. [ANNELIDA.]

DORSTE'NIA, a genus of Plants belonging to the natural order *Urticaceæ*. The roots of several species of this genus are all confounded under the appellation of Contrayerva Root; but as they all possess nearly the same chemical composition and properties, it is of little importance which particular species yields what is used. Indeed by the time the root reaches Europe whatever virtues it originally possessed are lost, so that it has scarcely any sensible qualities, and very little effect on the system. It consists of volatile oil, extractive, and starch. The first of these gives it some power over the nervous system, should it not have been dissipated by time. Hence it is recommended in the low stages of fever, especially of children; but Serpentaria Root may at all times be advantageously substituted for it. Contrayerva signifies antidote, and it was at one time supposed to be an antidote to all poisons, whether animal, vegetable, or mineral, except mercury.

DORY. [ZEUS.]

DOTO. [NUDIBRANCHIATA.]

DOTTEREL. [CHARADRIADÆ.]

DOUCKER. [COLYMBIDÆ.]

DOUM. [DOOM.]

DOURA. [SORGHUM.]

DOVES. [COLUMBIDÆ.]

DOWN, the fine hair of plants, is a cellular expansion of the cuticle, consisting of attenuated thin semi-transparent hairs, either simple or jointed end to end, or even branched, as in the Mullein. When attached to seeds, it enables them to be buoyed up in the air and transported from place to place. When covering the external surface of a plant it acts as a protection against extremes of temperature, and probably as a means of absorbing moisture from the air.

DRABA, a genus of Plants belonging to the natural order *Cruciferæ*, the sub-order *Latiseptæ*, and the tribe *Alyssineæ*. It has an oval or oblong pouch, slightly convex, the seeds many in each cell, not margined, in two rows, the filaments simple. The species are perennial or annual branched herbs, with linear oblong or ovate leaves, yellow or white flowers.

D. verna, common Whitlow-Grass, has a leafless scape, glabrous above, with lanceolate acute attenuated leaves, hairy below, the petals deeply cloven, the pouch oblong, shorter than its pedicel. It is an exceedingly common plant, ornamenting old walls and dry banks in the spring before other flowers make their appearance. It is found throughout Europe, and is most abundant in Great Britain. It is the *Erophila verna* of De Candolle.

D. aizoon, Evergreen Whitlow-Grass, has naked smooth scapes, linear acute keeled stiff ciliated leaves, the style as broad as the hairy pod, but one-half shorter. It is a native of Bavaria, Austria, Hungary, Transylvania, and the Carpathian Mountains, particularly on Mount Chocsz.

D. aizoides has a leafless glabrous scape, with linear rigid acute keeled glabrous ciliated leaves, the stamens as long as the slightly-notched petals, the style elongated. It is a native of gravelly soils in almost every country of Europe. It is a rare plant in Great Britain, and has been found on rocks and walls at Penuard Castle, near Swansea. The other British species are—*D. rupestris*, a rare plant found on mountains in Scotland; *D. incana*, also a mountainous species; and *D. muralis*, found on the shady sides of rocks, walls, and mountains, but it is a rare plant in Great Britain.

Above 60 species of *Draba* have been described. They are all insignificant plants inhabiting the temperate and colder parts of the world. They are not often cultivated, but are adapted for rock-work. They are apt to drop off in winter when exposed, and the best way to preserve them is to keep them in pots as other alpine plants. They grow best in a mixture of sand, loam, and peat, and the pots should be well drained with potsherd. They may be propagated by dividing the roots or by seeds.

(Babington, *Manual;* Don, *Dichlamydeous Plants.*)

DRACÆNA, a genus of Endogenous Plants of the natural family *Asparageæ* of Jussieu, now arranged as a section of *Liliaceæ* by Dr. Lindley. The genus was established by Linnæus, and named from one of its species yielding the resinous exudation, familiarly known by the name of Dragon's Blood, a translation of the Arabic name Dum al Akhwain, met with in Avicenna and other Arabian authors. *Dracæna* is characterised by having an inferior 6-partite perianth, of which the segments are nearly erect, and have inserted on them the 6 stamens, with filaments thickened towards the middle and linear anthers. The style is single, with a trifid stigma. The berry 2- or 3-celled, with its cells 1- or 2-seeded.

The species of *Dracæna* are now about 30 in number, and found in the warm parts of the Old World, and in many of both Asiatic and African islands, whence they extend southward to the Cape of Good Hope and Australia, and northward into China, and to the eastern parts of India, as the districts of Silhet and Chittagong. Species are also found in Socotra, and the Canary and Cape Verd Islands, as well as at Sierra Leone. From this distribution it is evident that the species require artificial heat for their cultivation in England. They are found to thrive in a light loam, and may be grown from cuttings sunk in a bark bed.

The species of *Dracæna* are evergreens, either of a shrubby or arboreous nature; and having long slender often columnar stems, they emulate palms in habit. Their trunks are marked with the cicatrices of fallen leaves; the centre is soft and cellular, having externally a circle of stringy fibres. The leaves are simple, usually crowded together towards the end of the branches, or terminal like the inflorescence; whence we might suppose that the name *terminalis* had been applied to some of the species, if Rumphius had not stated that it was in consequence of their being planted along the boundaries of fields. The structure of the stem and leaves is particularly interesting, as the fossil genera *Clathraria* and *Sternbergia* have been assimilated to *Dracæna*, the former by M. Adolphe Brongniart, and the latter by Dr. Lindley; and as Rumphius compares the leaves of a *Dracæna* with those of *Galanga*, it is as probable that the fossil leaves called *Cannophyllites* may be those of a plant allied to *Dracæna*, as that they belong to one of the *Canneæ*.

Of the several species of *Dracæna* which have been described by botanists, there are few which are of much importance either for their useful or ornamental properties. Among them however may be mentioned *D. terminalis*, a species rather extensively diffused. The root is said by Rumphius to be employed as a demulcent in cases of diarrhœa, and the plant as a signal of truth and of peace in the Eastern Archipelago. In the islands of the Pacific Ocean a sweetish juice is expressed from its roots, and afterwards reduced by evaporation to a sugar, of which specimens were brought to Paris by Captain D'Urville from the island of Tahiti (Otaheite). The root is there called Ti or Tii, and thence no doubt corrupted into Tea-Root by the English and Americans. M. Gaudichaud mentions that in the Sandwich Islands generally an intoxicating drink is prepared from this root, to which the name Ava is often applied, as well as to that made with the roots of *Piper methysticum*.

D. Draco is the best known species, not only from its producing Dragon's Blood, but also from one specimen having so frequently been described or noticed in the works of visiters to the Canary Islands. The erect trunk of the Dragon-Tree is usually from 8 to 12 feet high, and divided above into numerous short branches, which terminate in tufts of spreading sword-shaped leaves, pointed at the extremity. The most celebrated specimen of this tree grows near the town of Orotava, in the island of Teneriffe, and was found by Humboldt in 1799 to be about 45 feet in circumference. Sir G. Staunton had previously stated it to be 12 feet in diameter at the height of 10 feet; and Ledru gave even larger dimensions. It annually bears flowers and fruit; and though continuing thus to grow, does not appear much increased in size, in consequence of some of its branches being constantly blown down, as in the storm of July 1819, when it lost a great part of its top. The great size of this enormous vegetable is mentioned in many of the older authors; indeed as early as the time of Bethencourt, or in 1402, it is described as large and as hollow as it is now; whence, from the slowness of growth of Dracænas, has been inferred the great antiquity of a tree which four centuries have so little changed. Humboldt indeed remarks that there can be no doubt of the *Dracæna* of Orotava being, with the Baobab (*Adansonia digitata*), one of the oldest inhabitants of our planet; and as tradition relates that it was revered by the Guanches, he considers it as singular that it should have been cultivated from the most distant ages in the Canaries, in Madeira, and Porto Santo, although it comes originally from India. This fact he adduces as contradicting the assertion of those who represent the Guanches as a race of men completely isolated from the other races of either Asia or Africa. To this it may be replied, that we know too little of the botany of the interior of Africa to be able to draw from it any inferences; while the Dragon-Tree on the other hand is not known to exist farther to the eastward than the island of Socotra.

DRACO. [DRACONINA.]

DRACOCELLA. [DRACONINA.]

DRACONINA, a sub-family of Saurians belonging to the family *Agamidæ*, the tribe *Strobilosaura*, and the sub-order *Pachyglossæ* of Dr. J. E. Gray's arrangement. . The family of Agamas, or *Agamidæ*, is thus defined by Dr. Gray:—"Teeth implanted on the end of the jaws. Tongue short, depressed, apex entire or slightly nicked. Eyelids connivent, valvular. Feet, for walking. Toes all free, unequal; the thumb of the hind feet on the same plane as the other toes; the little toes lower down on the ankle than the thumb. The thumb is anterior and internal, and the great toe of the hind feet occupies the same position, the thigh and foot being bent forwards. This is proved by analogy; this toe being the one that is clawless in the *Gecko*, which have the clawless thumb, and in *Anolis*, where the thumb and great toes are simple, and not dilated beneath, like the other toes."

The synopsis of the genera of this family, according to the 'British Museum Catalogue,' is as follows:—

I. Body compressed. Living on trees.

A. Femoral and pre-anal pores none. Scales imbricate. Asiatic.

a. Ribs elongated, exserted, supporting wing-like lateral expansions. Throat with 3 pouches.

1. *Draco.*—Ears naked. Nostril below the face-ridge.
2. *Dracocella.*—Nostril above the face-ridge.
3. *Dracunculus.*—Ears covered with scales.

b. Ribs simple. Back crested.

* Toes 4 or 5. Ears exposed.

4. *Sitana.*—Males with an elongated pouch. Females without any pouch.

** Toes 5—5. Tail with elongated keeled scales beneath. Scales of back small, often with scattered larger ones.

† Ears hidden under the skin.

5. *Lyriocephalus.*—Head lyrate. Muzzle with a round tubercle in front. Scales unequal.
6. *Ceratophora.*—Head square. Muzzle with a prolonged horn-like process. Scales unequal.
7. *Otocryptis.*—Head squarish. Muzzle nearly flat, simple. Eyebrows bluntly angular behind.

†† Ears exposed.

8. *Gonyocephalus.*—Scales of the belly smooth, of the back unequal. Eyelids angular, produced.
9. *Dilophyrus.*—Scales of the belly smooth; of the back equal. Eyebrow rounded, simple.
10. *Tiaris.*—Scales of the belly keeled, of the back unequal. Eyebrow and parotids unarmed.
11. *Acanthosaura.*—Scales of the belly keeled, of the back unequal. Eyebrows and parotids armed.

*** Toes 5—5. Tail with broad rhombic keeled scales beneath. Scales of back uniform.

12. *Bronchocela.*—Nuchal crest simple. Scales in descending series.
13. *Salea.*—Nuchal crest double. Scales large, in longitudinal series.
14. *Calotes.*—Back crested. Scales in ascending series. Head swollen behind, with one or two ridges of spines.

**** Toes 5—5. Tail with truncated keeled scales beneath. Scales small, keeled, in cross rings.

15. *Chelasonia.*—Parotids swollen, armless. Throat lax. The nape and back with a low crest. Tail rather compressed. Face-ridge rounded, with small scales.
16. *Charasia.*—Parotids swollen, with some spines above. The nape and back with a low crest. Tail tapering. Face-ridge distinct, with enlarged imbricated scales.
17. *Gindalia.*—Parotids rather swollen, with 2 or 3 spines above. Nape and back not crested. Tail tapering, round. Face-ridge indistinct.

B. Femoral pores distinct.

a. Scales rhombic, placed in rings. Toes fringed on each side. Back crested. Throat lax, folded across.

18. *Lophura.*—Back and tail with a fin-like crest, supported by bony rays. Head squarish.
19. *Phrysignathus.*—Back and tail with a crest of compressed scales. Head swollen behind.

b Scales irregular, imbricate. Australian.

* Neck with a frill-like expansion on each side.

20. *Chlamydosaurus.*—Head rhombic.

** Neck simple.

21. *Hatteria.*—Back and tail crested. Head elongate. Pre-anal pores numerous. Scales small.
22. *Lophognathus.*—Back crested. Head elongate. Pre-anal pores 2—2. Femoral pores 2—2.

23. *Diporophora.*—Back keeled. Head short. Pre-anal pores 1—1. Scales rhombic, of belly larger.
24. *Amphibolurus.*—Back crested, with longitudinal series of larger keeled scales. Femoral pores numerous.
25. *Grammatophora.*—Back not crested, with cross rows of larger scales. Femoral pores numerous.

II. Body depressed. Back with imbricate scales. Throat with a cross fold. Terrestrial.

a. Pre-anal pores distinct. Femoral pores none. Ears exposed.

* Pre-anal and abdominal pores in several rows.

26. *Landakia.*—Tail with rhombic keeled scales. Parotids spinose.
27. *Stellio.*—Tail with rings of large spinose scales. Parotids spinose.

** Pre-anal pores in a single line. Abdomen poreless.

28. *Agama.*—Parotids spinose. Scales rhombic, keeled.
29. *Trapelus.*—Parotids unarmed. Scales minute. [AGAMA.]

b. Pre-anal and femoral pores none.

* Ears exposed. Body and limbs with large spinose tubercles.

30. *Moloch.*—Neck with a convex tubercle above.

** Ears hidden. Scales small, granular. Back not crested.

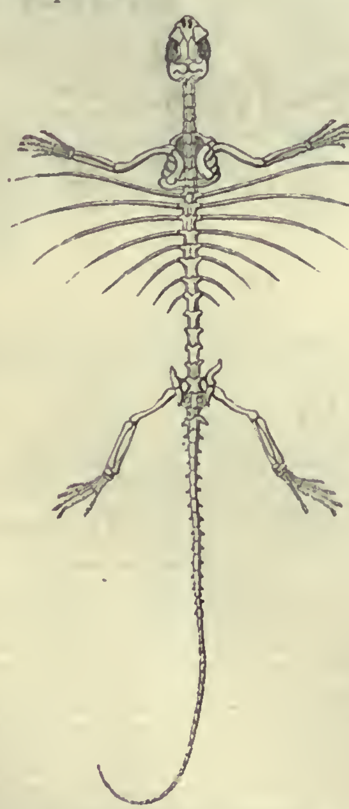
31. *Phrynocephalus.*—Angle of mouth simple. Toes toothed on the sides.
32. *Megalochilus.*—Angle of mouth fringed. Toes fringed on the sides.

c. Femoral pores distinct. Pre-anal pores none. Ears exposed. Scales small, granular. Back not crested.

33. *Uromastyx.*—Tail broad, depressed, with complete rings of spinose scales.
34. *Saara.*—Tail broad, depressed, with scales of the upper part of the rings spinose; of lower, armless.
35. *Leiolepis.*—Tail round, elongate, tapering, with whorls of smooth scales.

The genera and species of the family *Draconina* are as follows :—

1. *Draco.*—Head small. Nostril in a scale, rather tubular on the side of the face-ridge. Tympanum of the ear visible, opaque, white. They live on trees, walking with agility with their wings folded on their sides, but they expand them and use them as a parachute when they throw themselves from the tops of trees. They spread out their pouches as they lie on the trunks of the trees. Scales unequal, some larger, keeled. Nape crested.

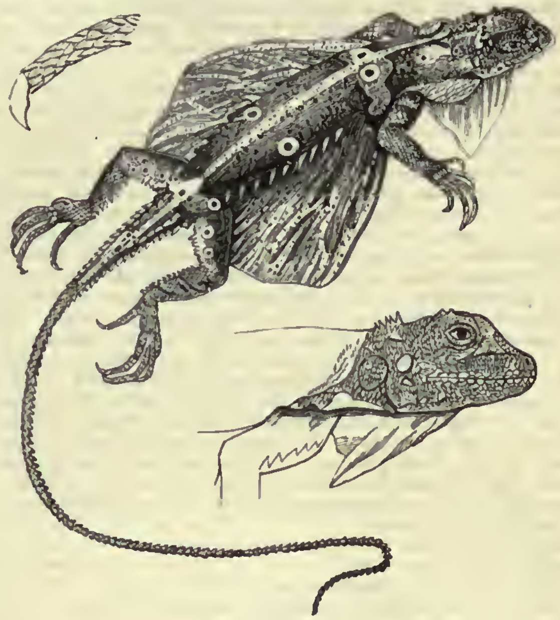


Skeleton of a species of *Draco*.

D. volans, Linn., the Flying Lizard. It is the *D. major* of Lamarck, *D. viridis* of Daudin, *D. Bouroniensis* of Lesson, and the *D. Daudini* of Duméril. The scales of the back are rather broad, generally smooth; of the throat granular, of the same size; the lateral pouches of the males moderate, rounded at the end, covered with ovate keeled scales; the throat black-spotted; wings gray, fulvous, or brown, spotted and marbled with black, sometimes forming four or five oblique black bands near the outer edge: the sides with a series of large broad keeled scales.

D. Timorensis, the Timor Flying-Lizard. It is the *D. viridis Timorensis* of Schlegel. It has flat scales, rather large, smooth, unequal, with a row of rather larger keeled scales upon and on each side of the vertebral line; wings reddish, brown-spotted; lateral pouches (of male) moderate, rounded at the end, covered with large keeled scales; sides with an interrupted series of large keeled scales.

D. fimbriatus, Kuhl, the Fringed Flying-Lizard. Scales of the back small, equal, mostly smooth; the throat with many circular spaces, covered with larger granular scales; head white, brown-netted; lateral pouches of male elongate, angular, acute, covered with large keeled scales; wings with short whitish longitudinal lines; sides with a series of small triangular keeled scales, placed in groups of two or three; nostrils sub-superior.



Draco fimbriatus.

2. *Dracocella.*—Head small, covered with small unequal scales; the nostrils roundish, in a scale, erect, vertical on the face-ridge; tympanum exposed, and opaque.

* Nape crested.

D. Dussumieri, Dussumier's Dragon, has moderate scales, rather rhombic; the sides with a series of rather larger scales, placed in roundish groups; orbit with a small bony point at back and front angle; wings with large brown spots near the body, and largely marbled near the outer edge; a black band across the throat; base of the pouch blue-black; the limbs moderate.

** Nape not crested.

D. Nacuratopogon, the Red-Throated Dragon. The orbit with a small bony point above, upon the front and back edge; scales of the back equal, smooth, the sides with a series of large keeled scales; nape not crested; a large round black spot on each side of the base of the pouch; wings brown-spotted; the limbs elongate.

3. *Dracunculus.*—Head quadrangular, covered with small unequal scales; nostrils lateral, on the face-ridge; tympanum hid under the skin, covered with scales. Weigmann described *D. lineatus* as having but five exserted ribs, but the specimens in the British Museum, like the other dragons, have six on each side.

* Nape not crested, with a longitudinal fold.

D. quinquefasciatus, the Banded Flying-Lizard. Wings with five cross bands; scales of the back keeled; nape with a longitudinal fold, not crested; nostrils superior, erect; ears covered with many equal granular scales.

** Nape crested. Ears slightly concave.

D. lineatus, the Lined Flying-Lizard. Head gray, white-spotted; wings dark-banded, with small white longitudinal lines; the sides and throat bluish-black, with large white spots; the ears indistinctly marked, covered with three flat scales; base of the tail rounder above, with a slight crest on each side.

D. ornatus, the Banded-Head Dragon. Gray; head black, cross-banded; chin black, dotted; wings gray, reticulated with black, and with broad black bands at the edge; scales rhombic, of the middle of the back larger, keeled, of the sides smaller, smooth; ears covered with small equal granular scales; tail slender, compressed, with five keels above and two stronger keels beneath, rather depressed at the base, with five slight keels above.

D. maculatus, the Spotted-Winged Dragon. Gray, black-spotted; wings black-spotted; throat gray; pouch of the male elongate; scales of the back rather unequal, rhombic, keeled, of the sides rather smaller; sides with a series of large keeled scales; ears rather sunk, with unequal flat scales; tail slender, with a central keel above and five more small ones on the sides; base dilated, with five nearly equidistant equal keels above.

D. spilopterus, Weigmann's Flying-Lizard. Wings reddish near the body, with large brown spots, yellow near the edge; throat yellow, black-spotted. This may be the same as the former species, but the wings are subelliptic, and the scales do not exactly agree.

DRACONTIUM (from δράκων, a snake, because the stem is mottled like the skin of a serpent), a genus of Plants belonging to the natural order *Araceæ*. It has a cymbiform spathe, with a cylindrical spadix, quite covered with hermaphrodite flowers, the perianth 7-9-parted; 7-9-stamens, with oblong 2-celled anthers, opening obliquely by a pore at the apex, and distinct from their filaments; the ovary 2-3-celled, each cell containing one pendulous ovule; a 1-3-seeded berry; seeds without albumen.

D. polyphyllum has a tuber resembling a small cake, producing one or two leaves, with long clouded spotted petioles, resembling the skin of a snake. The spathe is large, of a purple colour, very deep inside, hooded, acute, and appearing after the leaves have withered. It smells so powerfully on first expanding, that persons have been known to faint from the stench. It is also said to excite the nerves of hearing, and even induce a state of catalepsy. It is a native of Guyana, Surinam, and other parts of equinoctial America, where it is called Labarri, and regarded as a remedy against the bite of the Labarri Snake, which its spotted leaf-stalks resemble in colour. Its use in this respect is doubtful, but its powerful action on the system might render it available in the treatment of many diseases. There is a species of *Dracontium* in India, called by Ainslie by the same name, which is a valuable remedy in asthma, and is used in hæmorrhoids.

The *Dracontium fœtidum* of Linnæus, the Skunk-Weed and Skunk Cabbage of the United States, is now referred to the genus *Symplocarpus*. It differs from *Dracontium* in its ovaries being 1-celled, and in its spathe being cucullate. It emits a powerful odour. When the tubers are dried and powdered they are used as an antispasmodic in America. It has been recommended in asthma and chronic bronchitis, also in certain cases of hysteria, dropsy, and epilepsy. (Lindley, *Flora Medica*.)

DRACUNCULUS. [DRACONINA.]

DRAGON. [DRACONINA.]

DRAGON-FLY. [LIBELLULIDÆ.]

DRAGON'S-BLOOD. [CALAMUS; DRACÆNA.]

DRAGON-TREE. [DRACÆNA.]

DRAGONET. [CALLIONYMUS.]

DRAKÆA, a genus of Plants belonging to the natural order *Orchidaceæ*. *D. elastica* has a single flower placed at the end of a slender smooth erect scape from 12 to 18 inches long, and its labellum, which is hammer-headed and placed on a long arm with a moveable elbow-joint in the middle, is stated by Mr. Drummond to resemble an insect suspended in the air and moving with every breeze.

DREELITE, a Mineral, found at Nuisière, near Beaujeu, France, occurs crystallised. Its primary form is a rhomboid, without any modifications. It presents three cleavages parallel with the faces of the primary crystal. Its colour and streak are white. Its hardness 3·25. Its lustre pearly. Its specific gravity 3·2 to 3·4. The following is an analysis by Dufrénoy:—

Sulphate of Barytes	61·731
Sulphate of Lime	12·274
Carbonate of Lime	8·050
Lime	1·521
Silica	9·712
Alumina	2·404
Water	2·308
	—— 98.

DRILL. [BABOON.]

DRIMYS. [WINTERA.]

DRIZZLE. [LOTA.]

DROMEDARY. [CAMELUS.]

DRO'MIA (Fabricius), a genus of Brachyurous Decapod *Crustacea*, placed by M. Latreille in the section of *Notopoda*, and referred by Dr. Leach to the family of *Thelxiopoda*. In the 'British Museum Catalogue' they are referred to the order *Anomoura* and the family *Dromiadæ*.

It has the following characters:—External antennæ small, inserted below the ocular peduncles; the intermediate antennæ placed below and a little within the eyes; external jaw-feet with their third joint nearly square, slightly notched at the extremity and within; claws (chelæ) great and strong; feet of the second and third pair terminated by a simple joint, and larger than those of the fourth and fifth pair, which are elevated on the back and provided with a claw, inasmuch as the last joint, which is bent and pointed, is opposed to a spine nearly of the same form, which terminates the penultimate joint; carapace oval, rounded, very convex, cut (découpée) on its anterior borders, hairy or rough (hérissée), as well as the feet and chelæ; eyes small, supported on short peduncles, rather approximated, and lodged in orbicular or cylindrical fossæ. (Desmarest.)

The species are found in the seas of warm climates. They are indolent in their motions, and live in spots where the sea is moderately deep, choosing for their habitation places where the rocks are not hidden under the sand. They are almost always found covered with a species of *Alcyonium*, or with valves of Conchifers, which they retain with their four hinder feet, and which seems to serve them as a shield against their enemies. The *Alcyonia*, which are in general of the species named *Alcyonium Domuncula*, continue even to develop and extend themselves upon their carapace, which they at last entirely conceal. In the month of July, according to M. Risso, the females come out of the state of torpor (engourdissement) in which they ordinarily are, and betake themselves to the shallows for the purpose of depositing there a great number of eggs. (Desmarest.)

Dynomene, according to Desmarest, should be placed next to *Dromia*, the former differing from the latter principally in having the feet of the fifth pair only instead of the last four elevated on the back. In general the *Dromiæ* bear a great resemblance to the Crabs, properly so called, in the general form of the body, the structure of the parts of the mouth, the position of the antennæ, &c.; but they differ from them in the elevated situation of their four posterior feet and in their manners.

Dromia hirsutissima. Carapace very convex, with six dentations on its lateral borders, and with a large sinus on each side of the front, which is nearly trilobated. Body covered with long red hairs. It is a native of the Cape of Good Hope.

Dromia hirsutissima.

The other species, of which there are specimens in the British Museum, are—*D. vulgaris*, Mediterranean; *D. Rumphii*, Japan; *D. Indica*, Indian Ocean; *D. fallax*, Mauritius; *D. verrucosipes*, Philippine Islands.

DRONE. [BEE.]

DRONTE. [DODO.]

DROPWORT, a poisonous wild Umbelliferous Plant, with fleshy-fingered roots, inhabiting ditches and wet places. It has been sometimes sold fraudulently by itinerant gardeners as a new species of dahlia. Its botanical name is *Œnanthe crocata*.

DRO'SERA (from δρόσος, dew), a genus of Plants belonging to the natural order *Droseraceæ*. It has a calyx deeply 5-cleft; 5 petals; 5 stamens; 3-5 styles, deeply bifid; a many-seeded 1-celled capsule, with 3-5 valves. The species are herbs inhabiting bogs and mossy swamps. The leaves are furnished with reddish glandular hairs, which discharge from their point a viscid acrid fluid. Insects are often caught upon these hairs, and hence they have been supposed to be irritable, and to resemble those of the *Dionæa muscipula*, Venus's Fly-Trap, a plant belonging to the same order.

D. rotundifolia, Common or Round-Leaved Sun-Dew, has orbicular spreading leaves, hairy petioles, erect peduncles, seeds with a loose chaffy coat. This plant is a native of Europe, in boggy places especially where the Sphagnum grows. It is found in Great Britain, and has many localities near London, especially Wimbledon Common and Hampstead Heath. It is employed in Italy for making the liqueur called Rossoli. It is an acrid and caustic plant, and has been supposed to cause rot in sheep. It curdles milk, and has a reputation for removing corns, bunions, and warts. When distilled with wine a stimulating spirit is procured, which was formerly much used as an excitant.

D. lunata has viscid leaves with glandular fringes, which close upon flies and other insects that happen to alight upon them. It is probable that it would yield a valuable dye. It is also believed that some of the species of *Drosera* found near Swan River, in Western Australia, might be turned to accouut in that way, for every part of *D. gigantea* stains paper of a beautiful purple colour; and when fragments are treated with ammonia they yield a clear yellow.

Two other species, *D. longifolia* and *D. Anglica*, are natives of Great Britain. The first is a common bog-plant, but the latter is only common in the British Islands in Ireland. About 40 species of this genus have been described. They have been found in boggy places in all parts of the world, except in the extremes of heat and cold. They are all singularly beautiful and worthy of cultivation. They thrive best in small pots, which should be three-parts filled with peat-earth, and Sphagnum should be planted on it; the Droseras should be planted iu the moss, and the pots placed in pans of water. The Australian and Cape of Good Hope species will require the stove. They may be propagated by seeds, but foreign plants should be brought over in cases, for which purpose those of Mr. Ward are admirably adapted.

Don, *Dichlamydeous Plants;* Loudon, *Encyclopœdia of Plants.*)

DROSERA'CEÆ, *Sun-Dews*, a natural order of Albuminous Exogenous Plants, consisting of marsh herbs whose leaves are usually covered with glands or glandular hairs, and whose flowers are arranged in circinate racemes. The calyx consists of 5 sepals: there are 5 petals; 5 or 10 hypogynous stamens; a 1-celled many-seeded capsular fruit; and minute seeds, having an embryo lying at the base of a large quantity of albumen. There are many species of the genus *Drosera*, called in England Sun-Dews, more remarkable for the singular structure of their glandular hairiness than for the beauty of their flowers. A few other little known genera are associated with it; and it is probable that *Dionœa* [DIONÆA], whose singular irritable leaves have much analogy with those of *Drosera*, also forms a part of the order, notwithstanding its indehiscent fruit and erect vernation.

De Candolle having inexactly described the embryo as lying in the axis of the albumen, the true affinities of the order were overlooked; they have since however been more correctly determined to be with *Cephalotaceœ* and *Francoaceœ* rather than with *Violaceœ, Polygalaceœ,* or *Frankeniaceœ.*

Round-Leaved Sun-Dew (*Drosera rotundifolia*).

1, a complete flower magnified; 2, a ripe capsule magnified—the seeds are seen between the valves of the capsule; 3, a seed very much magnified—the dark space in the middle is the nucleus, the remainder is a loose integument that invests the seed; 4, a section of the nucleus still more magnified—here the minute dicotyledonous embryo is seen at the base of the albumen.

DRUPA'CEÆ, the name given by some botanists to that division of Rosaceous Plants which comprehends the Peach, the Cherry, the Plum, and similar fruit-bearing trees. They are more generally called *Amygdaleæ.* [AMYGDALEÆ.]

DRUPE, a close 1-celled, 1- or 2-seeded seed-vessel, whose shell is composed of three layers; the outer membranous or leathery, the inner hard and bony, the intermediate succulent or fibrous. A peach, a cherry, a mango, are all fruits of this description. A cocoa-nut is a Compound Drupe, being composed of three consolidated carpels, two of which are abortive; and a date is a Spurious Drupe, the hard inner shell being represented by a membrane. In theory the stone or inner bony layer of the shell is equivalent to the upper side of a carpellary leaf, the external membrane to the lower surface, and the intermediate pulp or fibre to the parenchyma.

DRYANDRA, a genus of Australian Shrubs belonging to the natural order *Proteaceœ*, with hard dry evergreen serrated leaves, and compact cylindrical clusters of yellow flowers, seated upon a flat receptacle, and surrounded by a common imbricated involucre. It is in the latter respect that the genus principally differs from *Banksia*. The species are much esteemed by cultivators for their beautiful evergreen leaves. They are commonly regarded as greenhouse plants, but will in several cases survive an English winter without injury, if protected by a glass roof in winter, and planted among rock-work high above the dampness of the level of the soil.

DRYAS, a genus of Plants belonging the natural order *Rosaceœ*, and to the tribe *Dryadeœ*. It has the calyx 8-9-cleft, in one row; 8-9 petals; numerous stamens; the fruit composed of numerous small nuts, tipped with the persistent hairy styles, which are straight at the extremity, and aggregated on a dry receptacle; the seeds ascending. The species are herbs or under-shrubs, with the stipules adnate to the sides of the petioles.

D. octopetala has crenate-serrate obtuse leaves; the sepals three or four times as long as broad, more or less pointed; the base of the calyx hemispherical. The plant has white flowers, with a woody prostrate stem and simple leaves with a woolly pubescence beneath. It is a native of alpine districts of Europe, and is found iu the mountains of Scotland and Ireland, and in Yorkshire in England.

D. depressa has crenate-serrate obtuse leaves, the sepals twice as long as broad, and blunted and rounded at the end, the base of the calyx truncate and nearly flat. This species has only been found at Ben Bulben, in Sligo, and has been described by Babington in the 'Annals of Natural History.' Three other species have been described, one a native of Greenland, aud two natives of North America. They are all evergreen prostrate plauts. When cultivated they thrive best in a border of peat soil. They may be propagated by dividing the roots, or by seeds. They may be also planted in pots as other alpine plants.

(Babington, *Manual of British Botany;* Don, *Dichlamydeous Plants.*

DRYOBA'LANOPS, a genus of Plants belonging to the natural order *Dipteraceœ*, established by the younger Gærtner from specimens of the fruit found in the Banksian collection, supposed by him to belong to the tree which yielded the best cinnamon; but Mr. Colebrook, from specimens sent to Dr. Roxhurgh, which in the absence of the latter he received, ascertained that the fruit belonged to the Camphor-Tree of Sumatra, which he accordingly named *Dryobalanops camphora*, "until its identity with *D. aromatica* (of Gærtner) be established." ('Asiat. Researches,' xii.) Dr. Roxhurgh had, in his manuscript 'Flora Indica,' already named it *Shorea camphorifera.* Some botanists are of opinion that the genus is not sufficiently distinguished from *Dipterocarpus;* but Blume, tho latest author, and one who has had the fullest opportunity of examining the subject, has, in the article on *Dipterocarpeœ* in his 'Flora Javæ,' given it as his opinion that *Dryobalanops* should be kept distinct; as, like *Shorea*, it has all five instead of only two of its sepals prolonged into long foliaceous wings, while its cotyledons are unequal and rumpled.

According to Blume the existence of this camphor-yielding tree was first indicated by Grimm in 'Ephem. Nat. Cur.' Kæmpfer was so well acquainted with its distinctness that in describing the Camphor-Treo of Japan (*Laurus camphora*) he says, "that natural camphor of crystal-like appearance, which is scarce and of great value, is furnished by a tree of Borneo and Sumatra, which is not of the Laurel genus." The first notice of the treo is in the 4th volume of the 'Asiatic Researches,' where we learn that a tree named Tappanooly on the west coast of Sumatra yielded above three pounds of camphor, and at the same time nearly two gallons of camphor-oil; that the tree resembles the bay in leaves, is fond of a rich red loam tending to a blackish clay, and that it grows priucipally on the north-west coast of Sumatra, from the Line to 3° N. lat. The fullest account is given by Mr. Prince, resident of Tappanooly, who describes the tree as growing spontaneously in the forests, and as being found in abundance from the back of Ayer Bongey as far north as Bacongan, a distanco of 250 miles: he says that it may be classed among the tallest and largest trees that grow on this coast, several within daily view measuring 6 or 7 feet in diameter; but it will produce camphor when only 2½ feet in diameter. The same tree which yields the oil would produce camphor if unmolested, the oil being supposed to be the first state of the secretion, which ultimately changes into concrete camphor, as it occupies the same cavities in the trunk which the camphor afterwards fills; consequently it is found in young trees. The produce of camphor of a middling-sized treo is about eleven pounds, and of a large one double that quantity. ('Fl. Ind.' ii., p. 616.) This kind of camphor is very highly esteemed by the Chinese. It is commonly called Malay Camphor, or Camphor of Barus, from the port of Sumatra, wheuce it is mostly shipped. Its price in China is one hundred times greater than that of the common camphor of commerce. (M'Culloch, 'Com. Dict.') In the same work it is mentioned that camphor-oil being nearly as cheap as spirits of turpentine, might perhaps be profitably imported into England as a substitute for that article, or for medicinal use.

Camphor, which in many respects resembles the essential oils, has been shown by Dumas to be an oxide of hydrocarbon, indentical in composition with pure oil of turpentine: hence the term Camphene has been applied to it. But Dr. Thomson informs us that its camphor-oil differs in some respects from camphene, as he was not able to produce camphor with the same facility or in equal quantity by driving a stream of oxygen gas through highly-rectified oil of turpentine, which Dumas regards as pure camphene.

DRYOPS, the name given by Olivier to a genus of Pentamerous Coleopterous Insects of the family *Claricornes*. The type is the *Dermestes auriculatus* of Geoffroy, a little oblong gray sluggish beetle, not uncommon in Europe in the neighbourhood of watery places. Fabricius changed the name of this genus into *Parnus*. It includes 14 species, of which 7 are American and 7 European. The name *Dryops* was applied by Fabricius to another genus of *Coleoptera*, of which the *Œdemera femoralis*, a Swiss insect, was the type. Changes of this kind are highly censurable, increasing as they do the confusion arising from a complicated synonymy.

DRY ROT, a well-known disease affecting timber, and particularly the oak employed for naval purposes. When dry rot is produced by the attacks of fungi, the first sign of it consists in the appearance of small white points, from which a filamentous substance radiates parallel with the surface of the timber. This is the first stage of growth of the spores of the fungus, and the filamentous matter is their thallus or spawn. As the thallus gathers strength it insinuates its filaments into any crevice of the wood, and they, being of excessive fineness, readily pass down and between the tubes from which the wood is organised, forcing them asunder, and completely destroying the cohesion of the tissue. When the thalli of many fungi interlace, the radiating appearance can no longer be remarked; but a thick tough leathery white stratum is formed wherever there is room for its development, and from this a fresh supply of the destructive filamentous thallus is emitted with such constantly increasing rapidity and force, that the total ruin of timber speedily ensues where circumstances are favourable for the growth of the fungi.

It is generally stated that dry rot consists of the thallus of *Merulius lacrymans*, or *Polyporus destructor*, two highly-organised fungi, whose fructification is sometimes found upon rotten timber. But it is a great mistake to suppose that dry rot belongs exclusively to those two species, or that they are even the common origin of it: on the contrary, there is reason to believe that any of the fungi that are commonly found upon decaying trees in woods are capable of producing dry rot, and it is quite certain that one of the most rapidly-spreading and dangerous kinds is caused by the ravages of different species of *Sporotrichum*. The latter throw up from their thallus whole forests of microscopic branches loaded with reproductive spores, of such excessive smallness that they may insinuate themselves into the most minute crevices or flaws even in the sides of the tubes of which timber consists, and they are infinitely more dangerous than *Merulii* or *Polypori*, which seldom fructify.

The circumstances that are most favourable to the development of the dry rot fungi are damp, unventilated situations, and a subacid state of the wood. The latter condition, especially in oak, is easily produced by a slight fermentation of the sap which remains in the timber, especially if the latter has not been well-seasoned before being employed. It has been proved experimentally that fluids which, in their ordinary state, will not produce fungi, generate them abundantly if ever so slightly acidulated. Dutrochet found that distilled water holding in solution a small quantity of white of egg will not generate fungi in a twelvemonth, but upon the addition of the minutest quantity of nitric, sulphuric, muriatic, phosphoric, oxalic, or acetic acid, it generated them in eight days' time in abundance. Alkalescent infusions possess the same property. This observer states that the only poisons which will prevent the appearance of fungi are the oxides or salts of mercury. A solution of fish-glue yields fungi rapidly and in great abundance; but a small quantity of red precipitate or corrosive sublimate destroys this power entirely. It is moreover an important fact that no other mineral preparation has any such properties. Dutrochet ascertained that other metallic oxides acted differently. Oxides of lead and tin hastened the development of fungi; those of iron, antimony, and zinc, were inert; and oxides of copper, nickel, and cobalt, although they retarded the appearance of fungi, yet did not prevent their growth in the end. These facts are confirmed by the experience of the use of Kyan's process for preparing timber, which consists in submitting the wood to the action of corrosive sublimate. Immersing the wood in chloride of zinc also prevents the attack of fungi, and also submitting it to the action of the vapour of creasote.

Dry rot also occurs in animals. Specimens of hymenopterous insects resembling wasps have been brought from the West Indies, with a fungus allied to *Sphæria militaris* growing from between their anterior coxæ, and it is positively asserted by travellers that the insects fly about while burdened with the plant. Upon opening the bodies of the wasps they are found filled with the thallus of the fungus up to the orbits of the eyes and the points of the tarsi; the whole of the intestines being obliterated. In such cases it is to be supposed that the thallus of the *Sphæria* first kills the wasp by compressing and drying up the body, and then, continuing to grow, occupies the whole of the cavity of the shell of the insect. A more common instance of animal dry rot is the disease in silkworms called La Muscadine. Silkworms of all ages are occasionally liable to become sickly and to die, soon after death becoming stiff, and acquiring such a degree of firmness as to be readily broken. They then throw out from their surface a sort of white efflorescence, which is the fructification of the fungus called *Botrytis Bassiana*, their inside being filled by the thallus of the same plant. If some healthy caterpillars are placed beneath a bell-glass, along with a small portion of worm killed by the *Botrytis*, they soon catch the disease, exhibit the same symptoms as those already mentioned, and eventually perish; having, no doubt, been infected either by rubbing themselves against the dead worm, or, which is more probable, having received upon their skins the infinitely minute seeds dispersed by the *Botrytis*. If healthy crysalids are inoculated by the introduction below their shell of a little of the *Botrytis* matter upon the point of a needle, they also sicken and die.

In these cases effects are produced upon insects similar to those upon timber; that is to say, vitality in the one case and cohesion in the other is destroyed by the growth of the thallus of certain fungi, which spread with great and irresistible rapidity, and fructify where occasion offers.

For other instances of the agency of fungi in producing the destruction of vegetable and animal tissues, see FUNGI.

DSHIKKETEI (*Zikketei*). Cuvier writes the word *Dziggu̇etai*, and Buffon *Dzigithai*, the native name for the *Eques Hemionus* of Pallas, *Asinus Hemionus* of Gray. [EQUIDÆ.]

DUCK-BILL. [ORNITHORHYNCHUS.]

DUCKS, *Duck Family*, *Anatidæ*, a family of Birds belonging to the order *Natatores*, *Anseres*, or *Palmipedes*. They are all Aquatic Birds, and have webbed feet.

Willughby distinguishes the whole-footed birds with shorter legs into such as want the back toe, and such as have it; these latter into such as have all four toes webbed together, and such as have the back toe loose or separate from the rest; these latter again he subdivides "into narrow-billed and broad-billed; the narrow-billed have their bills either hooked at the end, or straighter and sharp-pointed. The hook-billed have their bills either even or toothed on the sides. Those that have straighter and sharp-pointed bills are either short-winged and divers, called Douckers and Loons, or long-winged and much upon the wing, called Gulls. The broad-billed are divided into the Goose kind and the Duck kind. The Duck kind are either Sea-Ducks or Pond-Ducks." He afterwards, in his section on the Broad-Billed Birds of the Duck kind, thus treats (chap. i.) of the Duck in general:—"The Duck kind have shorter necks and larger feet in proportion to their bodies than Geese: lesser bodies. Howbeit, the biggest in this kind do equal if not exceed the least in that. They have shorter legs than Geese, and situate more backward, so that they go waddling; a broader and flatter back, and so a more compressed body; and lastly, a broader and flatter bill. Their tongue is pectinated or toothed on each side, which is common to them with Geese.

"These are of two sorts, either wild or tame. The wild again are of two sorts—1. Sea-Ducks, which feed mostwhat in salt water, dive much in feeding, have a broader bill (especially the upper part) and bending upwards (to work in the slem), a large hind toe, and thin (likely for a rudder), a long train, not sharp-pointed. 2. Pond-Ducks, which haunt plashes, have a straight and narrower bill, a very little hind toe, a sharp-pointed train, white belly, speckled feathers, black with glittering green in the middle wing, with a white transverse line on either side. For this distinction of Sea-Ducks and Pond-Ducks we are beholden to Mr. Johnson."

Ray divides his 'Palmipedes latirostræ minores, seu Anatinum genus' into *Anates marinæ* and *A. fluviatiles, aquas dulces præcipuè frequentantes*, *A. exoticæ Brasilienses*, and *A. domesticæ*. Brisson's 24th order, consisting of birds with four toes, the three anterior being joined together by membranes, the posterior separated, and with a dentilated bill, includes the genera Harle, Oie, and Canard (Goosanders, Geese, and Ducks). This order is placed between that order of birds the arrangement and connection of whose toes is similar to the modifications of those parts in the 24th order, but which have a bill without dentilations (Puffins, Petrels, Gulls, Terns, &c.), and the 25th order, which is distinguished by the birds arranged under it having all the toes joined by membranes (the Darters, Boobies, Pelicans, &c.).

Linnæus, under his third class of birds, *Anseres*, included the genera *Anas*, *Mergus*, *Alca*, *Procellaria*, *Diomedea*, *Pelecanus*, *Plotus*, *Phäeton*, *Colymbus*, *Larus*, *Sterna*, and *Rynchops*; in short, all those birds which possess a rather blunt bill, covered with an epidermis, gibbous at the base, dilated at the apex, and with denticulated fauces, a fleshy tongue, and palmated natatorial feet. The class stands between the *Picæ* and the *Grallæ*. The genus *Anas* comprehends the Swans, the Geese, and all the Ducks in the general acceptation of the term.

Pennant's 24th genus, Duck, is placed between the genus Merganser (Goosander) and the genus Corvorant; and it comprehends the Swans, the Geese, and all the Ducks, like the Linnæan genus *Anas*.

Latham, who divides the birds into terrestrial and aquatic, makes his 9th order, *Palmipedes*, consist of two great sections—the first consisting of those with long feet—Avoset and Flamingo for example —and the second of those with short feet, comprehending all the short-limbed aquatic birds with webbed feet.

Lacépède's second sub-class of birds consists of those the lower part of whose legs is denuded of feathers, or have many toes united by a membrane. The first division of this sub-class consists of those which have three anterior toes and one posterior toe, or none. The first sub-division consists of the Water-Birds (Oiseaux d'Eau); and the 23rd order of Lacépède comprehends those genera which have a dentilated bill, namely, Canard, *Anas;* Harle, *Mergus;* Priom, *Prion.* The genus *Anas* consists of all the birds which combine with the characters above stated a wide bill, rounded at its extremity, and furnished around the mandibles with small vertical laminæ.

Cuvier's 6th and last order is the Palmipèdes; and the last family of that order, Lamellirostres, contains the great genus Des Canards (*Anas*, Linn.). Cuvier remarks that they are commonly divided into three sub-genera, the limits of each of which are not very precise, namely, the Swans (*Cygnus*, Meyer), the Geese (*Anser*, Brisson), and the Ducks, in the general acceptation of the term (*Anas*, Meyer). The other great genus of Cuvier's Lamellirostres is *Mergus*, Linn.

Cuvier separates the genus *Anas* into two divisions. The first consists of those whose hind toe is bordered by a membrane, whose head is larger and neck shorter in comparison, and which have also the feet placed more backwards, the wings smaller, the tail stiffer, the tarsi more compressed, the toes longer, and the webs more entire. They walk badly, live more exclusively upon fishes and insects, and dive more frequently. (*Platypus*, Brehm; *Hydrobates*, Temminck; *Fuligula*, Carlo Bonaparte). This first division contains the following sub-divisions: Les Macreuses (*Oidemia*, Fleming, *Anas nigra*, *A. fusca*, Linn., &c.); Les Garrots (*Clangula*, Leach; *A glacialis*, *A. histrionica*, Linn., &c.); Les Eiders (Eider-Ducks, *Somateria*, Leach, *A. mollissima*, Linn.); Les Millonins (*Fuligula*, Leach).

The second division is formed by those Ducks which are without the membranous border on the hind toe, and have the head smaller, the feet less, the neck longer, the bill more equal, and the body less clumsy (épais). These walk better, and seek aquatic plants and their seeds as much as fish and other animals. It would seem, adds Cuvier, that the swellings of their tracheæ are of a homogeneous bony and cartilaginous substance. It is to this division that Carlo Lucien Bonaparte, prince of Canino, confines the appellation *Anas*. The following are the sub-divisions:—Les Souchets, *Rhynchaspis*, Leach; Les Tadornes, *A. tadorna*, Linn., &c.; those which have naked parts about the head, and often a boss or convexity on the base of the bill, as the Muscovy Duck; those with a pointed tail, *A. acuta*, Linn., for instance; those whose male has curled feathers in the tail, as the Wild Duck, *Boschas*, *A. Boschas*, Linn.; those which have a tuft on the head, and the bill rather narrower anteriorly, as the Summer-Duck, *Anas sponsa*, Linn., and the Mandarin-Duck, *A. galericulata*, Linn., *Dendronessa*, Swainson; those which have the bills of ducks, but legs even longer than those of the geese, and which perch and nestle in trees, *A. arborea*, Linn., &c. One of these Cuvier observes has the feet only semipalmated, *A. semipalmata*, Latham. Finally, Cuvier goes on to state that we possess, especially in winter, among those which have nothing remarkable about them, *A. strepera*, Linn., *A. Penelope*, Linn.; and many small species which are distinguished by the name of Sarcelles, Teals, *A. querquedula*, Linn., the Common Teal, for example.

Mr. Vigors, in his paper 'On the Natural Affinities that connect the Orders and Families of Birds,' read before the Linnæan Society, December 3, 1823 ('Trans. Linn. Soc.' vol. xiv. p. 395), makes his 5th order *Natatores* consist of the families stated in the article COLYMBIDÆ. The family of *Anatidæ* (Leach), to which he leads his readers from the preceding order (*Grallatores*) by means of the connection between the *Rallidæ* and *Cereopsis*, consists, he observes, of the groups which compose the Linnæan genera *Anas* and *Mergus*, and with respect to the affinities that prevail throughout the families of the order, he remarks that the more extensive subdivisions of the Linnæan *Anas* which have been acknowledged by all systematic writers, either under the name of sections or genera, display in conjunction with *Mergus* a regular series of affinities conformable to the principles advanced by him as regulating the order. The first group, he observes, upon which we enter in this first aberrant family of the order, has been formed into a sectional subdivision by M. Temminck, under the denomination of Les Oies; and with equal signification and more effect has been made into a genus, under the title of *Anser*, by M. Illiger, who therein followed the older naturalists that preceded Linnæus. These birds retain much of the manners of the Waders. They are endowed with considerable facility in walking, are found to swim but seldom, and do not dive at all. In these characters, as well as in other particulars, they correspond with the family of *Laridæ*, which meets them at the other extremity of the circle of *Natatores*.

To this division succeeds *Cereopsis*, Latham [CEREOPSIS], strongly allied to the preceding *Anseres* by its general structure, but still more typical in the family in consequence of the length and nakedness of the tarsi above the knee: characters which indicate a greater power of walking, and a greater deficiency in swimming. It joins the third division, or the genuine *Anates*, by means of a group of which *Anas arborea*, Linn., is the representative. This third and most typical group of the family, which accords with M. Temminck's first section of 'Canards proprement dits,' still approaches more closely to the land birds than the birds which follow: the species swim with ease, and even dive, but the latter faculty they seldom exercise unless when pursued. Their food is also less exclusively marine than that of the succeeding groups, being composed of vegetables, grains, and insects, in addition to fish. This division, consisting of many prominent forms, of which *Anas arborea* before mentioned, *A. tadorna*, *Boschas*, *clypeata*, *Penelope*, and *querquedula* may be considered types, is distinguished from the remainder of the 'Canards proprements dits' of M. Temminck by the hind toe being entire, or free from the lobated membrane which is attached to the hind toe of these last. Mr. Vigors proceeds to state that this character of the lobated membrane, which is of considerable importance as pointing out the approach of the birds in which it is found to the more typical oceanic families, prevails in all the remaining groups of the present family. It is strongly conspicuous in *Mergus*, Linn., the next division that appears to follow: and we consequently find that the species of that genus carry the powers of swimming and diving to the greatest extent, making use of their wings also in their progress through the water; and at the same time exhibiting a constrained and embarrassed mode of walking, in consequence of the backward position of the legs. It thus forms the passage to the succeeding family of *Colymbidæ*. In the shape of its bill, which is slender and partially compressed, it exhibits a distinct form in its own family: but still, by means of the bill of an intervening species, *M. albellus*, Linn., which is intermediate in its breadth and depression, it preserves its connection with the *Anates*. "We hence," continues Mr. Vigors, "pass to the 5th and last group of the family which, with the bill of the *Anates*, retains most of the characters conspicuous in *Mergus*. The forms most prominent in it, represented by the different Linnæan species *Anas ferina*, *clangula*, *histrionica*, and *mollissima*, possess a strongly lobated hind toe; they frequent the ocean for the most part, where they dive with the greatest facility and for a length of time; and they live chiefly on marine animals. Their legs are also thrown behind the equilibrium of their body; and thus also they evince their contiguity to the typical *Natatores*. By means of the group which contains *A. mollissima*, our well-known Eider-Duck and its congeners, where the bill, with an elevated protuberance at the base, approaches that of the *Anas olor*, Linn., we find ourselves brought round to the *Cygnus* of the present day, which forms part of the first division. That genus in like manner deviates partially from the conterminous genus *Anser*, in its legs being thrown more backward, and its consequently greater awkwardness in walking. Here then the affinities are evident which thus establish the perfect return of the series of the *Anatidæ* into itself. Before we leave the family I must indulge myself in observing a most conspicuous peculiarity which marks the series of affinities among these groups. The long and slender neck observable in the *Grallatores* is preserved in such groups of the *Anatidæ* as are most conterminous to that order, such as *Cygnus*, *Anser*, *Bernicla*, and *Cereopsis*, until it is superseded by the short necks of the more Oceanic *Anatidæ*, which exhibit all the expansion and capaciousness of throat observable in the typical *Natatores*."

In the 'Zoological Journal' (vol. ii.), Mr. Vigors gives a disposition of the *Anatidæ*, which exhibits a slight deviation from that drawn out in his paper referred to above. The following is the arrangement.

ORDO V. *Natatores*, Ill. (*Anseres*, Linn.)

1. Family *Anatidæ*, Leach. (Gen. *Anas Mergus*, Linn.)

*

Sub-Family *Anserina*.

Anser, Briss.; *Bernicla*, Steph.; *Cheniscus*, Brookes's M.M.S.; *Chenoplex*, Steph.; *Plectropterus*, Leach.

* *

Sub-Family *Cereopsina*.

Cereopsis, Lath.

* * *

Sub-Family *Anatina*.

Tadorna, Leach; *Cairina*, Flem.; *Anas*, Auct.; *Dafila*, Leach; *Mareca*, Steph.; *Querquedula*, Ray; *Rhynchaspis*, Leach.

* * * *

Sub-Family ?

Clangula, Flem.; *Harelda*, Ray; *Mergus*, Linn. (*Merganser*, Briss.); *Somateria*, Leach; *Oidemia*, Flem.; *Biziura*, Leach.

* * * * *

Sub-Family *Cygnina*.

Cygnus, Meyer.

The other four families are—2. *Colymbidæ*, Leach; 3. *Alcadæ;* 4. *Pelecanidæ*, Leach; 5. *Laridæ*, Leach.

Mr. Yarrell in his 'Observations on the Tracheæ of Birds' ('Linn. Trans.' vol. xv.), after speaking of the form of the windpipe, among others of the Black Swan of Australia, *Anas atrata*, Linn., and of that of the Semi-palmated Goose, *Anas semipalmata* of Dr. Latham, goes on to remark that the different species of geese considered British present nothing remarkable in their tracheæ, the Egyptian Goose alone excepted, the male of which species possesses a bony enlargement at the bottom of its windpipe; and he notices the circumstance that systematic authors seem to agree in placing this bird at the bottom of the list of the geese, where it appears to occupy its proper situation; and observes that, combining as it does some of the characters common to those birds and the true ducks, it becomes a very natural link between them, and he closes his interesting paper with an arrangement of the British species of the latter portion of this family founded upon internal as well as external conformation.

"The first division of true ducks," says Mr. Yarrell, "will contain the Shieldduck, Muscovy Duck, Wild Duck, Gadwall, Shoveler, Pintail, Wigeon, Bimaculated Duck, Garganey, and Teal, all of which will be found to have the following characters in common. Externally they exhibit considerable length of neck; the wings are also long, reaching to the end of the tail; the tarsi somewhat round; the hind toe free or having no pendent lobe. In habits they may be stated generally as frequenting fresh water, but passing much of their time on land, feeding in ditches and about the shallow edges of pools on aquatic plants, insects, worms, and occasionally fish, taking their food at or near the surface; possessing great powers of flight, but seldom diving unless pursued. Of their internal soft parts, the stomach is in the greatest degree muscular, forming a true gizzard; the intestines long, the cæcal appendages from 6 to 9 inches in length in the larger birds, and decreasing only in proportion to the size of the species. Of the bones it may be observed that the ribs are short, extending but little beyond the line of the posterior edge of the sternum; the keel of the breast-bone deep, affording great extent of surface for the insertion of large and powerful pectoral muscles; the enlargement at the bottom of the trachea in all of them is of bone only. The wild duck may be considered the type of this division."

Mr. Yarrell then proceeds to state that the Eider-Duck, King-Duck, Velvet-Duck, and Scoter, possessing some characters common to the preceding class, and others belonging to that next in succession, appear to supply the link between these two divisions; and he regrets that the extreme rarity of the last-named species had prevented him from making any examination beyond that afforded by the external parts of preserved specimens in collections.

The next division of true ducks, according to Mr. Yarrell, includes in the following order the Red-Crested, the Pochard, Ferruginous, Scaup, Tufted, Harlequin, Long-Tailed, and Golden-Eye; and their general distinctions, he remarks, internal as well as external, compared with those of the birds of the first division, will be found of an opposite character. Externally, they exhibit the neck and wings short, the latter only reaching to the origin of the tail-feathers; the tarsi short and compressed; the hind toe lobated, and an extended web to the inner toe. They frequent the sea, or the deep parts of the fresh-water lakes, and have been called Oceanic Ducks; they are seldom seen on land; their walk is embarrassed from the backward position of their legs, but they dive constantly and with great facility, taking their prey at various depths below the surface; their food consists of finned and shell-fish, and marine insects, but of little or no vegetable production; and their powers of flight are moderate. With regard to their soft parts, Mr. Yarrell states that the œsophagus is capable of great dilatation, that the stomach is a muscular gizzard, but that the internal cavity increases in size; the stomachs of the Long-Tailed Duck and Golden-Eye most resembling the stomach of the Mergansers, whilst the intestines and cæcal appendages are shorter, the latter diminishing from 6 inches in the first to 4½ inches in the Tufted Duck, 3 inches in the Long-Tailed, and but 2 inches in the Golden-Eye. The ribs of the birds of this division, according to the same author, are elongated; the keel of the breast-bone gradually decreases in depth; the position of the wings is more forward, and the legs are placed farther back. The tracheæ of these ducks, moreover, are particularly distinguished from those of the others by the enlargement at the bottom of the tube being covered with a delicate membrane, supported by slender portions of bone; the trachea of the Red-Crested Duck is an example of this form, and Mr. Yarrell is of opinion that it may be considered the type of this division.

"As the Egyptian Goose," continues Mr. Yarrell, "has in this arrangement been considered the link between the geese and the first division of the true ducks, from its possessing, with the characters of the former, the bony enlargement of the trachea common to the latter; and the Velvet-Duck, for similar reasons, supplying the link between the two divisions of true ducks, possessing, among other characters, an altered form of the bony enlargement of the trachea of the one, with the lobated toe of the other; so the Golden-Eye, the last of the series, appears to complete the arrangement, by exhibiting some of the characters found in the Mergansers, which are next in succession."

The first point of similarity is found by Mr. Yarrell in the elongated feathers of the top of the head, forming a crest; they agree also, he adds, in the shape of the sternum, and a particular extension of its posterior edge, becoming an ensiform process; and this extension of the edge of the breast-bone prevails in the genera *Colymbus*, *Alca*, and *Uria*: and, with the elongation of the ribs observable in all good salt-water divers, seems intended as a protection to the important viscera of the abdomen, and enables them to resist pressure when below the surface. The Golden-Eye, in the opinion of the same author, is also intermediate in its stomach, intestines, and cæcal appendages, the latter being only 2 inches in length. In the Goosander indeed Mr. Yarrell found that these appendages reached 3 inches; but, as he well observes, the size of the bird being considered, they are reduced on a comparative estimate to less than 2 inches; in the Red-Breasted Merganser he found them to measure but 1 inch, and the Swan he states is without any. In the form of its trachea, the Golden-Eye, it seems, more closely resembles the Mergansers than that of any other duck, by the enlargement in the tube, and in the shape of the labyrinth. "Thus the whole of the numerous species of the *Anatidæ* appear to descend to the more perfect water-birds by gradations, but with well-marked divisions throughout."

Prince C. L. Bonaparte, in his 'Tabella Analitica dei Generi,' ('Specchio Comparativo,' 1827) makes his Ordine *Anseres* consist of five families: the *Longipennes*, the *Lamellosodentati*, the *Steganopodes*, the *Lobipedes*, and the *Pygopodes*. His Famiglia *Lamellosodentati* comprises the two genera *Anas* and *Mergus*, the first of which he characterises thus—"Becco depresso, ottuso, con denti lamelliformi;" and it comprehends the swans, geese, and ducks in the large meaning of the term.

M. Lesson, in his 'Manual' (1828), makes the *Anatidæ* (*Lamellirostres* of Cuvier) the fifth and last family of the sixth order, Les Palmipèdes, *Natatores* of Illiger and Vieillot. Under the *Anatidæ* he arranges the genera *Cygnus*, Meyer; *Anser*, Brisson, with its subgenera; *Cereopsis*, Latham; *Anas*, Linnæus; and *Mergus*, Linnæus. The genus *Anas* he divides into two sections.

Mr. Swainson, in his paper 'On those Birds which exhibit the Typical Perfection of the Family of Anatidæ' ('Journal of the Royal Institution of Great Britain'), remarks, that the most superficial observer, on looking to the family of the *Anatidæ*, or Ducks, under which he will include the geese and swans, must be struck by the remarkable shape and structure of the bill, totally different from that of all other birds. This, in fact, he adds, is the only group in the aquatic order wherein the bill is very considerably dilated in its breadth, and of a texture unusually soft. In addition to these, a third and a very important character is discerned; the cutting margins of the bill are provided with numerous transverse lamellar plaits, so much developed in some species as to project beyond the bill, thus assuming an analogy to the teeth of quadrupeds. This analogy however is more imaginary than real, since these appendages are destined for a very different purpose. The feet, although in general short, are adapted to more than one purpose, since they are not only used for swimming and diving, but for walking.

Mr. Swainson proceeds to state that "the gulls feed indiscriminately upon marine animals, whether living or dead: they are the purifiers of the waters, as the vultures are of the land. The pelicans and the penguins derive their support from those large fish which the more feeble gulls can neither capture nor swallow, while the terns skim the ocean in search of small fish which rise to the surface. But the inconceivable multitudes of minute animals which swarm, as voyagers assert, in the northern seas, and the equally numerous profusion inhabiting the sides of rivers and fresh waters, would be without any effectual check upon their increase, but for a family of birds destined more particularly for that purpose. In the structure accordingly of the ducks we see all these qualifications in the utmost perfection. By means of their broad bill, as they feed upon very small and soft substances, they capture at one effort considerable numbers. Strength of substance in this member is unnecessary: the bill is therefore comparatively weak, but great breadth is obviously essential to the nature of their food. As these small insects also which constitute the chief food of the *Anatidæ* live principally beneath the surface of the mud, it is clear that the bill should be so formed that the bird should have the power of separating its nourishment from that which would be detrimental to the stomach. The use of the laminæ thus becomes apparent: the offensive matter is ejected between their interstices, which however are not sufficiently wide to admit the passage of the insect food at the same time. The mouthful of stuff brought from the bottom is, as it were, sifted most effectually by this curiously-shaped bill; the refuse is expelled, but the food is retained. It is probable also that the tongue is materially employed on this process; for unlike that of all other birds, it is remarkably large, thick, and fleshy. From being so highly developed, it must be endowed with an unusual degree of sensation; and indeed, a very exquisite sense of taste must belong to any animal which has to separate its food from extraneous substances, without deriving any assistance in the process from its powers of sight; against this deficiency nature has wisely provided, by heightening and increasing the senses of taste and touch."

In the physiological series of the Museum of the Royal College of Surgeons in London—Gallery (317)—is the head of a Muscovy Duck, *Anas Moschata*, Linn., showing the serrated character of the margins of the mandibles, and the peculiar tuberosity at the base of the beak; and a good opportunity of studying the structure of the tongue is afforded by the preparations numbered 1468 and 1469. In the former are seen the bones of the tongue and upper larynx of a swan (*Cygnus olor*, Brisson). The glosso-hyal part is broader and longer than it is in the land-birds, corresponding to the greater development of the tongue in the lamellirostral swimming birds, but is devoid of the cartilaginous processes to its posterior angles in the gallinaceous tribe. In the larynx may be distinguished the thyroid, cricoid, and arytenoid cartilages, which in most birds are more or less bony: the thyroid cartilage is the largest, and covers the whole anterior part of the larynx like a shield: the posterior broad part of the cricoid (which is not in this class developed in the form of a ring) supports as usual the arytenoid cartilages which form the rima glottidis; they have muscles for opening and closing that fissure, and the larynx is defended by the latter action alone from the entrance of food or fluid. No. 1469 exhibits the lower jaw, with the tongue and larynx of the same bird, and it will be seen that the tongue is so far developed as to correspond with the form of the lower jaw. It is a thick and fleshy organ, beset with four longitudinal rows of horny tooth-like processes, two at the sides, and two on the dorsum, separated by a mesial furrow: the base of the tongue is also armed with retroverted spines arranged in a chevron figure; similar spines again occur behind the larynx. The apo-hyal and cerato-hyal bones are dissected on one side, but covered by the muscles on the other.

Mr. Swainson, in the paper above quoted, divides the genus *Anas* (which he thus characterises—"bill longer than the head, depressed nearly its whole length; the base not enlarged, the tip very obtuse; the laminæ of the upper mandible generally projecting; hinder toe not dilated, short; claws short, thick") into the following sub-genera:—

1. Typical Group.	Sub-Genera.
Bill spatulate, simple; laminæ considerably projecting	*Anas*, Linn.
2. Sub-Typical Group.	
Bill spatulate, furnished with a lobed membrane; laminæ considerably projecting . .	*Malacorhynchus*, Sw.
3. Aberrant Group.	
Bill of equal breadth; projecting laminæ short, slender, acute, crowded	*Chauliodus*, Sw.
Bill more cylindrical, lengthened; tail long .	*Dafila*, Leach.
Bill depressed, of equal breadth; laminæ distant, obtuse, and generally concealed; tail short	*Boschas*, Antiq.

The type of the genus *Anas* is considered by Mr. Swainson to be the Shoveler Duck; and he thus speaks of the arrangement above set forth:—"In regard to the tabular disposition of the five sub-genera, or types of form, it will be expected that I should say a few words, since it is at variance with the mode of exhibiting circular affinities adopted by that distinguished writer who first detected this arrangement. On this point I must refer the reader to the ornithological volume of the 'Northern Zoology,' now about to appear, where he will find our peculiar views explained and illustrated. I have, indeed, chosen to enumerate, in both instances, the subordinate divisions of the aberrant group, but they are always viewed by me as forming a distinct circle of their own, the primary divisions of every natural group being considered as three and not five. In the present instance, the three sub-genera of *Chauliodus*, *Dafila*, and *Boschas*, possess one common character, in not having the bill conspicuously dilated at its extremity; while their circular succession can hardly be questioned, when we find the greatest modern reformers * leave the Gadwall and the Mallard in the same group; these writers having overlooked the modifications of the laminæ, and passed over the difference in the habits of these birds, as not bearing upon the question. The theory that the mallard is the typical representation of this family has now, I trust, been thoroughly investigated, and demonstrated to be erroneous; † nor can I consider the two circular arrangements ‡ that have been made of the whole family, each apparently perfect, but essentially different, in any other light. They appear to me to be the result of abstract theory, and of a theory misapplied. On the other hand, I deem it but justice to the great merits of another ornithologist of our own country to acknowledge the assistance I have derived from his highly valuable paper on the trachæa (tracheæ) of birds, and, at the same time, to declare that if there is any truth in his own inferences, drawn from internal structure, or in mine, resulting from attention to external form and habits, he has himself marked out the true circle of the *Anatidæ*, so far as the British species are concerned, totally unconscious of having done so. There is, and there cannot be, but one plan of creation. In our efforts to develop this plan we must, as Mr. Yarrell justly observes, 'combine ascertained habits, external characters, and anatomical structure;' and in proportion as we can do this so may we assume that our arrangement is 'natural.'"

Sir John Richardson ('Fauna Boreali-Americana') observes that the *Anatidæ* are "of great importance in the Fur Countries, as they furnish at certain seasons in the year, in many extensive districts, almost the only article of food that can be procured. The arrival of the water-fowl marks the commencement of spring, and diffuses as much joy among the wandering hunters of the arctic regions as the harvest or vintage excites in more genial climes. The period of their migration southward again, in large flocks at the close of summer, is another season of plenty, bountifully granted to the natives, and fitting them for encountering the rigour and privations of a northern winter. The *Anatidæ* have therefore very naturally been observed more attentively than any other family of birds, both by the Indians and white residents of the Fur Countries; and as they form the bulk of the specimens that have been transmitted to England, they are also better known to ornithologists."

* Dr. Leach, Dr. Fleming, Stevens (Stephens ?), Vigors.

† For the demonstration, see the paper quoted.

‡ Linn. 'Trans.' xiv. p. 499; 'Zool. Jour.' iii. (ii.) p. 401.

We shall now proceed to speak of the genera and species of this family under the sub-families—*Phœnicoptinæ*, the Flamingoes; *Anserinæ*, the Geese; *Anatinæ*, the True Ducks; *Fuligulinæ*, the Sea-Ducks; and *Merganinæ*, the Mergansers. The Swans are described in the article CYGNINÆ.

The *Phœnicoptinæ* include a single genus, *Phœnicopterus*, Flamingo of the English, Flammant of the French, *Phœnicopterus* of the ancients and moderns. The position of these birds has been a matter of considerable doubt. The form approaches in some points to *Recurvirostra* [AVOSET] and *Platalea* (the Spoonbills), and in others comes nearest to the *Anserinæ* (Geese). C. L. Bonaparte places it in a family, *Hygrobatæ*, with *Recurvirostra* and *Platalea*, between his family *Pinnatipedes* (Phalaropes, &c.) on the one side and the *Anserinæ* on the other. Mr. Vigors, in his paper 'On the Natural Affinities that connect the Orders and Families of Birds,' thus marks its position among the *Grallatores*:—"Intermediate between *Ardea* and *Ciconia* appear those forms which display so remarkable a dilatation of the bill, the *Cancroma* [BOAT-BILL] *Phœnicopterus*, and *Platalea* of Linnæus. The two last of these groups are equally distinguished by a greater development of the membrane that connects the toes than is observable in the other Waders which join them on each side; and in one of them, the *Phœnicopterus*, this character is carried so far to the extreme as to have occasioned some systematists to place the birds of this genus among the *Natatores* (Swimmers). But the whole of the family have a membrane, more or less extensive, at the base of the toes; and if we compare the feet of the common *Ciconia alba* (Stork), of the *Platalea*, and the *Phœnicopterus*, together, we shall see a gradual increase of this membrane in extent, until it reaches the extreme in the latter genus." Mr. Swainson places the Flamingo among the Swimmers. In his 'Natural History and Classification of Birds' (1836), he says, "The Flamingo, which has the longest legs in the Natatorial order, is so good a walker that it only swims occasionally."

The genus *Phœnicopterus* has the bill strong, higher than it is large, dentilated, conical towards the point, naked at the base; upper mandible suddenly bent, curved at its point on the lower mandible, which is larger than the upper. Nostrils longitudinal in the middle of the bill, pierced through and through near the dome of the upper arête, covered beneath by a membrane. Feet very long; three toes in front, hind toe very short, articulated high up on the tarsus; anterior toes united to the nails by a lunated membrane (membrane découpée). Nails short, flat. Wings moderate; first and second quills longest.

Temminck, whose generic characters we have given, says that the Flamingoes live on the sea-beach or in marshes formed by salt lakes, where their food consists of testaceous mollusks, marine insects (crustaceans?), and the spawn of fish, which they collect by plunging their long neck into the water and turning the head upside down, so as to employ with greater advantage the bend of their bill. They join in large troops and live in societies. Their nest is made in the marshes, and consists of earth piled up, and upon this nest the birds sit astride, because their length of limb hinders them from incubating otherwise. Whether they are reposing or fishing, sentinels are appointed which keep a sort of guard. If anything alarms the védette he utters a trumpeting kind of cry, and the whole flock follow him into the air. They rarely take their repose in any other than open places; and it is asserted that their sense of smelling is so acute that they scent from afar the hunter and fire-arms. Their moult appears to be simple and ordinary, but the young birds differ much from their parents. The red or rosy plumage which covers the adult shows itself gradually, after many moults and a period of about four years. The females are less than the males, and the colours of the former want the purity which distinguish the latter. The young, at their departure from the nest, are white. The body of the Flamingo has hardly a greater covering of down than that of the other Waders, the Avosets alone excepted; and accordingly they do not swim habitually, like the latter birds, when they wish to go from one bank to another in deep water. The palmated feet of the Flamingoes appear to be given them to enable them to sustain themselves on the slimy bottoms of rivers and creeks into which they wade as far as their long legs will allow them, and to walk thereon. As they fly in flocks they make an angle like the Geese. In walking they often apply their upper mandible to the ground, and lean on it as a point of support.

M. Temminck positively asserts that the Flamingo of Europe and that spread over the warm climates of America are different. He states that he knows the plumage of the American Flamingo from its youth to its adult state, and declares that they are all different from the various states of the Flamingo of the ancient continent. The orange-red which pervades the whole of the plumage of the American species when it has arrived at its complete state of development is sufficient to distinguish that bird from our European Flamingo, which is of a rose-colour with wings of purple-red. The young of the latter (*Phœnicopterus Antiquorum*) has the plumage whitish, covered with brown streaks (mèches), very distinctly marked and long, principally on the greater wing-coverts; the American Flamingo (*Phœnicopterus ruber*) is covered in its youth with a dull whitish-gray plumage. Three species are given by M. Temminck:—

1. *P. Antiquorum*, the Flamingo of the ancients; Flammant Phœnicoptère of Buffon; the Flammant and Flamingo of old authors. Locality, south of Europe, Africa, and part of Asia.

2. *P. ruber*, the American Flamingo; Red Flamingo of Wilson! Locality, South America and part of North America.

3. *P. minor*, Flammant Pygmée, previously described by Vieillot as *P. parvus*. Locality, South Africa.

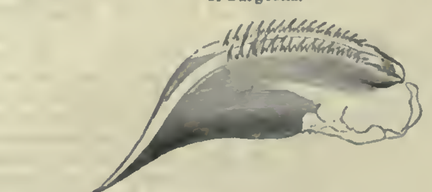
M. Lesson observes that at all events it would be more convenient to retain the original name of Linnæus, *Phœnicopterus ruber*, for the Flamingo of the old continent, and to allow that given by Molina to the American bird, namely, *Phœnicopterus Chilensis*, to remain; although Wilson, who does not appear to have recognised any specific difference, records the last-mentioned Flamingo under the name of *Phœnicopterus ruber*. The latter is used by most of the English zoologists to designate the Flamingo of the Old World; and we shall, adhering to the law of priority and to prevent confusion, adopt the nomenclature suggested by M. Lesson, wishing at the same time that Molina's name had not been a name of locality.

For a knowledge of the internal structure of the Flamingo we are principally indebted to Professor Owen. From the fact of Cuvier placing the Flamingo amongst the *Grallatores*, Professor Owen supposes that an opportunity of dissecting it had never occurred to Cuvier, and that probably the absence of any allusion to cæca in Perrault's anatomical description ('Mémoires de l'Académie,' t. iii. 3 P., p. 462) may have influenced his silence regarding the internal structure of a bird which he considers as one of the most extraordinary and most isolated of its class. Cuvier, in allusion to the small tooth-like laminæ which are arranged along the margins of the upper mandible, points out the relation which the Flamingo bears in this particular to the *Anatidæ;* and Professor Owen states that a like correspondence is observable in the rest of the alimentary canal. "The horny denticles of the upper mandible," he writes, "and the transverse marginal furrows of the lower mandible form together a sort of filter, and like the plates of whalebone in the *Balænæ* allow the superfluous moisture to drain away, while the small *Mollusca* and other littoral *Animalculæ* are detained and swallowed. The structure of the gullet is in accordance with the size of the substances which serve for nutriment. In the typical *Grallatores*, as *Ardea* and *Ciconia*, which swallow entire fish and other food in large morsels, the œsophagus is remarkable for its great and uniform capacity; but in *Phœnicopterus* it is not more than half an inch in diameter when dilated. At the lower part of the neck it expands into a considerable pouch, which measured in the specimen here described 3 inches in diameter and 4½ inches in length. In Perrault's specimen the diameter was only one and a half inch, and it was probably in a state of contraction, as he describes it as furnished internally with many small longitudinal rugæ. The circular fibres around this part were very distinct. Beyond this pouch the œsophagus again contracts to about 4 lines in diameter, and so continues for 3½ inches, when it terminates in the proventriculus. This glandular cavity was 1 inch 8 lines in length and 5 lines in diameter; the gastric follicles were broad, short, and simple, and were arranged in two long oval groups blending together at the edges. The proventriculus terminates in a small but strong gizzard of a flattened spheroidal form, measuring 1 inch 5 lines in length and the same in breadth; the lateral muscles were each half an inch in thickness. The gizzard was lined with a moderately thick and yellow-coloured cuticle disposed in longitudinal ridges, the extremities of which projecting into the pyloric aperture form a kind of valve, as in the gizzard of the Ostrich. In a Flamingo dissected by Colonel Sykes, in which the duodenum was blocked up by two large tape-worms, the muscles of the gizzard were 1 inch in thickness. The duodenal fold extended towards the left side 4 inches from the pylorus. This intestine was 4 inches in diameter. The pancreas, which occupied its common situation between the two portions of the fold, had a more complete peritoneal covering than usual. The intestinal canal soon diminished in diameter to 3 and then to 2 lines. The small intestines formed an oval mass, and were disposed in 21 elliptical spiral convolutions, 11 descending towards the rectum and 10 returning towards the gizzard in the interspaces of the preceding; a disposition analogous to that of the colon in Ruminants. The villi of the intestines were arranged in longitudinal zigzag lines. There were two cæca, each about 3½ inches in length and 5 inches in diameter. The testes were about the size of grains of wheat, and were situated on the anterior part of the renal capsules. The latter bodies were about the size of hazel-nuts. 'Both these glands were of a bright yellow colour. The fat of this bird is

of a remarkable orange tint. The principal diseased appearances were in the lungs, which were filled with tubercles and vomicæ. I was much struck with finding the inner surface of the latter cavities, and that of most of the smaller ramifications of the bronchial tubes, covered over with a green vegetable mould or *Mucor*. As the individual was examined within twenty-four hours after its death, it seemed reasonable to conclude this *Mucor* had grown there during the lifetime of the animal. Thus it would appear that internal parasites are not exclusively derived from the animal kingdom, but that there are *Entophyta* as well as *Entozoa*.' [ENTOPHYTA.]

"The tongue of the Flamingo is remarkable for its texture, magnitude, and peculiar armature. It is almost cylindrical, but slightly flattened above and obliquely truncate anteriorly, so as to correspond with the form of the inferior mandible. The lower part of the truncated surface is produced in a pointed form, and is supported beneath by a small horny plate. The whole length of the tongue is 3 inches; its circumference 2½ inches. Along the middle of the flattened superior surface there is a moderately deep and wide longitudinal furrow, on either side of which there are from 20 to 25 recurved spines, but of a soft and yielding horny texture, measuring from 1 to 3 lines in length. These spines are arranged in an irregular alternate series, the outer ones being the smallest, and these indeed may be considered a distinct row. At the posterior part of the tongue there are two groups of smaller recumbent spines directed towards the glottis. The substance of the tongue is not muscular, but is chiefly composed of an abundant yielding cellular substance, with fat of an almost oily consistence. It is supported by a long and thin concave cartilage articulated to the body of the os hyoides by a shallow ginglymoid joint allowing of a free motion. Excepting the straight hyoglossi, the muscles all terminate at the base of the tongue. The tendons of the former muscles run along the under part of the lingual cartilage, and expand to be inserted at its extremity, where a few fibres again proceed forwards to the extreme point of the tongue." In the Museum of the Royal College of Surgeons in London is a preparation of the crop, proventriculus, and gizzard of a Flamingo (*P. ruber*, Linn.), and a preparation of the tongue of that bird.

Skull and mandibles of the Flamingo. From a specimen in the Royal College of Surgeons.



Tongue of Flamingo. From a specimen in the Royal College of Surgeons.

There were no *Entozoa* in the specimen dissected by Professor Owen; but he characterises the species found by Colonel Sykes, and above alluded to, as *Tænia lamelligera:* length 7 inches; breadth 5 lines; thickness 1 line. ('Zool. Proc.,' 1832, pp. 141 and 143.)

P. ruber, Linn. (*P. Antiquorum*, Temminck). Its length from the end of the bill to that of the tail is 4 feet 2 or 3 inches, but to the end of the claws sometimes more than 6 feet. Bill 4½ inches long; upper mandible very thin and flat, and somewhat moveable; the under mandible thick, both of them bending downwards from the middle; nostrils linear and placed in a blackish membrane; end of the bill as far as the bend black, thence to the base reddish-yellow, round the base, quite to the eye, covered with a flesh-coloured cere; neck slender and of great length; tongue large, fleshy, filling the cavity of the bill, furnished with twelve or more hooked papillæ on each side, turning backwards; the tip a sharp cartilaginous substance. The bird when in full plumage wholly of a most deep scarlet, except the quills, which are black. From the base of the thigh to the claw 32 inches, of which the feathered part takes up no more than 3 inches; bare part above the knee 13 inches, and thence to the claws 16 inches; colour of the bare parts red; the toes furnished with a web deeply indented. Legs not straight, but slightly bent, the skin rather projecting. (Latham.)

The nest is formed of earth, and in the shape of a hillock, with a cavity at top; eggs two or three, white, of the size of those of a goose, but more elongated.

The flesh of this Flamingo is pretty good meat: the young are thought by some equal to partridge. The inhabitants of Provence however are said to throw away the flesh as fishy, and only to use the feathers as an ornament to other birds at particular entertainments. Not so the Roman epicures. Apicius has left receipts for dressing the whole bird with more than the minute accuracy of a modern cookery book, and the 'Phœnicopterus ingens' appears among the luxuries of the table in Juvenal's eleventh Satire. The brains and tongue figure as one of the favourite dishes of Heliogabalus, and the superior excellence of the latter was dwelt upon by the same Apicius, and noticed by Pliny, where he records the doctrine of that "nepotum omnium altissimus gurges." (Lib. x. c. 48.) Neither has it escaped the pointed pen of Martial—

> "Dat mihi penna rubens nomen; sed lingua gulosis
> Nostra sapit: quid si garrula lingua foret?" Lib. xiii.—lxxl.

The 'garrula lingua' most probably alludes to the tongues and brains of singing birds, which sometimes formed one of the monstrous dishes at the enormously-expensive Roman entertainments. Dampier does not forget the delicious tongue of the Flamingo, observing that a dish of these tongues is worthy of a place at a prince's table. The bird itself seems to have been held in high repute by the ancients, for it appears to have been one of the victims offered to Caligula, who is said to have been sprinkled while sacrificing with the blood of a Phœnicopter the day before he was murdered. (Suet. in 'Caligula,' 22, 57.)

European Flamingo (*Phœnicopterus ruber*).

The European Flamingo is recorded as having been seen everywhere on the African coast and the adjacent islands quite to the Cape of Good Hope. There is a specimen in the South African Museum, London. Le Vaillant found thousands of pelicans and flamingoes on the river Klein-Brak, where the water is brackish owing to the flowing of the tide. It has been occasionally observed on the coasts of Spain, of Italy, and on those of France which lie on the Mediterranean Sea; it has been met with at Marseille and some way up the Rhône. Prince C. L. Bonaparte notes it as very rare and accidental in the neighbourhood of Rome. In some seasons it has been remarked at Aleppo and in the parts adjacent. It has been noticed on the Persian side of the Caspian Sea, and thence along the west coast as far as the Volga, but at uncertain times, and chiefly in considerable flocks, coming from the north coast mostly in October and November. Colonel Sykes records it in his catalogue of birds in the Dukhun (Deccan) as the Rajah-Hans of the Hindoos. It breeds in the Cape de Verd Islands. This species is very shy. Dampier killed fourteen at once by secreting himself and two more; they are not to be approached openly. Kolben speaks of their numbers at the Cape, where by day they resorted to the borders of lakes and rivers, and lodged at night in the long grass on the hills.

M. de la Mormora, in his voyage to Sardinia, gives the following interesting account of this species:—It quits Sardinia about the end of March to return about the middle of August: then it is that from the bastion which forms the promenade of the inhabitants of Cagliari flights of these magnificent birds may be seen to arrive from Africa. Disposed in a triangular band they show at first in the heavens like a line of fire. They advance in the most regular order, but at the sight of the neighbouring lake there is a pause in their progression, and they appear for a moment immoveable in the air; then tracing by a slow and circular movement a reversed conical spiral figure they attain the end of their migration. Brilliant in all the splendour of their plumage, and ranged in a line, these birds offer a new spectacle, and represent a small army ranged in order of battle, the uniformity and symmetry of which leaves nothing to be desired; but the spectator should content himself with observing this peaceful colony from afar. Woe to him if he dare to approach the lake at this deadly season.

A group of nine of these beautiful birds are at present (1854) in the Gardens of the Zoological Society, Regent's Park.

P. parvus, Vieillot (*P. minor*, Flammant Pygmée, Temminck). M. Temminck observes that no difference is perceptible between the Flamingo of the ancient continent and that of the New World in the form of the mandibles; their upper mandible shuts on the lower one, and is so constructed as to offer when the bill is shut a very slight difference in the height of the two mandibles. In *P. parvus* the lower mandible, very deep and strongly arched, is formed to receive within the space which separates its walls the whole of the upper mandible, which it entirely hides, so that the upper edges of the lower mandible raise themselves to the height of the surface of the upper jaw.

Small Flamingo (*Phœnicopterus parvus*).

The plumage of the adult is pure rose-colour without spot or streak; the head, the neck, the back, and all the lower parts, are of this beautiful tint, which is more lively and pure in the living bird than in the preserved skin, for the fugitive brilliancy of this tint becomes tarnished, and passes into whitish from exposure to the light. The great wing-coverts and those of the tail are slightly deeper in colour than the other parts of the plumage. The whole wing is covered with feathers of a brilliant scarlet or purple, surrounded by a wide rosy border; the tail-feathers are black. Base of the bill, cere, and region of the eye, deep purple; middle of the lower mandible orange-red, and the point black. Joint of the knee, toes, and their membranes, of a fine red; the tarsus has a livid tint. Total length nearly 3 feet.

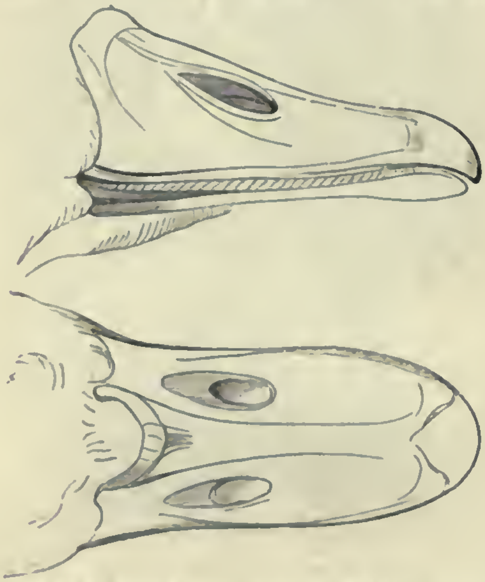
The young of the year are white or whitish, marked with small brown streaks (mèches) spread over the head, the neck, the breast, and the coverts of the wings. The first red tints show themselves on the wings. Bill black. Feet of a reddish livid tint.

This species inhabits the lakes of Africa. Those received by Professor M. Temminck were natives of the Cape of Good Hope. The young bird in the Museum at Paris was brought from Senegal.

P. Chilensis, Molina (*P. ruber*, Red Flamingo, Wilson). This species in its adult state scarcely differs from the European Flamingo: it is perhaps not so bright. Catesby says, "When they feed (which is always in shallow water, by bending their necks) they lay the upper part of their bill next the ground, their feet being in continual motion up and down in the mud, by which means they raise a small round sort of grain resembling millet, which they receive into their bills; and as there is a necessity for their receiving into their mouths some mud, nature has provided the edges of their bills with a sieve or teeth like a fine comb, with which they retain the food and reject the mud which is taken in with it. This account I had from persons of credit; but I never saw them feeding myself, and therefore cannot absolutely refute the opinion of others, who say they feed on fish, particularly eels, which seem to be the slippery prey Dr. Grew says that the teeth are contrived to hold." The development of the gizzard in this genus makes it very probable that vegetable substances form part of the diet of the Flamingoes; but it is not likely that large fish, or indeed water-animals of any great size, are ordinarily devoured by these birds. The bill is a colander, admirably coutrived for separating the nutritious parts, whether animal or vegetable, from the mud and other useless parts.

The Red Flamingo inhabits the warmer parts of North America, Peru, Chili, Guyana, coast of Brazil, and the West Iudia Islands, particularly the Bahamas, where they breed. Wilson speaks of it, but he gives Latham's description, &c. Prince C. L. Bouaparte, in his 'Specchio Comparativo,' states that it is very rare and accidental in the neighbourhood of Philadelphia.

The *Anserinæ* include those birds which are popularly known as Geese. Mr. Swainson, in the 'Classification of Birds,' considers that the *Anserinæ* constitute the rasorial sub-family of the whole group of *Anatidæ*. Although much nearer related, in Mr. Swainson's opiuion, to the True Ducks than are the Flamingoes, next to which he places them, they are, he remarks, nevertheless much more terrestrial in their habits; and in their strong and high legs, fondness for grain and vegetables, and comparative shortness of wing, he traces many of the chief characters of the rasorial type. The first form, after quitting the Flamingoes, seems to him to be the natatorial genus *Cygnus* [CYGNINÆ], which, by its great length of neck and large-sized body, softens down the interval between the Ducks and the *Phœni-*



Bill of Egyptian Goose (*Chenalopex Ægyptiacus*).

Bill of Gray-Lag, or Common Wild Goose (*Anser ferus*).

Bill of Pigeon-Goose (*Cereopsis*), Swainson. [CEREOPSIS.]

coptinæ. "We next," continues Mr. Swainson, "come to the True Geese, forming the genus *Anser*, the typical division of the whole group, and which contains most, if not all, of the usual sub-genera. The Tree Geese (or Ducks, as they have been called) next follow, among which the sub-genus *Chenaloplex* (Chenalopex?) will probably find a place. *Plectropterus* is the rasorial genus analogous, by its spur-wings, to the *Rallidæ*, while the Australian genus *Cereopsis* (equally representing the pigeons) appears alone necessary to complete this circle." In his 'Synopsis' Mr. Swainson makes the *Anatidæ* consists of the following sub-families: — *Phœnicoptinæ*, *Anserinæ*, *Anatinæ*, *Fuligulinæ*, and *Merganidæ* (Merganinæ?).

The cuts in the preceding page will in some degree illustrate the form of the bill in the Geese:—

The genus *Anser* has the following characters:—Beak not longer than the head, conical, elevated at the base, which is covered with a cere or skin; under mandible smaller than the upper; nostrils lateral, placed towards the middle of the beak, pierced anteriorly; legs under the centre of the body; the tarsi long, the hind toe free, articulated upon the tarsus.

A. hyperboreus, Pallas; *A. niveus*, Brisson, the Snow-Goose. It appears to be the *A. hyperborea* of Gmelin; *A. nivalis*, Forster; Snow-Goose of Pennant, Wilson, Bonaparte, and Nuttall; White Brant of Lawson, Lewis, and Clark; Wæwæoo, Wapow-Wæoo (the young Catch-catew-Wæwæoo) of the Cree Indians; Kangokh (plur. Kang-oot) of the Esquimaux; Wavey of the Hudson's Bay residents; L'Oie Hyperborée, ou de Neige, of the French; and Schnee-Gans of the Dutch.

Sir John Richardson gives the following description of a male Snow-Goose killed at Fort Enterprise, lat. 65°, June 1, 1821:—Colour white; quills pitch-black, their shafts white towards the base; head glossed with ferruginous; irides dark hair-brown; bill, feet, and orbits, aurora-red; ungues of both mandibles livid. The ferruginous tint occupies different portions of the head in different individuals, and in some extends to the neck and middle of the belly. An immature bird has a few feathers on the crown and nape, the fore part of the back, ends of the scapulars, some of their coverts, and the outer webs of the tail-feathers, grayish-brown, all tipped and more or less edged with white. Tertiaries and rest of the plumage as in the old bird. Some individuals deviate from the full plumage merely in the bastard wing and primary coverts retaining their gray colour, while in very young birds part of the under plumage is also grayish-brown; bill shaped much like that of *A. albifrons*.

The Snow-Goose feeds principally on rushes, insects, &c., and in the autumn on berries. The rushes, roots of reeds, and other vegetables it tears up, according to Wilson, from the marshes like the hogs, and here its powerful strongly-serrated bill becomes a most useful instrument. Of the berries, the Crow-Berry (*Empetrum nigrum*), appears to be the favourite. Sir John Richardson states that this species breeds in the Barren Grounds of Arctic America in great numbers, and that their eggs are of a yellowish-white colour and regularly ovate form, three inches in length, and two inches in their greatest breadth. At the end of August the young fly, and all have departed southward by the middle of September; but it is said that the young do not attain the full plumage of the old bird before their fourth year, and until then they appear to keep in separate flocks.

In common with most of the True Geese, the plumage of the Snow-Goose is available for adding to the comforts of man, and its flesh, when well fed, is excellent. Richardson states it to be far superior to that of the Canada Goose in juiciness and flavour. At the time of their departure southward from Severn Fort in October, Dr. Latham says that many thousands are killed by the inhabitants, who pluck them, and taking out the entrails, put their bodies into holes dug in the ground, covering them with earth, which, freezing above, keeps them perfectly sweet throughout the severe season, during which the inhabitants occasionally open one of these storehouses, and find the birds untainted and good. In Siberia the same mode of preserving them seems to be practised.

Nuttall states that the Snow-Goose is common to the north of both continents. He says that early in November they arrive in the river Delaware, and probably visit Newfoundland and the coasts of the Eastern States in the interval, being occasionally seen in Massachusetts Bay. They congregate in large flocks, and are very noisy: their note is more shrill than that of the Canada Goose, and they make but a short stay in winter, proceeding farther south as the severity of the weather increases. Prince C. L. Bonaparte notes it as rare and accidental in the winter at Philadelphia. Nuttall further remarks that the Snow-Geese begin to return towards the north by the middle of February, and until the breaking up of the ice in March are frequently seen in flocks on the shores of the Delaware and around the head of the bay. He observes that they are met with commonly on the western side of America, as at Oonalashka and Kamtchatka, as well as in the æstuary of the Oregon, where they were seen by Lewis and Clark. According to Sir John Richardson, they are numerous at Albany Fort, in the southern part of Hudson's Bay, where the old birds are rarely seen; and, on the other hand, the old birds in their migrations visit York Factory in great abundance, but are seldom accompanied by the young. The Snow-Geese, he adds, make their appearance in spring a few days later than the Canada Geese, and pass in large flocks both through the interior and on the coast.

Mr. Gould, who gives a very good figure of the adult in his magnificent work on the 'Birds of Europe,' says that the species inhabits all the regions of the arctic circle, but more especially those portions appertaining to North America. From the northern portions of Russia and Lapland, he adds, where it is sparingly diffused, it regularly migrates to the eastern portions of Europe, and is occasionally found in Prussia and Austria, but never in Holland. To the polar regions, he concludes, it retires as its congenial locality early in the spring, to perform the duties of incubation and rearing its young.

A. ferus, the Gray-Lag Goose. The Domestic Goose is the Oye Privée, and the Wild Goose is the Oye Sauvage of Belon; *Anser ferus* and *Anser* of Gesner and others; *Anser domesticus* and *Anser palustris noster*, Gray Lagg dictus of Ray; *Anas Anser ferus* of Latham; *Anas Anser* of Linnæus. It is the Oca (tame), Oca Salvatica, Oca Grossa col Becco Rosso (wild), and Oca Paglietane, of the Italians; Oie Domestique and Oie Sauvage of the French; Oie Cendrée ou Première of Temminck; Gans, Grau Gans, and Wilde Gemeine Gans, of the Germans; Gaas of the Danes; Gas and Will Gas of the 'Fauna Suecica;' Gwydd of the Welsh, and Goose and Wild Goose of the modern British.

The Gray-Lag, or common Wild Goose, is the origin of the Domestic Goose of our farm-yards. "It is," says Pennant, "the only species that the Britons could take young and familiarise; the other two"—the White-Fronted Goose (*Anser albifrons*) and the Bean-Goose (*Anas segetum*, Lath. and Gmel.) are probably the species meant—"never breed here, and migrate during the summer." The Gray-Lag Goose, then, and the Domestic Goose, may be considered identical. It is the Χὴν of the Greeks and *Anser* of the Romans—the same that saved the capitol by its vigilance, and was cherished accordingly. Pliny (lib. x. c. xxii.) speaks of the bird much at length, stating how they were driven from a distance on foot to Rome; he mentions the value of the feathers of the white ones, and relates that in some places they were plucked twice a year. "Mirum in hac alite, a Morinis usque Romam pedibus venire. Fessi proferuntur ad primos, ita cæteri stipatione naturali propellunt eos. Candidorum alterum vectigal in pluma. Velluntur quibusdam locis bis anno. Rursus plumigeri vestiuntur; molliorque quæ corpori quam proxima, et e Germania laudatissima. Candidi ibi verum minores Ganzæ vocantur. Pretium plumæ eorum in libras denarii quini," &c.

Though this bird is well known, there has been so much confusion, in consequence of there being three species of wild goose, namely, *Anas Anser*, Lin., *A.* (*Anser*) *segetum*, and *A.* (*Anser*) *albifrons*, White-Fronted Wild Goose, that it may be as well to give Pennant's description.

"This," writes Pennant, "is our largest species; the heaviest weigh ten pounds; the length is 2 feet 9 inches; the extent 5 feet. The bill is large and elevated, of a flesh-colour tinged with yellow; the nail white; the head and neck cinereous, mixed with ochraceous yellow; the hind part of the neck very pale, and at the base of a yellowish-brown; the breast and belly whitish, clouded with gray or ash-colour; the back gray; the lesser coverts of the wings almost white, the middle row deep cinereous slightly edged with white; the primaries gray, tipped with black and edged with white; the coverts of the tail and the vent-feathers of a pure white; the middle feathers of the tail dusky, tipped with white, the exterior feathers almost wholly white; the legs of a flesh colour."

In its reclaimed state it varies, like most domesticated animals, infinitely; but it is said always to retain the whiteness of the coverts of the tail and the vent-feathers; the whiter the plumage, the more it is esteemed.

The seas, the shores, and the marshes of the oriental countries are the habitation of the Gray-Lag Goose. It rarely advances northward above 53°; it is abundant in Germany and towards the centre of Europe; in very small numbers, on its passage, in Holland and France. The domestic races, all sprung from this species, multiply in all countries. (Temminck.) "The Gray-Lag is known to inhabit all the extensive marshy districts throughout the temperate portions of Europe generally; its range northward not extending farther than the fifty-third degree of latitude, while southward it extends to the northern portions of Africa, eastwardly to Persia, and, we believe, is generally dispersed over Asia Minor." (Gould, 'Birds of Europe.') Prince Bonaparte notes it as rather common in winter near Rome.

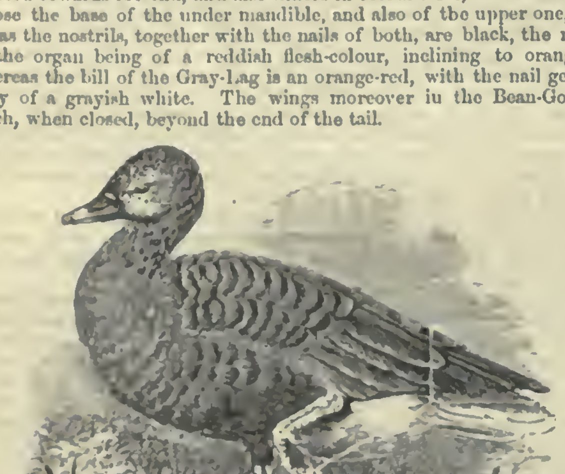
Aquatic vegetables and all sorts of seeds are the food of this bird. "The Gray-Lag," says Gould, "assembles in flocks, and, like the bean-goose, seeks the most open and wild districts, often descending upon fields of newly sprung wheat, which, with the blades of fine grasses, trefoil, and grain, constitute its food." Temminck says that the nest is made in heathy spots (bruyères), and in marshes, upon tussocks of rushes and dried herbs; and that the number of eggs is five, six, or eight, rarely twelve or fourteen, of a dirty greenish-white—Gould says sullied white. Pennant states that this species resides in the fens the whole year, breeds there, and hatches about eight or nine young, which are often taken, easily made tame, and esteemed most excellent meat, superior to the Domestic Goose. The old geese, which are shot, are, he says, plucked, and sold in the market as fine tame ones, and readily bought, the purchaser being deceived by the size, but their flesh is coarse. Towards winter, he adds, they collect in great flocks, but in all seasons live and feed in the fens.

The tame goose is very long lived. "A certain friend of ours"—it is Willughby who relates the story—"of undoubted fidelity, told us that his father had once a goose that was known to be 80 years old, which for ought he knew might have lived the other 80 years, had he not been constrained to kill it for its mischievousness in beating and destroying the younger geese."

It is one of the most useful of birds to man, whether we consider its flesh or its feathers. "Tame geese," writes Pennant, "are kept in vast multitudes in the fens of Lincolnshire; a single person has frequently 1000 old geese, each of which will rear seven, so that towards the end of the season he will become master of 8000. I beg leave to repeat here a part of the history of their economy from my tour in Scotland, in order to complete my account. During the breeding season these birds are lodged in the same houses with the inhabitants, and even in their very bed-chambers; in every apartment are three rows of coarse wicker pens, placed one above another; each bird has its separate lodge divided from the other, which it keeps possession of during the time of sitting. A person called a Gozzard, that is, Goose-Herd, attends the flock, and twice a day drives the whole to water; then brings them back to their habitations, helping those that live in the upper stories to their nests, without ever misplacing a single bird. The geese are plucked five times in the year; the first plucking is at Lady-Day, for feathers and quills, and the same is renewed four times more between that and Michaelmas for feathers only. The old geese submit quietly to the operation, but the young ones are very noisy and unruly. I once saw this performed, and observed that goslins of six weeks old were not spared; for their tails were plucked, as I was told, to habituate them early to what they are to come to. If the season prove cold, numbers of the geese die by this barbarous custom. When the flocks are numerous, about ten pluckers are employed, each with a coarse apron up to his chin. Vast numbers of geese are driven annually to London to supply the markets, among them all the superannuated geese and ganders (called the 'Cagmags'), which, by a long course of plucking, prove uncommonly tough and dry. The feathers are a considerable article of commerce; those from Somersetshire are esteemed the best, and those from Ireland the worst."

The liver seems to have been a favourite morsel with epicures in all ages, and their invention appears to have been active in exercising the means of increasing the volume of that organ. The pâté de foie d'oie de Strasbourg is not more in request now than were the great goose-livers in the time of the Romans. (Pliny, 'Hist.,' lib. x. c. 22, &c.)

A. segetum, the Bean-Goose, one of the wild geese, *Anas segetum*, Gmelin, *Anser ferus*, Ray. It is to be distinguished from the last species by its comparatively small and short bill, which is more compressed towards the end, and also differs in colour: for, in the Bean-Goose the base of the under mandible, and also of the upper one, as far as the nostrils, together with the nails of both, are black, the rest of the organ being of a reddish flesh-colour, inclining to orange; whereas the bill of the Gray-Lag is an orange-red, with the nail generally of a grayish white. The wings moreover in the Bean-Goose reach, when closed, beyond the end of the tail.



The Bean-Goose (*Anser segetum*).

Selby gives the following interesting account of its habits from personal observation:—

"In Britain it is well known as a regular winter visitant, arriving in large bodies from its northern summer haunts, during September or the beginning of October, and seldom taking its final departure before the end of April or beginning of May. The various flocks, during their residence in this country, have each their particular haunts or feeding districts, to which, on each ensuing season, they invariably return, as I have found to be the case in Northumberland and the southern parts of Scotland, where wild geese have been known to frequent certain localities for a continued series of years. The habits of this and the preceding species are very similar, and they show the same vigilance, and use the same means of guarding against surprise: their capture is therefore proportionally difficult, and it is only by stratagem that, when at rest on the ground or feeding, they can be approached within gun-shot. In stormy weather when they are compelled to fly lower than they usually do, they may be sometimes intercepted from a hedge or bank, situated in the route they are observed to take early in the morning, in passing to their feeding ground. At night they retire to the water, or else (as I have often remarked in Northumberland) to some ridge or bar of sand on the sea-coast, sufficiently distant from the mainland to afford a secure retreat; and where the approach of an enemy must become visible, or at least audible to their acute organs, before it could endanger their safety. The haunts or feeding-grounds of these birds are more frequently in the higher districts than in the lower and marshy tracts of the country, and they give the preference to open land, or where the inclosures are very large. They feed much upon the tender wheat, sometimes injuring these fields to a great extent; and they frequent also the stubbles, particularly such as are laid down with clover and other grasses. In the early part of spring they often alight upon the newly-sown bean and pea fields, picking up greedily such of the pulse as is left on the surface; and I am inclined to think that their trivial name has been acquired from their apparent predilection for this kind of food, rather than from the shape and aspect of the nail of the upper mandible, to which it has been generally attributed. They usually fly at a considerable elevation, either in a diagonal line, or in two such lines, opposed to each other, and forming a leading acute angle, like the other species; and when on wing they maintain a loud cackling, in which the voices of the two sexes may be easily distinguished. The rate at which they move, when favoured by a gentle breeze, is seldom less than from 40 to 50 miles an hour, a velocity which enables them to have their roosting-place far removed from the district they frequent by day. The principal breeding stations, or summer retreats, of the bean-goose are in countries within the arctic circle: it is said, however, that great numbers breed annually in Harris, and some of the other outermost Western Islands. The nest is made in the marshy grounds, and formed of grasses and other dry vegetable materials; the eggs are white, and from eight to twelve in number. The trachea of this species increases in diameter towards the middle, and the bronchiæ are short and tumid. The denticulated laminæ of the sides of the bill are similar in formation to those of the *A. palustris*, and form thin sharp cutting edges, and the manner in which they lock within each other renders the bill an instrument beautifully adapted for vegetable food."

In bulk, the Bean-Goose is generally rather less than the Gray-Lag and it is accordingly sometimes called provincially the Small Gray-Goose, but it not unfrequently equals the other in size and weight.

The head and upper part of the neck incline to brown, with a grayish tinge, and the feathers of the latter hue are so disposed as almost to produce a furrowed appearance. The lower parts of the body are ash-gray, with transverse darker shades; and the back and scapulars are brown, with a gray tinge, the feathers being edged with white. Wing-coverts gray; secondaries brown, edged and tipped with white; primaries gray-black; rump gray; upper tail-coverts white; tail brown, with the feathers deeply bordered and tipped with white; legs and toes reddish, inclining to orange, the intensity of the colour varying according to the bird's age.

A. Ægyptiacus, Brisson (*Anas Ægyptiaca*, Linnæus), the Egyptian Goose. It appears to be the Χηναλώπηξ of the Greeks, and accordingly the modern zoologists have named it *Chenalopex Ægyptiacus* (Gould, 'Birds of Europe'). Aristotle ('Hist. Anim.' lib. viii. c. 3) mentions the *Chenalopex* as a palmipede bird haunting the banks of lakes and rivers. Aristophanes names it in two of his comedies, namely, 'Birds,' v. 1295, 'Lysistr.' v. 956. (In the 'Lysistrate' the Ravenna Manuscript reads Χηναλώπηξ: but Bekker prints Χυναλώπηξ, noticing the Ravenna reading.) Athenæus mentions it with praise on account of its eggs, as claiming the second place in excellence, those of the peacock holding the first ('Deipn.' lib. ii. c. 16, p. 58). Ælian (lib. v. c. 30; lib. xi. c. 38) notices it, and speaks of its cunning.

But it is Herodotus who draws our attention to the bird as one of those held sacred by the Egyptians ('Hist.' lib. ii. c. 72), and the researches of modern travellers have fully shown that it was at least a favourite dish with the priests. It is impossible to look at the Egyptian paintings and sculptures—many will be found in the British Museum, and many more copied in Rosellini, and other works of the same kind—without being struck with the frequent occurrence of geese represented, both alive and plucked, and prepared for the table. That some of these represent the *Chenalopex* there can be no doubt. The author of the interesting book on Egyptian Antiquities ('Library of Entertaining Knowledge—Egyptian Antiquities,' vol. ii., London, 1836), gives a print containing, as he believes, all or nearly all the varieties of the animal forms, except perhaps the fishes, which he had been able to find on the great sarcophagus, the two obelisks, and some other monuments in the British Museum. Among them he figures a palmipede bird, which he considers to be the Egyptian Goose, the *Chenalopex* of Herodotus; and he observes that it is of frequent occurrence on the sculptures, though it was not a sacred bird; unless it may have some claims to that honour from having been a favourite article of food for the priests. A place in Upper Egypt, he remarks, had its name Chenoboscion, or Chenoboscia ('goose-pens'), from these animals being fed there, probably for sale; though these may have been sacred geese, for the goose, we are told, was a bird under the care of Isis. Every one recollects, he adds, the story in Livy, of the geese of Juno saving the capitol. The bird referred to, if accurately figured, and we are told that the drawing was executed with great care, seems too short upon its legs for the Egyptian Goose of modern authors, and has more the air of a Bernicle.

Belon gives a fair description of the Egyptian Goose; among other observations he says, "Estant de la forme d'une oye, et le col long, et la corpulence plus petite, semble estre haut enjambée;" and he applies to the bird, which he describes, the name of *Vulpanser*, or *Chenalopex*. He speaks also of its being kept "es cours des grand seigneurs seulement." M. Geoffroy St. Hilaire is also of opinion that the Egyptian Goose is the *Chenalopex*, or *Vulpanser*, of the ancients; and Mr. Stephens conferred the former generic title on the species.

The genus *Chenalopex* has the following characters:—Bill as long as the head, slender, nearly straight, rounded at the tip, laminated on the margin; upper mandible slightly curved, nail hooked, lower mandible flat. Nostrils sub-basal: upper mandible margined all round with brown, reddish flesh-colour in the centre; irides orange. Wings with spurs. Tarsi elongated; the three anterior toes fully webbed; hind toe simple. Legs placed in equilibrio with reference to the body.

The sexes are nearly similar; female rather smaller than the male, and with the colouring less intense. Narrow edging of feathers round the base of the bill, a line running nearly straight from that edging to the eye, and large patch surrounding the eye, chestnut; crown of the head, sides of the face, and anterior part of neck, pale buff approaching to white, gradually passing into rufous-brown on the back of the neck; lower part of the neck of the same reddish tinge, which forms there a slightly marked collar. Upper part of the back light chestnut-brown, rayed with very minute transverse irregular lines of dark brown approaching to black; middle of the back and upper part of scapulars dark reddish-brown, minutely rayed with irregular transverse lines of blackish-brown and gray; lower part of scapulars and tertiaries reddish chestnut; lesser wing-coverts white, except the posterior row of feathers, which are crossed with black near their extremities, so as to form a narrow oblique band across the wing; primaries, lower part of the back, rump, and tail, black; secondaries rich green, glossed with purple. In the middle of the breast there is a large patch of deep chestnut; the rest of the under part of the body, from the slight collar to the thighs, pale buff with fine irregular transverse blackish-brown lines. Vent and under tail-coverts rich buff. Legs and feet reddish flesh-colour.

Egyptian Goose (*Chenalopex Ægyptiacus*).

Mr. Gould, who gives an excellent portrait of an adult male in his 'Birds of Europe,' states that he has not been led to do so by the number of half-reclaimed individuals which are yearly shot in our island, but from the circumstance of its occasionally visiting the southern parts of the Continent from its native country, Africa. M. Temminck, he remarks, particularly mentions the island of Sicily as one of the places frequented by it; and he adds that this is the species which would appear to have been held in great veneration by the ancient Egyptians, as we frequently find a figure of it among the monuments of that celebrated people. It is, he says, abundant on the banks of the Nile, and is distributed over the whole of the vast continent of Africa.

This handsome species breeds freely in confinement, and is often seen in the aviaries and near the lakes of those who take pleasure in collecting and domesticating ornamental water-birds.

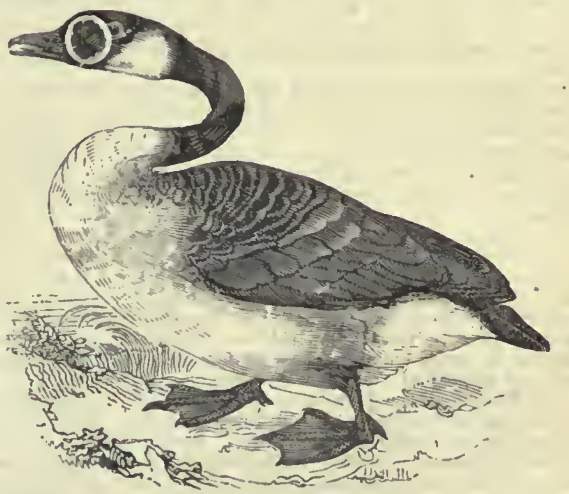
A. Gambensis of Ray and others, *Anas Gambensis* of Linnæus, *Plectropterus Gambensis* of modern ornithologists, the Spur-Winged Goose, or Gambo-Goose. This species was confounded by Willughby, and afterwards by Buffon, with the Egyptian Goose.

Size nearly that of the common goose; but the legs are long, and placed under the middle of the body. Bill broad and flat, with a tubercle at the base like that of the tame swan. This tubercle increases with age. Bend of the wing armed with a large blunt spur, which is sometimes double. Bill and its basal tubercle dull red; sides of the head white; upper parts of body glossy black, with metallic reflections; base of the wings with a white patch mottled with black spots; under parts white; legs slightly tinged with red; spur, which is only visible when the wing is expanded, horn-colour.

Mr. Swainson thus characterises the genus *Plectropterus*, Leach:—"Size large; wings armed with naked tubercles or spines; bill lengthened, wide at the tip; the base with a naked protuberance. Rasorial."

It is a native of Northern and Western Africa. One specimen was killed in Cornwall in 1821, hence it is enumerated in lists of British *Anatidæ*. More rare in collections than the Egyptian Goose, but has lived well in the Gardens of the Zoological Society of London, at the Regent's Park.

A. Canadensis of authors, the Canada Goose, or Cravat-Goose. This bird in its contour, especially about the neck, seems to approach the swans. Indeed, Mr. T. C. Eyton arranges it under the genus *Cygnus*. It is the Neescah, or Mistehayneescah, of the Cree Indians; L'Outarde of the French-Canadians; Bustard of the Hudson's Bay settlers; Wild Goose of the Anglo-Americans; and L'Oie à Cravate of the French.



Canadian Goose (*Anser Canadensis*).

Hearne, Pennant, Wilson, Audubon, Nuttall, and others, give very interesting accounts of the habits and chace of this species, whose annual advent furnishes such an abundant harvest of food to the residents in the countries visited by it. Our limits will not permit us to indulge in these entertaining but somewhat lengthened narratives, and we select Sir John Richardson's account as being at once clear and concise:—"The arrival of this well-known bird," says Sir John in the 'Fauna Boreali-Americana,' "in the Fur Countries is anxiously looked for, and hailed with great joy by the natives of the woody and swampy districts, who depend principally upon it for subsistence during the summer. It makes its first appearance in flocks of twenty or thirty, which are readily decoyed within gun-shot by the hunters, who set up stales, and imitate its call. Two or three, or more, are so frequently killed at a shot, that the usual price of a goose is a single charge of ammunition. One goose, which when fat weighs about nine pounds, is the daily ration for one of the Company's servants during the season, and is reckoned equivalent to two snow-geese, or three ducks, or eight pounds of buffalo and moose-meat, or two pounds of pemmican, or a pint of maize and four ounces of suet. About three weeks after their first appearance the Canada Geese disperse in pairs throughout the country, between the 50th and 67th parallels, to breed, retiring at the same time from the shores of Hudson's Bay. They are seldom or never seen on the coasts of the

Arctic Sea. In July, after the young birds are hatched, the parents moult, and vast numbers are killed in the rivers and small lakes when they are unable to fly. When chased by a canoe, and obliged to dive frequently, they soon become fatigued, and make for the shore with the intention of hiding themselves; but as they are not fleet they fall an easy prey to their pursuers. In the autumn they again assemble in flocks on the shores of Hudson's Bay for three weeks or a month previous to their departure southwards.

"It has been observed that in their migrations the geese annually resort to certain passes and resting-places, some of which are frequented both in the spring and autumn, and others only in the spring. The Canada Goose generally builds its nest on the ground; but some pairs occasionally breed on the banks of the Saskatchewan in trees, depositing their eggs in the deserted nests of ravens or fishing eagles. Its call is imitated by a prolonged nasal pronunciation of the syllable *wook* frequently repeated."

The principal food of this species consists of sedge-roots, herbage, and delicate marine plants, such as those of the genus *Ulva*. In the spring they feed on berries which have been preserved by the snow through the winter, such as those of the Silvery Buckthorn (*Eleagnus argentea*). M. Audubon found them breeding on the coast of Labrador; the eggs, six or seven in number, of a greenish-white, are laid in a roughly-made nest. Mr. Nuttall says that in the month of March, 1810, many were nesting in the Shave-Rush (*Equisetum hyemale*) bottoms of the Missouri, no farther up than Fire Prairie, considerably below the junction of the river Platte; so that the breeding range of the Canada Goose probably extends through not less than 30 degrees of latitude. Prince Bonaparte notes it as common in winter near Philadelphia, and as being an object of chase on the sea-shore in the autumn.

When it is remembered that the Hudson's Bay residents depend greatly on the supply of Canada Geese for their winter provision, and that in favourable years as many as 3000 or 4000 are said to have been killed and barrelled up, it is evident that without this aid numbers must be in a very forlorn condition. It has been asserted that on a good day a single native from the ambush of his bough hut will kill as many as 200. They are preserved in the frost with the feathers on, and the flesh is juicy and nutritious, though not equal to that of the Snow-Goose. The feathers also are of commercial value. The bird has been long domiciled in Europe, in France, and in this country particularly, where it breeds freely, and is a great ornament. Buffon states that it bred with the swans at Versailles; it will breed also with the Common Goose. The produce of the latter intermixture are said to be much more delicious in flavour and quality than the unmixed progeny of the Domestic Goose.

The following is the description of this bird:—Head, two-thirds of the neck, greater quills, rump, and tail, pitch-black. Back and wings broccoli-brown, edged with wood-brown. Base of the neck before and the under plumage generally brownish-gray. A few feathers about the eye, a large kidney-shaped patch on the throat, the sides of the rump, and upper and under tail-coverts, pure white. Bill and feet black.

Sir John Richardson observes that individuals differ considerably in dimensions.

The author last above quoted states, as a summary in the 'Fauna Boreali-Americana,' that the geese feed on vegetable substances, pasturing by day, and retiring in the night to repose on the water. This must be taken as a general proposition, for the Canada Goose is said rarely to sleep upon the water except in very calm weather, their roosting-place being mostly in the marshes. He says that they swim well, but dive only when moulting and unable to fly. If pursued at such times they leave the water, and try to hide themselves on shore. They fly high and swiftly in flocks arranged in two lines meeting in an acute angle: they alight on the ground, seldom on the water. The same author observes that *Anser albifrons* and *A. hyperboreus* feed chiefly on berries, and are seldom seen on the water except in the night or when moulting; that they frequent the sandy shores of rivers and lakes in flocks, one of their number generally doing duty as sentinel, and that both species breed in great numbers in Arctic America and on the islands of the Polar Sea. *A. albifrons* he states to be rare on the coast of Hudson's Bay, and says that it migrates over the interior, and chooses its breeding-places in the vicinity of woody tracts; while *A. hyperboreus* visits both the interior and the coast in its migrations, but resorts to the Barren Grounds to breed. "*A. Canadensis*," writes Sir John Richardson in conclusion, "is abundant in pairs throughout the Fur Countries up to a high latitude. It associates in flocks only on its first arrival. It feeds on grass and on all kinds of berries. Early in the spring I have found its crop filled with the farinaceous astringent fruit of the *Eleagnus argentea*. *A. Bernicla* and *A. Hutchinsii* breed in considerable numbers on the shores and islands of the Arctic Sea, but keep near the sea-coast in their migrations, and are seldom seen in the interior. They feed on marine plants and on the *Mollusca* which adhere to them, as well as on grass and berries. Prince C. L. Bonaparte enumerates *A. segetum* and *A. leucopsis* in his list of American Geese; but they did not come under our notice in the Fur Countries. Hutchins and Hearne speak of the Canada Goose under the name of Common Gray Goose, what they term Canada Goose being our *A. Hutchinsii*."

This sort of practical information is not merely interesting in a philosophical point of view. The observations which Sir John Richardson's opportunities enabled him to make become of great practical importance when it is considered that upon the habits and migratory movements of this useful tribe depend the comfort, nay, almost the existence, of multitudes of human beings. We shall therefore follow these birds through Sir John Richardson's 'Table;' and we would earnestly entreat all zoological travellers to keep such registers whenever their position will enable them to add such valuable contributions to natural history. The Table from which the following extract is made embraces the whole of the birds comprised in the 'Fauna Boreali-Americana.' Sir John Richardson remarks that the fourth column is taken from Prince Bonaparte's 'Specchio Comparativo,' and that the fifth column is filled up on the authority of that naturalist, Wilson, Audubon, and some others.

Species.	Extreme Northern range. Distribution in the Fur Countries. Whether resident or migratory.	Species observed on the Saskatchewan; lat. 53° to 54° N., and from 600 to 1000 miles distant from the sea-coast.	Species that frequent the vicinity of Philadelphia, lat. 40° N. (Bonaparte.)	Winter Quarters of the Species.
Anser albifrons	73° N. Lat. East of Rocky Mountains. Migratory.	Passage. Spring and Autumn. In flocks. Very abundant.	Winter. Accidental visiter.	Middle and Southern States.
Anser hyperboreus	73° N. Lat. Across the Continent. Migratory.	Passage. Spring and Autumn. In flocks. Very abundant.	Winter. Accidental visiter.	United States.
Anser Canadensis	70° N. Lat. Across the Continent. Migratory.	Summer. Common.	Winter. Common.	Middle States.
Anser Bernicla	73° N. Lat. East of Rocky Mountains. Migratory.	Passage. Spring and Autumn. Accidental.	Winter. Common.	Southern States.
Anser Hutchinsii	60° N. Lat. East of Rocky Mountains. Migratory.	Passage. Spring and Autumn. In flocks.		

With regard to the further geographical distribution of this tribe the reader will find *A. Indicus*, Barred-Headed Goose, Lath.; *A. melanotos*, Black-Backed Goose, Lath.; and *A. Coromandeliana*, *Anas Girra*, Gray and Hardw.; *Girra Teal*, Lath., in the catalogue of birds which were collected on the Ganges between Calcutta and Benares, and in the Vindhyian Hills between that place and Gurra Mundela, on the Nerbudda, by Major James Franklin, F.R.S., &c. ('Zool. Proc.,' 1830-31.) *Anser Girra* (*Anas Girra*, Gray), called the Cotton-Teal by the Europeans in the Deccan, on account of the quantity of white in the plumage, appears also in the account of Colonel Sykes's collection of birds from the Deccan. ('Zool. Proc.,' 1832.) *Anser inornatus* is recorded among the birds brought home from the Straits of Magalhaens by Captain Philip Parker King, R.N. ('Zool. Proc.,' 1830-31.) Mr. Gould, in his 'Century of Birds from the Himalaya Mountains,' figures *A. Indicus* as occurring there.

The sub-family *Anatinæ*, the True Ducks, have a very wide geographical distribution. Sir John Richardson, in the work last quoted, states that *Anas clypeata* and *A.* (*Dafila*) *acuta* frequent chiefly the clear lakes of the northern districts, and breed in the Barren Grounds, being found in numbers in the more southern woody districts in spring and autumn only. *A.* (*Boschas*) *domestica*, *A.* (*Chauliodus*) *strepera*, and *Mareca Americana* breed in the woody districts up to their most northern limits, in latitude 68°. *A.* (*Boschas*) *crecca* is abundant to the extremity of the continent both in the woody and barren districts. *A.* (*Boschas*) *discors*, though very plentiful on the Saskatchewan, was not observed farther north than the 58th parallel; while *Dendronessa sponsa* seldom goes to the northward of the 54th degree of latitude, and is rare even to the southward of that parallel.

It appears also from Sir John Richardson's 'Tables' that *Anas clypeata* was observed in 70° N. lat. migratory across the continent; numerous: that it was observed on the Saskatchewan, in 53° to 54° N. lat., and from 600 to 1000 miles distant from the sea-coast, very common as a bird of passage in spring and autumn; that it frequents the vicinity of Philadelphia, rather common in winter (Bonaparte); and that its winter quarters are in the United States and Mexico. *A.* (*Chauliodus*) *strepera* has been noticed in 68° N. lat. east of the Rocky Mountains, migratory; and on the Saskatchewan (same range of latitude and same distance from the sea-coast) common in summer; rare in the vicinity of Philadelphia in winter (Bonaparte): its winter quarters are the Mexican lakes. (Swainson.) *A.* (*Dafila*) *caudacuta*, in lat. 70° east of the Rocky Mountains; migratory; very common; and on the Saskatchewan, as above, in spring and autumn, but not rare; common in the vicinity of Philadelphia in winter (Bonaparte); and having its winter quarters in the Mexican lakes. (Swainson.) *A.* (*Boschas*) *domestica*, in lat. 68°; migratory across the continent: common on the Saskatchewan, as above, in the summer; common in the vicinity of Philadelphia in the winter (Bonaparte); and having its winter quarters in the Middle and Southern States, Columbia River and California. *A.* (*Boschas*) *crecca*, in lat. 70°; migratory across the continent; very abundant; on the Saskatchewan, as above, abundant in summer; very common near Philadelphia in the winter (Bonaparte): and with its winter quarters in the Middle and Southern States towards the tropics. *A.* (*Boschas*) *discors*, in lat. 58°; migratory across the continent; very abundant; and on the Saskatchewan, as above, abundant in summer; very common near Philadelphia in summer (Bonaparte); and with the Mexican States, Columbia River, and California for its winter quarters. *Mareca Americana*, in lat. 68°; migratory; rather common on the Saskatchewan, as above, in summer; common near Philadelphia in the winter (Bonaparte); wintering in the Middle and Southern States and in the West Indies. *Dendronessa sponsa*, in lat. 54°; migratory; rare on the Saskatchewan, as above, in summer; common in the vicinity of Philadelphia in summer (Bonaparte); wintering in the Southern States, Mexico (?) West Indies.

In the same work we find in the list of species which merely winter in Pennsylvania, and migrate in summer to rear their young in the Fur Countries, *A. clypeata*, *A.* (*chauliodus*) *strepera*, *A.* (*Dafila*) *caudacuta*, *A.* (*Boschas*) *domestica*, *A.* (*Boschas*) *crecca*, and *Mareca Americana*;—in the list of species which summer (or breed) in the Fur Countries and in Pennsylvania, but winter farther to the southward, *A.* (*Boschas*) *discors* and *Dendronessa sponsa*;—and in the list of species common to the Old World and the Fur Countries, *A. clypeata*, *A.* (*Chauliodus*) *strepera*, *A.* (*Dafila*) *acuta*, *A.* (*Boschas*) *domestica*, and *A.* (*Boschas*) *crecca*.

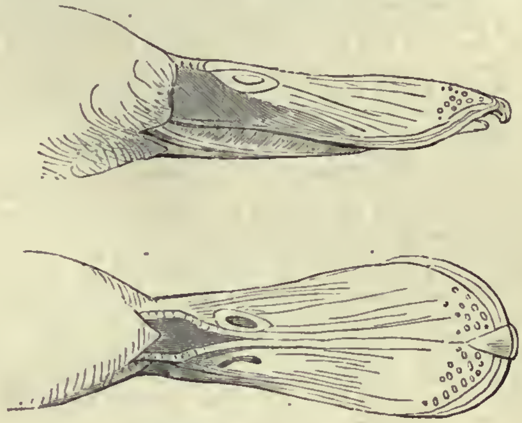
The *Anatinæ* feed on soft substances, such as fresh-water insects and tender aquatic plants, which they procure near the surface, or, aided by the length of their necks, at the bottom, in shallow muddy places, and worms and slugs, which they search for among the grass. By day they resort to small lakes and rivers, and in the night retire to the fields. They are strong and swift on the wing, and are watchful birds, that seldom dive to escape pursuit, unless when moulting; but when disturbed fly away, making at the outset a circle in the air to survey the cause of their alarm. ('Fauna Boreali-Americana.') Sir John Richardson gives in a note the following interesting information, derived from an intelligent keeper of a decoy in the neighbourhood of the Rev. W. Booth of Friskney, in Lincolnshire, to whom he expresses his obligation for the statement:—"Skelton is unacquainted with the habits of the gadwall; but he tells me that the widgeon and pintail do not willingly dive: of course, if driven to it, they can, but they do not dive for their food; and though in play they sometimes splash under water, they never remain beneath the surface like the pochard. With respect to food, the mallard, pintail, and teal, frequent rich flooded lands, 'swittering with their nebs in the soil, and sucking out its strength;' but the widgeon feeds quite differently, being 'an amazing fowl to grazo, a strange eater of grass.' It is especially fond of 'flutter-grass' (*Glyceria aquatica vel fluitans ?*), which it crops on the surface, but it likewise eats many other herbs. When the decoy has been so full of widgeons that they have devoured every blade on the landings, Skelton has taken advantage of their absence in the night, when they resort to the green salt marshes on the sea-coast, and laid down sods pared from the fields, on which they readily graze. In common, however, with the mallard, teal, and pintail, they are fond of willow-weed-seeds (*Epilobium ?*), with which he feeds all the fowl in the decoy, as they prefer it to oats and every other kind of grain. Mr. Waterton states that 'the widgeon feeds by day, eating grass like a goose; whilst its congener the mallard invariably refuses this food, and seeks for its susteuance by night.'"

The genus *Anas* has the following characters:—Bill about as long as the head, broad, depressed, sides parallel, sometimes partially dilated; both mandibles furnished on the inner edges with transverse lamellæ; nostrils small, oval, lateral, anterior to the base of the beak; legs rather short, placed under the centre of the body; tarsus somewhat rounded; toes three in front, connected by intervening membranes; hind toe free, without peudant lobe or membrane; wings rather long, pointed. Tail pointed or wedge-shaped. The sexes differ in plumage.

Anas clypeata (Linn.), the Shoveler. This is the Souchet of the French; Cucchiarone of the Italians; Schild-Ente and Löffel-Ente of the Germans; Mimenick of the Cree Indians; Hwyad Lydaubig of the Welsh; *Rhynchaspis clypeata* of Shaw's Zoology (Leach MSS.); *Spathulea clypeata* of Fleming. The *A. rubens* of Gmelin is said to be the young male, or a variety of the young male. It is provincially termed Blue-Winged Shoveler, Kertlutock, and Broad-Bill.

The following is the description of a male killed at Fort Franklin, May, 1826:—Colour: head, adjoining half of the neck, medial stripe to the interscapulars, the whole back, interior scapulars, and primaries, umber-brown; sides of the head, the neck, and crest, glossed with duck-green; rump and tail-coverts above and below, with blackish green. Lower half of the neck, the breast, shoulders, shorter scapulars, ends of the greater coverts, and sides of the rump, white; longer scapulars striped with berlin-blue, white, and blackish-brown. Lesser coverts berlin blue. Speculum brilliant grass-green, broadly bordered above, and narrowly edged below with white; bounded interiorly with greenish-black. Belly and flanks deep orange-brown, the latter undulated posteriorly with black. Bill black. Legs orange.

The bill is a little higher than wide at the base, much depressed, dilated, and rounded at the end; mandibles furnished with long slender crowded laminæ, the upper ones acute and projecting, forming an apparatus admirably fitted for sifting small insects from the water



Bill of Shoveler (*Anas clypeata*).

surface of the upper mandible pitted near its oblong unguis. Wings scarcely an inch longer than the tail, which is graduated, moderately acute, and consists of 14 acute feathers; tarsus scarcely compressed; hind toe not lobed, and the outer-toe shorter than the middle one, as in the rest of the *Anatinæ*.

The female is liver-brown above, with broad boarders of pale wood-brown; underneath pale wood-brown with obscure liver-brown marks. She wants the dark brown and green colours of the head, rump, and tail-coverts, the white of the neck, breast, sides of the rump, and scapulars, and also the orange-brown of the belly; the lesser coverts are slightly glossed with berlin-blue, and the speculum is less vivid than in the male. Length 21 inches 6 lines, &c. (Richardson.) The weight is about 22 ounces.

Temminck states that the young males in autumn, and the old males during their moult, have some of the feathers proper to the winter-plumage of the male, and others peculiar to the female, or to the young male before the moult, and that these feathers are indistinctly mingled. Young and old males in the summer-change are supposed to be the origin of the Red-Breasted Shoveler.

Shoveler (*Anas clypeata*).

The trachea of the male is of equal diameter, excepting towards the lower larynx, where it is very slightly enlarged. It forms a slight bony protuberance on the left side, which is dilated a little below. The bronchiæ are very long. (Temminck.)

It inhabits marshes, lakes, and rivers in Russia, and a great part of Asia. It is very abundant in Holland. In France, Germany, and England, it is a bird of passage, arriving in the British Islands generally about October, and departing about March. In England the principal resorts of the species are the fens of Lincolnshire and Cambridge. Bonaparte ('Specchio Comparativo') notes it as one of those birds common to the neighbourhoods of Rome and of Philadelphia, and as being rather common in both places in winter.

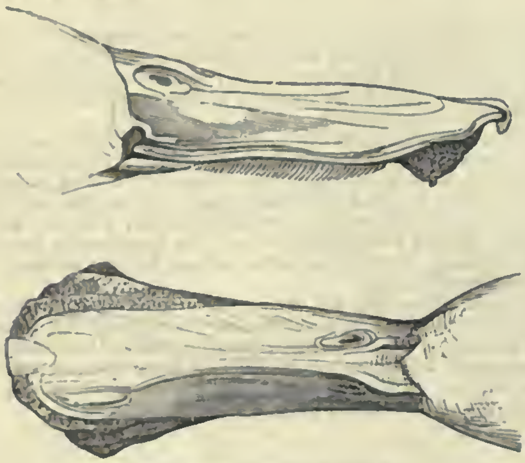
According to Latham it inhabits the Coromandel Coast and parts of India. The form occurs in Australia (New Holland Shoveler); and Swainson says that the geographical distribution of the true Shovelers may be deemed universal.

It lives on fishes and insects, rarely plants and seeds. (Temminck.)

It makes its nest upon the borders of lakes covered with reeds or coppice, and lays 12 to 14 eggs of a bright greenish-yellow, or oil-green. It is said to have bred in France, and has been known to breed in the marshes of Norfolk, and in the neighbourhood of the Tweed. But these may be deemed exceptions to the general place of nidification, which is far north.

The flesh is highly esteemed for the table, and is considered by many to excel that of the mallard, or common wild-duck, in flavour.

Malacorhynchus (Swainson).—Mr. Swainson ('Journal of the Royal Institution,' loc. cit.) observes that among the broad-billed ducks of the southern hemisphere there is a very remarkable modification of form. The breadth of the bill and the length of the laminæ are nearly the same; but the edge of the upper mandible, instead of being smooth, as in the European species, is furnished with a thin membranaceous skin, which projects considerably, and hangs down somewhat like a wattle on each side. Mr. Swainson proposes for this form the sub-generic name above given, remarking that the bill of the European Shoveler is flexible, but that in this group it is much more so. One species, he adds, described by authors under the name of the Soft-Billed Shoveler, can scarcely exhibit this debility more than another before him when he wrote his paper: it came, according to him, from the same country (Australia?), and seems to be undescribed.



Bill of *Malacorhynchus*, Swainson.

Chauliodus (Swainson).—Mr. Swainson states that the Gadwall certainly makes as near an approach to the Shovelers as any other yet known. "The form of the bill, indeed, is no longer spatulate, or perceptibly broader towards the end; but the laminæ of the upper mandible are still very fine, distinct, and more numerous than those of any other form subsequently mentioned, for they project a full tenth of an inch beyond the margin. The tail now begins to be lengthened, and in a new species from Africa (*C. Capensis*), which I have recently received, is so much attenuated, as to evince an evident affinity to the Pintail-Duck forming the sub-genus *Dafila* of Dr. Leach."

Bill of Gadwall (*Chauliodus*), Swainson.

C. strepera (Swainson), the Gadwall, or Gray.—This is the Chipeau, or Ridenne of the French; Anitra Montanara and Anatra Canapiglia of the Italians; Schwatter-Ente and Grave Mittel-Ente of the Germans; and Y gors llwyd lwyd of the Welsh.

The following is the description of a male killed on the Saskatchewan, May 22, 1827:—Top of the head and nape liver-brown, edged with gray; head beneath and neck gray, with small brown specks; base of the neck above and below, anterior part of the back, exterior scapulars, flanks, and sides of the vent, clove-brown, marked with concentric horse-shoe-shaped white lines; interior scapulars, lesser coverts, primaries, tertiaries, and tail, hair-brown; intermediate coverts chestnut-brown; greater coverts, rump, and upper and under tail-coverts, bluish-black; speculum white, its anterior border black; lower part of the breast, middle of the belly, and under surface of the wings, white; bill brownish-black, pale beneath; legs orange-coloured.

The bill as long as the head, of equal breadth and height at the rictus; depressed, but not widening anteriorly; laminæ of the mandibles rather stronger and much shorter than those of the Shoveler, but finer and more numerous than those of any northern species. The upper ones project a full tenth of an inch beyond the margin. Wings nearly equal to the tail; first and second quills equal and largest; tail consisting of 16 feathers, the lateral ones graduated; total length 23 inches, &c. (Richardson). Size rather less than that of the widgeon. Temminck makes the length 18 or 19 inches. The female has the feathers of the back of a blackish-brown, bordered by bright ruddy (roux); the breast reddish-brown, marked with black spots; no zigzags on the flanks; rump and lower coverts of the tail grayish. The trachea of the male is slightly enlarged in its diameter at about two-thirds of its length, but becomes narrower as it approaches the lower larynx: this consists of a large bony arch, with a globular or rather pyriform bladder attached to the left side, being in shape much like that of the common mallard, but smaller.

Gadwall (*Chauliodus strepera*).

This bird inhabits the marshes, &c. of the north and east of Europe, and is very abundant in Holland. It is rarely seen in the British Islands except at the period of its vernal migration, and then generally in the marshes of Norfolk. It is common in winter on the maritime coasts of France; rare in the interior. Bonaparte ('Specchio Comparativo') notes it as rather common in the neighbourhood of Rome in the winter.

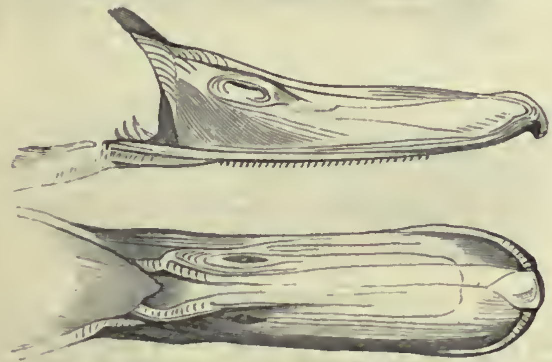
It feeds on fishes, mollusks (coquillages), insects, and aquatic plants. (Temminck.) Insects and their larvæ, aquatic plants, and seeds. (Selby.)

It makes its nest in the most covered part of marshes, or rushy meads, and lays 8 or 9 eggs of a greenish-ash, according to Temminck; 10 to 12 eggs of a pale oil-green. (Selby.)

Mr. Swainson observes that nature has now so far receded from the typical form that one of the chief peculiarities of that structure is nearly lost, and another considerably modified. The laminæ of the upper mandible, which in *C. strepera* are so much shorter than those of the true Shovelers, and are so much abbreviated in *C. Capensis*, become almost concealed by the margin of the bill in *Dafila*. "The most striking characteristic therefore of the genus we are now considering," continues Mr. Swainson, "has nearly disappeared, precisely in that form which is farthest removed from the type. But the shape of the bill, although essentially modified, has not undergone a total alteration; its breadth towards the tip is not only as great as at the base, but is even more dilated; so that in this respect it resembles the Shovelers more than the Gadwalls, while it differs from both in being higher at its base, considerably more lengthened in proportion, and much more convex throughout. It assumes, in short, a semi-cylindrical form, the end being particularly obtuse and slightly dilated; the precise point of junction between the Pintails and that group which was known to the ancients by the name of *Boschas*."

Dafila caudacuta, tbe Pintail-Duck. This is Le Canard à Long Queue ou Pilet of the French; Anitra Codilanza and Anatra di Coda Lunga of the Italians; Spiess-Ente and Fasan-Eute of the Germans; Aler, Ahlvogel, of the 'Fauna Suecica;' Sea-Pheasant, or Cracker, of Willughby; Keeneego Yaway-Sheep of the Chippeway Indians; Hwyad Gynffonfain of the Welsh; *Anas caudacuta* of Ray; *A. longicauda* of Brisson; *A. acuta* of Linnæus; *Querquedula acuta* of Selby.

The following is the description of a male killed on tbe Saskatchewan, May, 1827:—Head and adjoining part of the neck anteriorly umber-brown, witb paler edges; neck above blackish-brown; the whole of the back, shorter scapulars, sides of the breast and flanks, marked with fine waved transverse lines of brownisb white and black, most regular and broadest on the long feathers lying over the thighs; long scapulars and tertiaries black, the borders of the former and outer webs of the latter white; wing-coverts and primaries hair-brown; the primary shafts white, and the interior coverts mottled with the same; speculum dark-green, with purple reflections, bounded above by a ferruginous bar, and interiorly and below by wbite. Tail and most of its upper coverts dark-brown with pale borders. Two long ceutral npper coverts, vent, and under coverts, black; the latter bordered with wbite. A lateral streak on tbe upper part of the neck, the sides and frout of its lower part, the breast, and belly, white. The posterior part of the abdomen minutely marked with gray. Bill black; sides of the upper mandible bluish-gray. Feet blackish-gray.



Bill of Pintail-Duck (*Dafila caudacuta*), Swainson.

The bill is much lengthened, fully as long as the head, considerably higher tban wide at the base; tbe upper mandible of equal breadtb to the point; tbo laminæ not projecting beyond the margin. Wings two inches shorter than tbe tail. Scapulars, tertiaries, tail-feathers and their coverts, tapering and acute; the middle pair of tail-coverts having long slender points that project two inches and a half beyond tbe tail. Tail graduated. Tracbeal dilatation a small osseous sac, the size of a hazel-nut. Total length, 26 incbes 6 lines. (Richardson.) Selby observes that tho labyrinth of this species consists of a round long bladder situated on the left side of the arch of the lower larynx; its upper surface being ucarly even with the top of the arch, but its lower one reaching much below it. Its texture very fine, and in young birds may be indented by slight pressure, but becomes brittle in adults. The weigbt of the bird is about 24 ounces.

Pintail-Duck (*Dafila caudacuta*).

The femalo is smaller. Forehead and crown palc cbestnut-brown streaked with black. Cheeks and neck pale ochreous yellow, speckled with black. Chin and throat palc cream-yellow. Sides of the breast hair-brown, barred and tipped with wbite. Mantle and scapulars amber-brown, barred and varied with pale buff-orange and white. Tertials hair-brown, margined witb wbite. Lesser and greater wing-coverts pale broccoli-brown, edged and tipped with white. Speculum hair-brown glossed witb green, the feathers having white tips. Quills hair-brown. Tail deep hair-brown, witb imperfect bars of white and pale buff-orange; the two middle feathers exceeding tbe rest in length about half an inch. Belly and abdomen yellowish-white, indistinctly marbled witb broccoli-brown. Under tail-coverts white, speckled with chestnut-brown of different shades. Bill grayisb-black. Legs and toes gray, tinged with brown. (Selby.)

The young males bave the head red-brown spotted with black; belly yellowish; and tbe speculum of a green, inclining to olive, witbout reflections.

Selby remarks that, like many otber of tbe *Anatidæ* (particularly of the species belonging to this group), the plumage of the male Pintail, towards the end of summer, or after the sexual intercourse is completed, undergoes a remarkable change, and becomes very like that of the female. This appears to be an actual change of the colour in the feathers ratber than a renewal of them; and the same change, he adds, is observable in tbe Mallard, and the males of the Teal, Widgeon, &c. It also prevails, if not in all, at least in some species of the genus *Mergus*, as be noticed it in *M. serrator*.

It is found in the north of Europe and America; very numerous at its double passage in Holland and in France; equally abundant in Germany; in winter in the soutb. (Temmiuck.) Selby says, "It is with us a regular winter visitant, and considerable numbers are annually taken in tbe decoys of Lincolnshire, Norfolk, &c. Montagu says that it is most abundant in the north of England and Scotland, and especially in the Orkney Islands. This assertion however I must in part contradict, as the result of long observation tells me it is of rare occurrence in the northern counties of England; and the same may be said of the southern districts of Scotland, which Dr. Fleming confirms in his history of British animals. With respect to tbe Orkneys I cannot speak so confidently, although it appears probable tbat what bad becn represented to bim as tbe present species was in fact the Long-Tailed Duck (*Harelda glacialis*), whicb is found in great numbers during the winter in the bays of this group of islands. The Pintail has a wide geograpbical range, being met with in all the northern parts of Europe, Asia, and America, and retires in the summer to breed in high latitudes. Its equatorial migration extends as far as Italy; and during its periodical flight to the soutbward it occurs abundantly in Holland, France, Germany, and other contiuental states. Tbe marshes of the interior part of the country, and fresh-water lakes, are its usual places of resort." Pennant states tbat Mr. Hartlib, in the Appendix to his 'Legacy,' tells us tbat these birds are found in great abundance in Connaught in Ireland, in the month of February only, and that tbey are much esteemed for their delicacy. Prince C. L. Bonaparte ('Specchio Comparativo') notes it as not very rare in the winter near Rome.

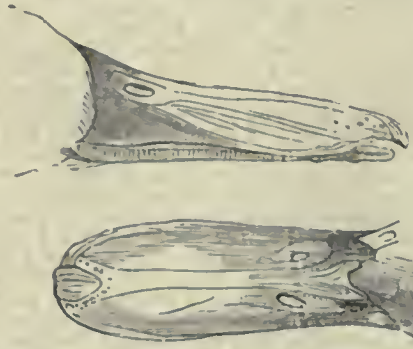
Its food is similar to that of tbe Gadwall. (Temminck.) Selby says tbat its food consists of insects and tbeir larvæ, the seeds of aquatic plants, particularly of some species of *Epilobium*, and vegetables.

The season of courtship is indicated in tbe male by suddenly raising bimself upright in tbe water, bringing his bill close to his breast, and uttering at tho same time a low soft note. This gesticulation is often followed by a jerk of the hinder part of the body, which is tben also thrown above the water. The nest is built in rushes aud the thick herbage of marshes. Eggs, from 8 to 10, bluish-white (Selby); 8 or 9, greenish-blue. (Temminck.)

Selby observes that the Pintail is easily domesticated, but rarely breeds in confinement. A hybrid progeny has been produced between it and tbe Widgeon; and to such an extent do the sexual propensities seem to be affected in this state by difference of food and other causes, that Montagu mentions a male Pintail in his menagerie which for want of the other sex showed an inclination to pair witb a female Scaup, and even with a Bernicle Goose. He further adds, that one of them did pair with a tame duck, but that none of the eggs (upwards of 20 in number) proved to be fccundated.

Boschas.—Mr. Swainsou comprehends under this sub-genus all tbose ducks usually denominated Teals, together with the Mallard, long domesticated in our poultry-yards. "As this," continues Mr. Swainson, "is by far the most uumerous group, so it exhibits a greater diversity of form among the species. They are all however characterised by a bill longer than the head, whose breadth is equal throughout; it is sometimes indeed a littlo dilated, but never contracted at its tip, wbile the laminæ of thc upper mandible are entirely concealed by the margin of tbe bill. The ueck and thc tail, which in *Dafila* are both considerably lengthened, are much shorter in this group, which is further distinguished by the brightness and beauty of plumage observed in nearly all the species. On comparing the bill of the common Teal with that of the Pintail, we see a close affinity between the two forms. But as the tail of the first is so much developed in comparison to tbat of the Teal, it becomes essential to discover, if these sub-genera actually followed each other in nature, what species united them more closely. By the uniform liberality of the zoologists attacbed to the British Museum, and more particularly Dr. J. E. Gray, I am now enabled to do tbis. The beautiful *Anas* (*Boschas*) *formosa*

Sw., or Baikal Teal of methodists, is precisely a bird which intervenes between these two sub-genera. Essentially a Teal, it differs from all others I have yet seen in the superior length of its tail, the feathers of which are a full inch longer than the under-covers; while the convexity of the bill, from being greater than in the common Teal, establishes its close approximation to *Dafila*. Proceeding thus by analysis, we find several foreign species which may be either called Teal or Ducks. The *Boschas Javensis*, Sw., is more especially a bird of this description. It is closer allied to the Mallard than to any other of the group: this is indicated by the more depressed form of the bill, and the white collar round the neck; the nape also is very conspicuously crested, a peculiarity found in no other group of the genus. To this and to the curled tail of the tame duck we shall presently advert. Having now reached what appears to be the typical form of *Boschas*, we see that nature as usual again departs from it. The bill of the Mallard is throughout more depressed than that of the common Teal. This depression in fact, from being greater than that of the Gadwall, or of the Pintail, obviously assimilates more to the Shoveler. The affinity however appears remote, since the laminæ of the Mallard are concealed, while those of the Shovelers are conspicuously projecting. If therefore the affinity was immediate, it could only be demonstrated by a species having the bill of the common duck, but with the laminæ projecting. Now such a species is actually the Blue-Winged Teal of North America, in which these



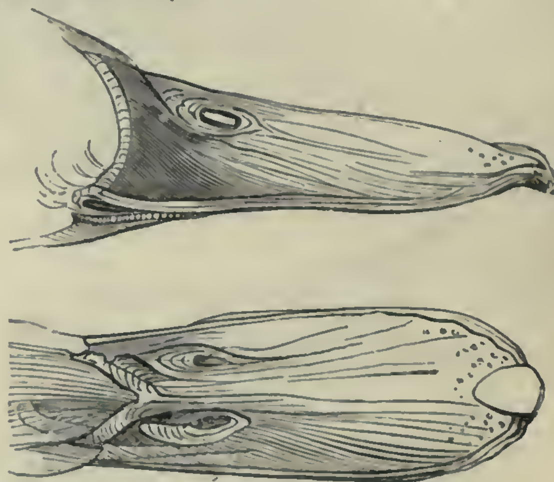
Bill of Blue-Winged Teal (*Boschas discors*).

laminæ project nearly as much as in the Gadwall, while the upper mandible exhibits that peculiar sinuosity towards the base which is seen in no other ducks besides the Shovelers. If this affinity required any further support, it is placed beyond doubt by the fact mentioned in the 'General History of Birds,' that the plumage of the New Holland Shoveler, excepting the white facial crescent, is precisely the same as that of the Blue-Winged Teal,—the very bird which thus unites the sub-genus *Boschas* to that of *Anas*, and completes the circle of the whole group."

Blue-Winged Teal (*Boschas discors*).

B. domestica, the Common Mallard, or Wild Duck. Both sexes of this beautiful bird are so well known that either description or figure would be superfluous. It is the Canard Sauvage of the French; Capo Verde (the male), Anitra (the female), Germano, and Paperone, of the Italians; Wilde Ente and Gemeine Ente of the Germans; Ethinneesen Sheesheep of the Cree Indians; Stock-Duck of the Hudson's Bay residents; and Cors Hwyad, Garan Hwyad, and Hydnwy, of the Welsh.

The weight of the wild Mallard is usually about two pounds and a half. The abundance of the bird at one time in Britain may be judged of from the following passage in Pennant:—"Amazing numbers of ducks, widgeons, and teals are taken: by an account sent us of the number caught, a few winters past, in one season, and in only ten decoys, in the neighbourhood of Wainfleet, it appeared to amount to 31,200, in which are included several other species of ducks; it is also to be observed that, in the above particular, widgeon and teal are reckoned but as one, and consequently sell but at half the price of ducks. . . . The account of the numbers here mentioned relates only to those that were sent to the capital. It was customary formerly to have in the fens an annual driving of the young ducks before they took wing. Numbers of people assembled, who beat a vast tract, and forced the birds into a net placed at the spot where the sport was to terminate. A hundred and fifty dozens have been taken at once; but this practice being supposed to be detrimental, has been abolished by act of parliament." Selby observes upon this, that the same district at the present time does not produce perhaps a dozen broods in the year.



Bill of Mallard (*Boschas domestica*), Swainson.

Mr. Waterton has pointed out that the duck and the drake are clothed in the same plumage only for a very short time in the summer. Mr. Selby's observations on the change of plumage are referred to under the account of the Pintail.

The trachea of the Mallard has at its lower extremity a labyrinth much larger than that of the Gadwall, but not unlike it; the tube does not differ much in diameter throughout its length.

The Wild Duck is widely spread over a considerable portion of the globe. Few of the temperate and arctic regions are without it. Temminck places its habitation in the northern countries, and observes that it is known as a bird of passage nearly throughout Europe, haunting rivers, lakes, and marshes. Prince C. L. Bonaparte ('Specchio Comparativo') mentions it as very common near Rome in winter.

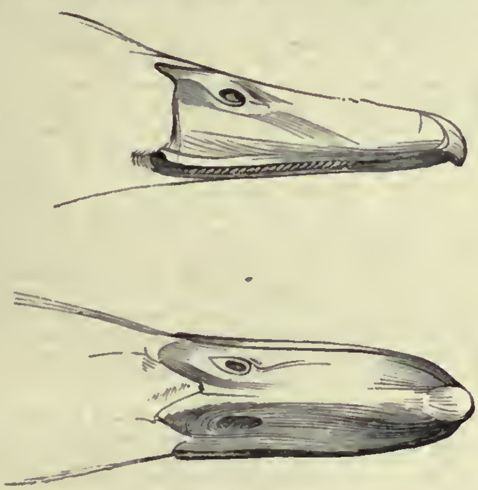
The Wild Duck feeds on fishes, fry or spawn, slugs, water-insects, aquatic plants, their seeds, and all sorts of grain (Temminck)—insects, worms, slugs, and all kinds of grain, &c. (Selby.)

"In a natural state," says Selby, "wild ducks always pair, though in a state of domestication they are observed to be polygamous. The pairing takes place towards the end of February or beginning of March, and they continue associated till the female begins to sit, when the male deserts her, joining others of his own sex similarly situated; so that it is usual to see the mallards, after May, in small flocks by themselves. About this time also they begin to undergo the changes of colour that assimilate them in a great degree to the female, and which is retained till the period of the autumnal or general moult. The care of the young thus devolves entirely upon the duck, and is not partaken by the male, as Wilson and others appear to think; and this fact I have had frequent opportunities of verifying, as many wild ducks annually breed upon the edges of our Northumbrian moors, and the young broods are of course frequently under inspection as they descend the rivulets to the lower marshy parts of the country. The nest of the wild duck is generally made in some dry spot of the marshes, and not far from water, to which she can lead her progeny as soon as hatched. It is composed of withered grass and other dry vegetable matter, and usually concealed from view by a thick bush or some very rank herbage, though other and very dissimilar situations are occasionally chosen, as several instances have been recorded where they have deposited their eggs on the fork of a large tree, or in some deserted nest. Such an instance once occurred within my knowledge, and near my own residence, where a wild duck laid her eggs in the old nest of a crow, at least thirty feet from the ground. At this elevation she hatched her young; and as none of them were found dead beneath the tree, it is presumed she carried them safely to the ground in her bill, a mode of conveyance known to be frequently adopted by the Eider-Duck." Montagu ('Ornith. Dict.' Suppl.) says, "We have been assured by a person of undoubted veracity that a half-domesticated duck made a nest in Rumford Tower, hatched her young, and brought them down in safety to a piece of water at a considerable distance. Others have been known to breed in trees; and we recollect the nest of this bird being found in the head of an old pollard willow, impending the water, from whence the young might readily drop unhurt into their natural element. Mr. Tunstall mentions one, at Etchingham, in Sussex, which was found sitting upon nine eggs, on an oak-tree, twenty-five feet from the ground: and the author of the 'Rural Sports' records an instance of one taking possession of the nest of a hawk in a large oak. To these we can add, upon the testimony of a gentleman of the strictest veracity, that out of a large flock of half-domesticated ducks, one deposited her eggs in the principal fork of a large tree near his house." The eggs are 10 to 14, of a bluish-white; the female, when she quits the nest for food, covers them with down and other substances.

In a domesticated state it is most widely distributed. All the varieties that the fancy of the breeder can produce are to be seen in the various poultry-yards. To say nothing of the Aylesbury and other breeds, where size and delicacy of flesh have been principally considered, we find penguin ducks standing nearly erect, hooked-bill ducks, and even a variety where the caprice of man has succeeded in nearly obliterating the webs of the feet, and curtailing the bill till it has lost its spatulate shape and is become a deformity, bearing some resemblance to the bill of a common fowl. Some of these birds have been shown as the offspring of a cock and a duck, we need hardly say, without the slightest foundation for the monstrous assertion. Selby observes, that in the domesticated varieties the peculiar specific distinction of the curled feathers of the tail is still retained. In China and the other countries of the East, numbers of ducks are hatched by artificial means.

Latham states that the male Muscovy Duck and common duck will breed together. The young bear a greater resemblance to the common duck than to the Muscovy Duck.

Mareca, Stephens.—In 'Fauna Boreali-Americana,' Mr. Swainson places the genera *Mareca* and *Dendronessa* in his sub-family *Anatinæ*.



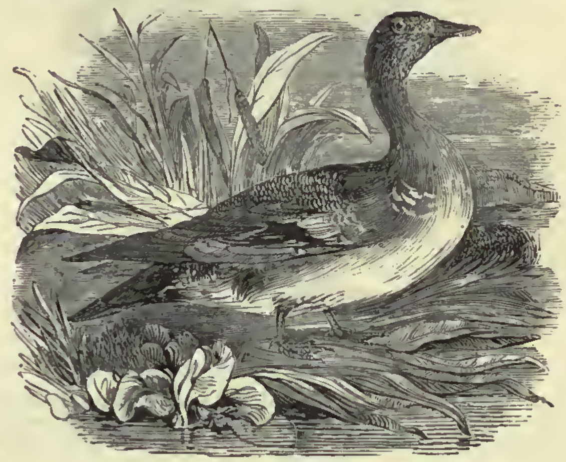
Bill of Widgeon (*Mareca*).

Selby says that the Widgeons are distinguished from the Teals by a much shorter and less cylindrical bill; and from the Ducks, by that member becoming more contracted and narrow, instead of widening towards its tip. The laminæ of the bill are also broader and set wider apart, approaching in form nearer to those of the sub-family *Anserina*. These birds, he adds, also vary in their habits, for instead of searching and sifting the mud with their bills for insects, seeds, &c., upon which food most of the other genera live, they subsist principally on grasses and vegetable diet, which they pluck in the same manner as geese. Their flight is strong and swift, and they have a peculiar shrill whistling call-note. In the shape of the tracheal labyrinth they resemble the Pintail more than any other species: the middle feathers of the tail are also acute, and considerably longer than the rest.

M. Americana (Stephens), American Widgeon. This is the *Anas Americana* of Gmelin and of Sabine, in Frankland's 'Journal,' and Atheekemow-weeshep of the Cree Indians.

The following is a description of a male killed on the Saskatchewan, May, 1827:— A white band from the forehead to the nape, bounded behind the eye by a broad dark-green patch, which ends in the nuchal crest. Upper part and sides of the breast brownish-red, glossed with gray. Base of the neck above, interscapulars, scapulars, and flanks, minutely undulated with brownish-red and black; hind part of the back undulated in a similar manner with clove-brown and white, the latter colour prevailing on the tail-coverts. Lesser wing-coverts, primaries, and tail, clove-brown; intermediate and greater coverts, sides of the rump, breast, and belly, pure white. Speculum velvet-black below, duck-green above, bounded superiorly with black and posteriorly with white. Exterior webs of the tertiaries, and lateral and inferior tail-coverts, greenish-black, the first bordered with white. Bill bluish-gray, bordered and tipped with black.

The bill is particularly short, being not so long as the head, armed with laminæ resembling those of the mallard. Plumage of the nape somewhat lengthened. Wings, above an inch shorter than the acutely-pointed tail, which consists of 14 feathers. Total length, 23 inches. The female has the upper plumage dark liver-brown, edged and remotely barred with pale-brown and white. The intermediate wing-coverts are merely edged with white, and there is no green on the head. Tail, shorter and not so tapering. Total length about two inches less than the male. (Richardson.)



American Widgeon (*Mareca Americana*).

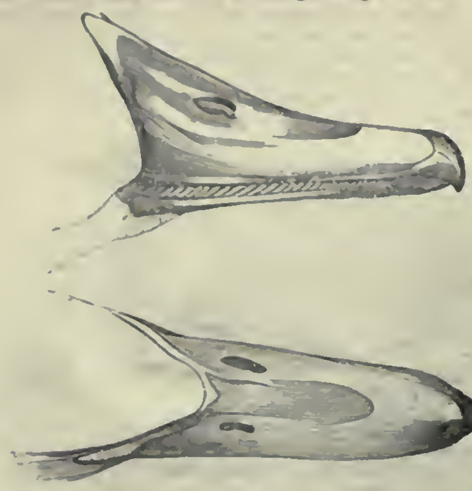
Wilson says this bird is very common in winter along the whole coast from Florida to Rhode Island; but most abundant in Carolina, where it frequents the rice plantations. In Martinico great flocks take short flights from one rice-field to another during the rainy season, and are much complained of by the planters. They are said to be in great plenty in St. Domingo and Guyana, where they are called Vingeon or Gingeon. Are said sometimes to perch on trees. Feed in company (but little in the day), and have a sentinel on the watch. Come out from their hiding-places in the evening. Are not known to breed in any part of the United States. Are common in the winter months along the bays of Egg Harbour and Cape May, and also those of the Delaware. They leave their places in April, and appear upon the coast of Hudson's Bay in May, as soon as the thaws come on, chiefly in pairs; lay there only from six to eight eggs, and feed on flies and worms in the swamps; depart in flocks in autumn. (Wilson here quotes Hutchins.) Wilson further states, that the Widgeon is extremely fond of the tender roots of that particular species of aquatic plant on which the Canvass-Back Duck, so abundant in Chesapeak Bay, feeds. The Widgeon is its constant companion; and the Widgeon, which never dives, watches the moment of the Canvass-Back's rising with the morsel for which the latter bird has dived, and before he has his eyes well opened, snatches it and makes off. On this account the Canvass-Backs and Widgeons, or, as they are called round the bay, Bald Pates, live in a state of perpetual contention.

Dendronessa (Swainson).—Head crested. Bill as high at the base as it is broad; towards the tip narrow and contracted. Nostrils placed towards the middle of the bill. Tertial feathers ornamented. Feet as in *Anas*. Type, *Dendronessa galericulata*, Chinese Teal. Edwards, pl. 102.

Mr. Swainson, who thus characterises the genus, observes ('Fauna Boreali-Americana') that "this is obviously the Rasorial type of the *Anatinæ*. The *D. sponsa*, by the lateral advancement of the bill towards the eye, is a more aberrant species, and shows the connection of the group to *Somateria*."

D. sponsa (Swainson), the Summer-Duck. This is the Wood-Duck of Audubon, Ansee-awmo of the Chippeways, *Anas sponsa* of Linnæus.

The following is a description of a male killed at Cumberland House, lat. 54°; June, 1827. Head above and space between the eye and bill glossy dark-green; cheeks and a large patch on the sides of the throat purple, with blue reflections; pendent occipital crest of green and auricula purple, marked with two narrow white lines, one of them terminating behind the eye, the other extending over the eye to the bill; sides of the neck purplish-red, changing on the front of the neck and sides of the breast to brown, and there spotted with white. Scapulars, wings, and tail, exhibiting a play of duck-green, purple, blue, and velvet-black colours; interscapulars, posterior part of the back, rump, and upper tail-coverts, blackish green and purple; several of the lateral coverts reddish-orange; a hair-like, splendent, reddish-purple tuft on each side of the rump; the under coverts brown. Chin, throat, a collar round the neck, a crescentic bar on the ears, the middle of the breast, and whole of the abdomen, white. Flanks yellowish-gray, finely undulated with black; the tips of the long feathers, and also those on the shoulder, broadly barred with white and black. Inner wing-coverts white, barred with brown. Almost all the coloured plumage shows a play of colours with metallic lustre. Bill red; a space between the nostrils, its tip, margins, and lower mandible, black. Legs orange-coloured.



Bill of Summer-Duck (*Dendronessa sponsa*), Swainson.

The bill shorter than the head; considerably narrowed towards the tip, like that of the Eider; its height at the rictus greater than its width; its frontal angles prolonged. Mandibles strongly toothed. Unguis strong, arched or hooked. Nostrils large, pervious, lateral. Forehead sloping. Occipital crest long and pendent. Wings shorter than the tail, which consists of 16 wide rounded feathers. Total length 21 inches. The female wants the fine lines on the flanks and the hair-like tufts on the sides of the rump. She has a shorter crest; and the plumage is less vivid, especially about the head, where it is mostly brown. (Richardson.)

Summer-Duck (*Dendronessa sponsa*), male.

Audubon states that this species ranges over the whole extent of the United States, and that he saw it in all parts, from Louisiana to the confines of Maine, and from the vicinity of the Atlantic coasts as far inland as his travels extended. It also occurs sparingly during the breeding season in Nova Scotia; but farther north he did not observe it. Everywhere in this immense tract he found it an almost constant resident; for some spend the winter even in Massachusetts, and far up the warm spring waters of brooks on the Missouri. It confines itself however entirely to fresh-water, preferring at all times the secluded retreats of the ponds, bayous, or creeks, that occur so profusely in the woods. Well acquainted with man, they carefully avoid him, unless during the breeding season, when, if a convenient spot is found by them, they will even locate themselves about the miller's dam.

Catesby says that the Summer-Ducks breed in Virginia and Carolina, and make their nests in the holes of tall trees (made by woodpeckers) growing in water, particularly cypress trees. "While they are young and unable to fly, the old ones carry them on their backs from their nests into the water; and at the approach of danger, they fix with their bills on the backs of the old ones, which fly away with them." Audubon's evidence, which we here give, differs from that of Catesby in some particulars. "The Wood-Duck breeds in the Middle States about the beginning of April, in Massachusetts a month later, and in Nova Scotia or on our northern lakes seldom before the first days of June. In Louisiana and Kentucky, where I have had better opportunities of studying their habits in this respect, they generally pair about the 1st of March, sometimes a fortnight earlier. I never knew one of these birds to form a nest on the ground or on the branches of a tree. They appear at all times to prefer the hollow broken portion of some large branch, the hole of our largest woodpecker (*Picus principalis*), or the deserted retreat of the fox squirrel; and I have been frequently surprised to see them go in and out of a hole of any one of these, when their bodies while on wing seemed to be nearly half as large again as the aperture within which they had deposited their eggs. Once only I found a nest (with ten eggs) in the fissure of a rock on the Kentucky river, a few miles below Frankfort. Generally however the holes to which they betake themselves are either over deep swamps, above cane-brakes, or broken branches of high sycamores, seldom more than 40 or 50 feet from the water. They are much attached to their breeding places, and for three successive years I found a pair near Henderson, in Kentucky, with eggs in the beginning of April, in the abandoned nest of an ivory-billed woodpecker. The eggs, which are from six to fifteen, according to the age of the bird, are placed on dry plants, feathers, and a scanty portion of down, which I believe is mostly plucked from the breast of the female. They are perfectly smooth, nearly elliptical, of a light colour between buff and pale green, two inches in length by one and a half in diameter; the shell is about equal in firmness to that of the mallard's egg, and quite smooth. No sooner has the female completed her set of eggs than she is abandoned by her mate, who now joins others, which form themselves into considerable flocks, and thus remain apart until the young are able to fly, when old and young of both sexes come together, and so remain until the commencement of the next breeding season. In all the nests which I have examined, I have been rather surprised to find a quantity of feathers belonging to birds of other species, even those of the domestic fowl, and particularly of the wild goose and wild turkey. On coming upon a nest with eggs when the bird was absent in search of food, I have always found the eggs covered over with feathers and down, although quite out of sight in the depth of a woodpecker's or squirrel's hole. On the contrary, when the nest was placed in the broken branch of a tree, it could easily be observed from the ground, on account of the feathers, dead sticks, and withered grasses about it. If the nest is placed immediately over the water, the young, the moment they are hatched, scramble to the mouth of the hole, launch into the air with their little wings and feet spread out, and drop into their favourite element; but whenever their birthplace is at some distance from it the mother carries them to it one by one in her bill, holding them so as not to injure their yet tender frame. On several occasions however when the hole was thirty, forty, or more yards from a bayou or other piece of water, I observed that the mother suffered the young to fall on the grasses and dried leaves beneath the tree, and afterwards led them directly to the nearest edge of the next pool or creek."

D. galericulata and *D. sponsa* breed freely in captivity. Both species have produced several broods in the Gardens of the Zoological Society in the Regent's Park, where most of the *Anatinæ* are exhibited. The latter has also bred in St. James's Park, where they and other *Anatinæ* may be always seen.

Mandarin Duck (*Dendronessa galericulata*), male.

Colonel Sykes, in his 'Catalogue of Birds observed in the Dukhun' (Deccan), enumerates the following British *Anatinæ*—*Anas strepera*, Linn., males identical with specimens in the British Museum, from

Kent; no females for comparison; numerous in Dukhun; *Rhynchaspis virescens*, Leach, Manuscripts, *Anas clypeata*, Linn.; identical with British specimens of the common Shoveler, but differing from the description of that bird in Shaw; *Mareca fistularis*, Steph., *Anas Penelope*, Linn., Widgeon, absolutely identical with specimens from Devonshire; *Querquedula Circia*, Steph., *Anas Circia*, Linn., Garganey, identical with British specimens; *Querquedula crecca*, *Anas crecca*, Linn., Common Teal, identical with male and female British specimens.

Mr. Keith Abbott ('Zool. Proc.,' 1834), in his 'List of Trebizond Birds,' ennmerates *Anas Boschas*, Linn., the Mallard, as almost universal; and *A. Querquedula*, Linn., which is noted as inhabiting India as well as Europe, and as common in the Himalaya range.

The sub-family *Fuligulinæ* includes the genera *Somateria*, *Oidemia*, *Fuligula*, *Clangula*, and *Harelda*.

The *Fuligulinæ*, or Sea-Ducks, as they have been not inaptly named, frequent the sea principally; but many of them are to be found in the fresh-water lakes and rivers where the water is deep. The plumage is very close and thick in comparison with that of the True Ducks (*Anatinæ*), and the covering of the female differs much in hue from that of the male, which when adnlt undergoes but little change in its dress from the difference of season. The young resemble the female in their feathered garb, and do not assume the adult plumage till the second or third year. Moulting takes place twice a year, without change of colour. In the male the capsule of the trachea is large.

The Sea-Ducks are not good walkers, on account of the backward position of their feet, but they run, or rather shuffle along rapidly, though awkwardly. They swim remarkably well, though low in the water, and excel in diving, whether for amusement, safety, or food, which last consists of insects, mollusks, the fry of fish, and marine or other aquatic vegetables. They take wing unwillingly as a security from danger, relying more confidently on their powers of diving and swimming as the means of escape than on those of flight. Though they are often strong, steady, rapid, and enduring in their passage through the air, they generally fly low, laboriously, and with a whistling sound.

This sub-family may be considered to be monogamous, and the nest is frequently made near the fresh waters; the female alone incubating, though both parents, in several of the species at least, strip the down from their breasts as a covering for the eggs, which are numerous.

The North may be considered the great hive of the *Fuligulinæ*; though some of the forms are spread over the greater part of the globe. Large flocks are seen to migrate periodically, keeping for the most part the line of the sea-coast, and flying and feeding generally by night, though often, especially in hazy or blowing weather, by day.

Somateria (Leach).—Bill small, with the base elevated and extending up the forehead, where a central pointed line of feathers divides it; the anterior extremity narrow but blunt; nostrils mesial; neck thick; wings short; tertiaries long, and generally with an outward curve, so as to overlie the primaries. Tail moderate, consisting of 14 feathers.

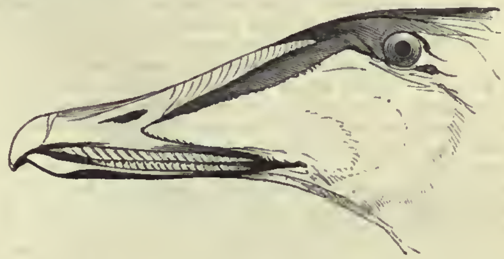
This genus is peculiarly marine. Sir John Richardson, whose opportunities of observing the northern birds were so great and so well used, says that *Somateria spectabilis* and *S. mollissima* are never, as he believes, seen in fresh water; their food consisting mostly of the soft *Mollusca* in the Arctic Sea. They are, he says, only partially migratory, the older birds seldom moving farther southward in winter than to permanent open water. He states that some Eider-Ducks pass that season on the coast of New Jersey, but that the King-Ducks (*S. spectabilis*) have not been seen to the southward of the 59th parallel. Audubon however says that in the depth of winter the latter have been observed off the coast of Halifax in Nova Scotia, and Newfoundland, and that a few have been obtained off Boston, and at Eastport in Maine.

The genus is remarkable for the high development of the exquisitely soft and elastic down so valuable in commerce, and so essential to the keeping up of the proper balance of animal heat in the icy regions inhabited by these birds.

S. mollissima (*Anas mollissima*, Linn.), the Eider-Duck. This is the Oie à Duvet ou Eider of the French; Eider-Gans and Eiter-Ente of the Germans; Oca Settentrionale of the Italians ('Stor. degli Ucc.'); the Eider-Goose, Eider-Duck, St. Cuthbert's Duck, Cuthbert Duck or Cutbert Duck, Great Black and White Duck, and Colk Winter Duck, of the British; Hwyad fwythblu of the Welsh; Dunter Duck of the Hudson's Bay residents; and Mittek of the Esquimaux.

The following is Sir John Richardson's description of a male killed June 14, 1822, at Winter Island, 66° 11½′ N. lat.:—Circumference of the frontal plates, forehead, crown, and under eye-lid, deep Scotch blue; hind head, nape, and temples, siskin-green. Stripe on the top of the head, cheeks, chin, neck, breast, back, scapulars, lesser coverts, curved tertiaries, sides of the rump, and under wing-coverts, white; the tertiaries tinged with greenish-yellow, and the breast with buff. Greater coverts, quills, rump, tail and its coverts, and the under plumage, pitch black; the end of the quills and tail fading to brown. Bill, oil-green. Legs, greenish-yellow.

The bill is prolonged on the lengthened depressed forehead into two narrow flat plates that are separated by an angular projection of the frontal plumage. Nostrils not pervious. Neck short and thick. Wings nearly three inches shorter than the tail. Hind toe attenuated posteriorly into a broad lobe. The length of this bird was 25 inches 6 lines. The female is pale rufous or yellowish brown with black bars; wing-coverts black with ferruginous edges; greater coverts and secondaries with narrow white tips; head and upper part of the neck striped with dusky lines; beneath, brown with obscure darker blotches.



Bill of Eider-Duck (*Somateria mollissima*).

The young at the age of a week are of a dark mouse-colour, thickly covered with soft warm down.

The young male is like the female; and does not appear in the full adult male plumage till the fourth year.

The icy seas of the north appear to be the principal localities of this species. Colonel Sabine enumerates it among the animals which were met with during the period in which the expedition under Captain Parry remained within the arctic circle. He mentions it as abundant on the shores of Davis's Strait and Baffin's Bay; but adds that, deriving its food principally from the sea, it was not met with after the entrance of the ships into the Polar Ocean, where so little open water is found. The females were without the bands on the wings described by authors. ('Appendix to Captain Sir W. E. Parry's First Voyage,' 1819-20.) Captain Lyon saw the Eider in Duke of York's Bay. ('Journal.') Sir James Ross ('Appendix to Captain Sir John Ross's Last Voyage') notices vast numbers of the King-Duck as resorting annually to the shores and islands of the arctic regions in the breeding season, and as having on many occasions afforded a valuable and salutary supply of fresh provision to the crews of the vessels employed in those seas. Speaking of the Eider-Duck he says it is so similar in its habits to the King-Duck that the same remarks apply equally to both. In Lapland, Norway, Iceland, Greenland, and at Spitzbergen, the Eider-Duck is very abundant; and it abounds also at Behring's Island, the Kuriles, the Hebrides, and Orkneys. In Sweden and Denmark it is said to be more rare, and in Germany to be only observed as a passenger. Temminck states that the young only are seen on the coasts of the ocean, and that the old ones never show themselves. Sir James Ross, in the 'Appendix' above alluded to, speaking of the eider-down, says that the down of the King-Duck is equally excellent, and is collected in great quantities by the inhabitants of the Danish colonies in Greenland, forming a valuable source of revenue to Denmark. A vast quantity of this down, he adds, is also collected on the coast of Norway and in some parts of Sweden. The Eider-Duck is found throughout Arctic America, and is said to wander in severe winters as far south to sea as the capes of the Delaware. From November to the middle of February small numbers of old birds are usually seen towards the extremities of Massachusetts Bay and along the coast of Maine. A few pairs have been known to breed on some rocky islands beyond Portland, and M. Audubon found several nesting on the island of Grand Manan in the Bay of Fundy. Prince Bonaparte notes it as rare and adventitious in the winter at Philadelphia. The most southern breeding-place in Europe is said to be the Fern or Farn Isles on the coast of Northumberland.

Willughby, quoting Wormius, says that the Eider-Ducks "build themselves nests on the rocks, and lay good store of very savoury and well-tasted eggs; for the getting of which the neighbouring people let themselves down by ropes dangerously enough, and with the same labour gather the feathers (Eider-Dun our people call them), which are very soft and fit to stuff beds and quilts; for in a small quantity they dilate themselves much (being very springy), and warm the body above any others. These birds are wont at set times to moult their feathers, enriching the fowlers with this desirable merchandise." Willughby also remarks that "when its young ones are hatched it takes them to the sea, and never looks at land till next breeding time, nor is seen anywhere about our coasts." This early account is in the main correct, but there are two kinds of eider-down—the live-down, as it is termed, and the dead-down; the latter, which is considered to be very inferior in quality, is that taken from the dead bird. The down of superior quality, or live-down, is that which the duck strips from herself to cherish her eggs. Its lightness and elasticity are such, it is asserted, that two or three pounds of it squeezed into a ball which may be held in the hand, will swell out to such an extent as to fill a case large enough for the foot covering of a bed. It is collected in the following manner:—The female is suffered to lay her five or six eggs, which are about three inches in length and two in breadth. These, which are very palatable, are taken, and she strips herself a second time to supply the subsequent eggs. If this second batch be abstracted, the female being unable to supply any more down, the male plucks his breast, and his contribution is known by its pale colour. The last deposit, which rarely consists of more than two or three eggs, is always left; for if deprived of this their last hope the bereaved birds forsake the inhospitable place; whereas, if suffered to rear their young, the parents return the following year with their progeny. The quantity of down afforded by one female during the whole period of laying is stated at half a pound neat, the quantity weighing nearly a pound before it is cleansed. Of this down Troil states that the Iceland Company sold in one year (1750) as much as brought 850*l.* sterling, besides what was sent to Glückstadt.

Eider-Duck (*Somateria mollissima*), male and female.

The haunts of birds capable of producing so valuable an article are not unlikely to be objects of peculiar care. We accordingly find that in Iceland and Norway the districts resorted to by them are reckoned valuable property, and are strictly preserved. Every one is anxious to induce the Eiders to take up their position on his own estate; and when they show a disposition to settle on any islet the proprietor has been known to remove the cattle and dogs to the mainland in order to make way for a more valuable stock which might be otherwise disturbed. In some cases artificial islets have been made by separating promontories from the continent; and these eider-tenements are handed down from father to son like any other inheritance. Notwithstanding all this care to keep the birds undisturbed, they are not, as we shall presently see, scared by the vicinity of man, in some places at least. We proceed to give the personal observations of some of those who have visited eider-settlements:—"When I visited the Farn Isles," writes Pennant (it was on the 15th of July, 1769), "I found the ducks sitting, and took some of the nests, the base of which was formed of sea-plants and covered with the down. After separating it carefully from the plants it weighed only three-quarters of an ounce, yet was so elastic as to fill a larger space than the crown of the greatest hat. These birds are not numerous on the isles, and it was observed that the drakes kept on those most remote from the sitting-places. The ducks continue on their nests till you come almost close to them, and when they rise are very slow flyers. The number of eggs in each nest was from three to five, warmly bedded in the down, of a pale olive colour, and very large, glossy, and smooth." Horrebow declares that one may walk among these birds while they are sitting without scaring them; and Sir George Mackenzie, during his travels in Iceland, had an opportunity, on the 8th of June at Vidöe, of observing the Eider-Ducks, at all other times of the year perfectly wild, assembled for the great work of incubation. The boat in its approach to the shore passed multitudes of these birds, which hardly moved out of the way; and between the landing-place and the governor's house it required some caution to avoid treading on the nests, while the drakes were walking about even more familiar than common ducks, and uttering a sound which was like the cooing of doves. The ducks were sitting on their nests all round the house, on the garden wall, on the roofs, nay even in the inside of the houses and in the chapel. Those which had not been long on the nest generally left it when they were approached; but those that had more than one or two eggs sat perfectly quiet and suffered the party to touch them, though they sometimes gently repelled the intrusive hand with their bills. But if a drake happen to be near his mate when thus visited he becomes extremely agitated. He passes to and fro between her and the suspicious object, raising his head and cooing.

M. Audubon saw them in great numbers on the coast of Labrador—where, by the way, the down is neglected—employed about their nests, which they begin to form about the end of May. They arrive there and on the coasts of Newfoundland about the first of that month. The eggs were of a dull greenish-white, and smooth, from 6 to 10 in number. The nest was usually placed under the shelter of a low prostrate branched and dwarf fir; and sometimes there were several under the same bush, within a foot or two of each other. The ground-work of the nests consisted of sea-weeds and moss, and the female did not add the down till the eggs were laid. The duck, having at this time acquired an attachment for her eggs, was easily approached, and her flight was even and rather slow. Audubon states that, as soon as incubation has commenced, the males leave the land, and join together in large flocks out at sea: they begin to moult in July, and soon become so bare as to be scarcely able to rise from the water. By the 1st of August, according to the same author, scarcely an Eider-Duck was to be seen on the coast of Labrador. The young, as soon as hatched, are led by the female to the water, where they remain, except at night and in stormy weather. Their greatest feathered enemy is the Saddle-Backed Gull, or Black-Backed Gull (*Larus marinus*), which devours the eggs and young, but whose pursuit the young, after they have left the nest, elude by diving, at which both old and young are very expert.

According to Brunnich and others, the male utters a hoarse and moaning cry at the pairing time, but the cry of the female is like that of the common duck. Both sexes assist in forming the nest, though the female only sits: but the male watches in the vicinity, and gives notice of the danger. This seems to be confirmed by the account given of the nesting-place at Vidöe. Sometimes two females deposit their eggs in the same nest, and sit amicably together. The gulls are not their only enemies in addition to man, for the ravens often suck their eggs and kill their young. At sea, several hatches congregate, led by the females, and there they may be seen splashing the water in the shallows, to beat up the small crustaceans and mollusks, and diving in deeper water for the larger marine animals, among which muscles and other conchifers, turbinated testaceans, and occasionally Sea-Eggs (*Echini*) are said to be taken.

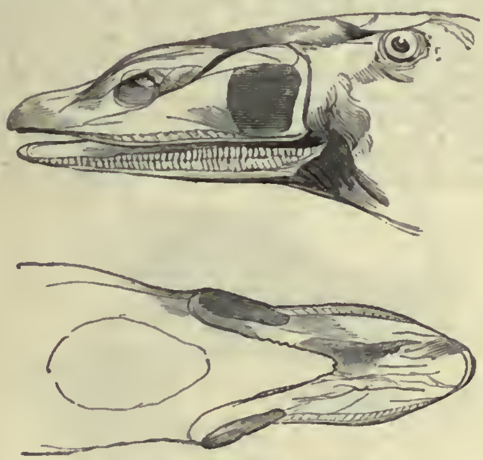
The down above described is the principal tribute paid by the Eider-Duck to man: but the Indian and Greenlander eat the flesh, which is dark and fishy, and their skin is converted into a warm inner garment. According to Sir W. E. Parry, the Esquimaux Indians catch these birds with springes made of whalebone, and take the eggs wherever they can find them. The skin, prepared with the feathers on, forms an article of commerce, particularly with the Chinese. M. Audubon is of opinion that if this valuable bird were domesticated, it would prove a great acquisition, both on account of its down, and its flesh as an article of food; and he is persuaded that very little attention would effect this. Indeed, it appears that the experiment was made at Eastport with success, but the greater number of the ducks were shot, being taken by gunners for wild birds. The same author says that, when in captivity, it feeds on different kinds of grain and moistened corn-meal, when its flesh becomes excellent. Mr. Selby succeeded twice in rearing Eiders from the egg, and kept them alive upwards of a year, when they were accidentally killed.

Oidemia (Fleming).—Bill broad with dilated margins, and coarse lamelliform teeth, gibbous above the nostrils, which are nearly mesial, large, and elevated; tail of 14 feathers.

The *Oidemiæ* seek their food at sea principally; and have obtained the name of Surf-Ducks, from frequenting its edge. The prevailing colour of the tribe is black in the male, and brown in the female. The plumage is very thick and close; and, according to Audubon, the down in the Velvet-Duck (*Oidemia fusca*) is similar to that of the Eider-Duck, and apparently of equal quality. Their flesh is high-flavoured and oily, according to Sir John Richardson, who gives that character to the flesh of three species, namely, *O. perspicillata*, *O. fusca*, and *O. nigra*. The two former, according to that enterprising zoologist, breed on the arctic coasts, migrate southward in company with *Clangula* (*Harelda?*) *glacialis*, halting both on the shores of Hudson's Bay and on the lakes of the interior, as long as they remain open, and then feed on tender shelly *Mollusca*. *O. nigra*, he adds, frequents the shores of Hudson's Bay, and breeds between the 50th and 60th parallels. It was not seen in the interior.

O. perspicillata, *Anas perspicillata* of Linnæus, the Black or Surf-Duck. This is the Macreuse à Large Bec, ou Marchand, and Canard Marchand, of the French; the Black-Duck, of Pennant; and the Great Black-Duck from Hudson's Bay of Edwards.

The male is velvet black, with a reddish reflection; throat brownish; a broad white band between the eyes, and a triangular patch of the same on the nape; bill reddish-orange, the nail paler; a square black spot on the lateral protuberance; legs orange; webs brown; bill much like that of the Velvet-Duck (*O. fusca*), but the lateral protuberances are naked and horny, and the central one is feathered farther down; the laminæ are distant, and the lower ones particularly prominent, with cutting edges. As in the other *Oidemiæ*, the bill and forehead are inflated, causing the head to appear lengthened and the crown depressed; the nostrils are rather large, and nearer to the point than to the rictus. Length 24 inches. (Richardson.)



Bill of Surf-Duck (*Oidemia perspicillata*).

The female and young are of a black ashy brown wherever the male is deep black. Head and neck lighter; frontal band and great angular space upon the nape indicated by very bright ashy brown. Lateral protuberances of the bill but little developed, and the whole bill of an ashy yellowish colour. Feet and toes brown; webs black. (Temminck.) Sir John Richardson observes that the under plumage in particular is paler, that the back and wing-coverts are narrowly edged with gray, that the breast, flanks, and ears have some whitish edgings, that the bill is black, its base not so much inflated, and that the nostrils are smaller than in the male.

This bird is rare and accidental in the Orcades, and in the higher latitudes towards the pole; very rare in the cold and temperate countries bathed by the ocean; very common and numerous in America, at Hudson's and Baffin's Bays. Such is Temminck's account. Nuttall says that this species of duck, with other dark kinds commonly called on the other side of the Atlantic 'coots,' may be properly considered as an American species; its visits in the Orkneys and European seas being merely accidental. They breed on the arctic coasts, and extend their residence to the opposite side of the continent, having been seen at Nootka Sound by Captain Cook. The bird is not mentioned in the notice of the animals which were met with during the period in which the expedition remained within the arctic circle, appended to Captain Sir W. E. Parry's 'First Voyage,' nor in Captain James Ross's 'Appendix to Captain Sir John Ross's Last Voyage.' Prince Bonaparte notes it as very common, and most abundant in the sea in the neighbourhood of the shore at Philadelphia.

In summer the Surf-Duck feeds principally in the sea, and haunts shallow æstuaries, bars, and bays, where it may be seen constantly diving for its shelly food. The surf is a favourite station with it. Hudson's Bay and Labrador are among its breeding places, and the nest is formed of grass with a lining of down or feathers, on the borders of fresh-water ponds. The eggs are white, and from four to six in number. The young are hatched in July, and detained on the borders of the ponds, where they were excluded from the egg, until they are able to fly. Their migrations extend to Florida, but they often remain throughout the winter along the shores and open bays of the United States. At the end of April or early in May they again proceed northward.

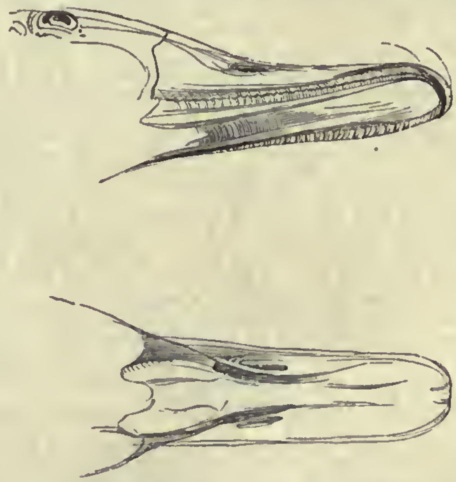
Surf-Duck (*Oidemia perspicillata*), male.

The flesh of the old birds is very dark, red, and fishy when dressed; the young are of better flavour. They are however often eaten by the inhabitants of the coasts frequented by them; and being difficult to approach, they are decoyed by means of a wooden figure of a duck of the same general appearance with themselves.

Fuligula (Ray).—Bill flat, broad, long, with hardly any gibbosity at the base, and rather dilated at the extremity. Nostrils suboval, basal. Tail short, of 14 feathers, graduated laterally. First quill longest.

The sea, and its bays and æstuaries, are the principal haunts of this genus. Sir John Richardson states that *F. Valisneria*, *F. ferina*, *F. marila*, and *F. rufitorques*, breed in all parts of the Fur Countries, from the 50th parallel to their most northern limits, and associate much on the water with the *Anatinæ*. *F. rubida*, he remarks, frequents the small lakes of the interior up to the 58th parallel, and he adds that it is very unwilling to take wing, and dives remarkably well. In swimming, according to the same observer, it carries its tail erect, and, from the shortness of its neck, nearly as high as its head, which, at a little distance, causes it to appear as if it had two heads.

F. Valisneria (*Anas Valisneria* of Wilson), Canvass-Back-Duck. The male has the region of the bill, top of the head, chin, base of the neck, and adjoining parts of the breast and back, rump, upper and



Bill of Canvass-Back Duck (*Fuligula Valisneria*).

under tail-coverts, pitch-black; sides of the head and the neck reddish-orange; middle of the back, scapulars, wing-coverts, tips of the secondaries, tertiaries, flanks, posterior part of the belly and thighs, grayish-white, finely undulated with hair-brown; primaries and their coverts hair-brown, their tips darkest; secondaries ash-gray, tipped with white; the two adjoining tertiaries edged with black. Belly white, faintly undulated on the medial line. In some specimens the white parts are glossed with ferruginous. Bill and legs blackish-brown. The bill is lengthened, the depressed frontal angle longer, the nostrils farther from the front, and the unguis differently shaped and smaller than in *F. ferina* (the Pochard); the upper laminæ flat, cuneate, not prominent, and confined within the margin of the mandible. The bill and head of the Canvass-Back approach somewhat to the form of the Pintail-Duck, being much lengthened, and of equal breadth throughout. First quill the longest. Length, 24 inches 6 lines.

The female has the ground-colour of the upper plumage and flanks liver-brown; sides of the head, neck, and breast, ferruginous; shoulders, shorter scapulars, and under plumage, edged with the same. Middle of the back and wing-coverts clove-brown, finely undulated with grayish-white. There are no undulated markings on the tertiaries and secondaries, and only a few on the tips of the scapulars. Bill as in the male; the neck more slender. (Richardson.)

Canvass-Back-Duck (*Fuligula Valisneria*).

It breeds from the 50th parallel to the most northern limits of the Fur Countries. When the work of incubation is past, flocks of Canvass-Backs pursue their course to the southward, and arrive about the middle of October on the sea-coasts of the United States. The Hudson, the Delaware, and the bays of North Carolina, are visited by some of these flocks; and it is stated that they are abundant in the river Neuse, in the vicinity of Newbern, and probably in most of the other southern waters down to the coast of the Gulf of Mexico, being seen in winter in the mild climate of New Orleans, at which season a few pairs arrive in Massachusetts Bay, near Cohaset and St. Martha's Vineyard. But it is to Chesapeake Bay, its æstuaries and rivers, among which the Susquehanna, the Patapsco, James's River, and the Potomac, may be particularly mentioned, that the great multitude of Canvass-Back-Ducks resort. (Wilson; Nuttall.)

The Canvass-Backs associate with the Pochards, and are waited upon by the Bald-Pates or Widgeons (*Mareca Americana*), which rob them in the manner already described. They are named in different parts of the Union White-Backs and Sheldrakes, as well as Canvass-Backs. *Zostera marina* and *Ruppia maritima* form their food, as well as the fresh-water *Valisneria*, which last is limited in its distribution. The Sea-Wracks or Eel-Grass, as the long marine vegetables above alluded to are called in America, are widely spread over the Atlantic, and over the mud-flats, bays, and inlets where salt or brackish water finds access. The Canvass-Backs dive for and generally pluck up the sea-wrack, and feed only on the most tender portion near the root. They are very shy birds, and most difficult to be approached. Various stratagems are resorted to for getting within gunshot of them; and in severe winters artificial openings are made in the ice, to which the ducks crowd, and fall a sacrifice to their eagerness to obtain food. That they will eat seeds and grain as well as sea-wrack, &c., was proved by the loss of a vessel loaded with wheat near the entrance of Great Egg Harbour, New Jersey, to which great flocks of Canvass-Backs were attracted. Upon this occasion as many as 240 were killed in one day. (Wilson; Nuttall.)

The Canvass-Back, which is lean on its first arrival in the United States, becomes, in November, about three pounds in weight, and in high order for the table: there are few birds which grace the board better. Prince Bonaparte is eloquent in its praise:—"Carne della massima squisitezza, grandemente ricercata dai gastronomi. La migliore delle Anitre. Forse il miglior uccello d'America." Any attempt to introduce the bird into England would, it is feared, prove a failure; for even if the ordinary difficulties should be got over, the absence of the food to which it is supposed to owe its exquisite flavour would render the success of the experiment very doubtful.

Clangula (Boié).—Bill narrow, elevated at the base, somewhat attenuated at the anterior extremity, and short. Nostrils inclining to oval, submesial, or rather anterior to the middle of the bill. Tail rather long, of 16 feathers generally.

Though many of this genus frequent the sea, the species are more generally met with in the fresh waters than the other Sea-Ducks. Thus, Sir John Richardson remarks that *C. vulgaris* (Common Golden-Eye) and *C. albeola* (Spirit-Duck) frequent the rivers and fresh-water lakes throughout the Fur Countries in great numbers. They are, as he states, by no means shy, allowing a near approach to the sportsman; but at the flash of a gun, or even at the twang of a bow, they dive so suddenly that they are seldom killed. Hence the natives impute supernatural powers to them, as the appellations of 'Conjuring Ducks' and 'Spirit-Ducks' sufficiently testify. Richardson says that the manners of *C. Barrovii* (Richardson and Swainson), described in 'Fauna Boreali-Americana,' and which has hitherto been found only in the valleys of the Rocky Mountains, do not differ from those of the Common Golden-Eye. He speaks of *C. histrionica* as haunting eddies under cascades and rapid streams, as very vigilant, taking wing at once when disturbed, as rare, and as never associating, as far as he saw, with any other bird. The high northern latitudes may be considered generally as the localities of this genus.

C. albeola, the Spirit-Duck, *Anas albeola* of Linnæus. It is the Buffel-Duck of Pennant; the Buffel's-Head-Duck of Catesby; the Little Black and White Duck of Edwards; the Buffel-Headed Duck of Wilson; Wakaishee-Weesbeep, Waw Haisheep, and Wappano-Sheep, of the Cree and Chippeway Indians.

The male has the forehead, region of the bill, nuchal crest, and upper sides of the neck, rich duck-green, blending with the resplendent auricula-purple of the top of the head and throat. Broad band from the eye to the tip of the occipital crest, lower half of the neck, the shoulders, exterior scapulars, intermediate and greater coverts, outer webs of five or six secondaries, flanks, and under plumage to the vent, pure white. Back, long scapulars, and tertiaries, velvet black; lesser coverts bordering the wing the same, edged with white; primaries and their coverts brownish black. Tail-coverts blackish-gray; tail broccoli-brown. Vent and under tail-coverts grayish. Bill bluish-black. Legs yellowish. In many spring specimens the under plumage is ash-gray. The bill smaller in proportion than that of the common Garrot, and the nostrils nearer the base; but otherwise similar. Head large, with the upper part of the neck clothed in velvety plumage, rising into a short thick crest. Wings $2\frac{1}{2}$ inches shorter than the tail. Tail—lateral feathers graduated, three middle pairs even. Length 16 inches; but individuals differ in size.

Bill of Spirit-Duck (*Clangula albeola*).

The female is considerably smaller. Head and dorsal plumage dark blackish-brown; the fore part of the back, scapulars, and tertiaries, edged with yellowish brown. Fore part of the neck, sides of the breast, flanks, and vent-feathers, blackish-gray; breast and belly white, glossed with brownish-orange. White band on the ears and occiput much narrower than in the male. The white speculum is less perfect, and the whole of the lesser coverts and scapulars are unspotted blackish-brown. Bill and feet brownish. Total length $14\frac{1}{2}$ inches. Young males resemble the females. (Richardson.)

This bird is abundant in the summer on the rivers and fresh-water lakes of the Fur Countries. In autumn and winter very common in the United States, sometimes on the sea-shores. Catesby says that the Buffel's-Head-Duck appears in Carolina during the winter only. On the river Neuse, in North Carolina, they have been seen in abundance in February. In April and May those in the south take their departure northward.

This species is a most expert diver, whether it resorts to that feat as a mode of escape, or as the means of procuring the sea-wrack and laver (*Ulva lactuca*), and crustaceans and mollusks, which, at particular seasons of the year when it visits the sea-bays and salt marshes, form its favourite food. The rapidity of its disappearance from the surface, and the artful way in which it conceals itself after it has vanished under water, have earned for it the appropriate name of 'Spirit-Duck,' or 'Conjurer.' A bird is rarely hit, and when it is, if not killed outright, it can rarely be captured; so quick is the Spirit-Duck in avoiding the shot altogether, and so dexterous in evading its pursuer, if only wounded. About Hudson's Bay they are said to form their nests in hollow trees in woods adjacent to water. (Wilson; Nuttall.)

The flesh of the Spirit-Duck is not in high repute, but the females and young are tender and well flavoured in the winter. The bird becomes so fat that, in Pennsylvania and New Jersey, it is commonly called 'Butter-Box,' or 'Butter-Ball.'

Spirit-Duck (*Clangula albeola*), male and female.

C. vulgaris, Anas Clangula Linn., the Common Golden-Eye, or Garrot, is an inhabitant of the arctic regions of the New and Old Worlds, and is frequently met with in this country, and in Europe generally. The species is distributed over the Swiss lakes. Mr. Gould figures *C. Barrovii* and *C. histrionica* among the Birds of Europe, the former having been shot in Iceland by T. C. Atkinson, Esq., and the latter having been frequently captured in the British Islands.

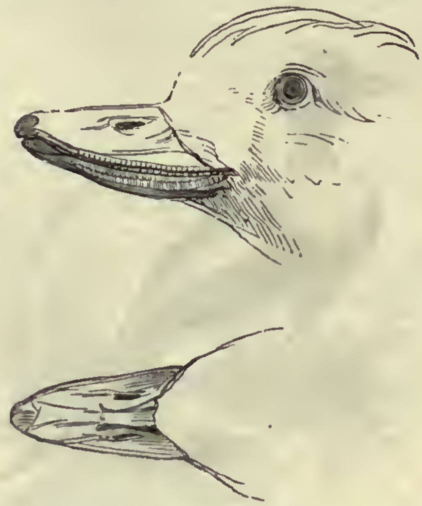
Harelda (Leach).—Bill very short, high at the base, nail broad and arched. Laminæ prominent, trenchant, and distant; the upper laminæ projecting below the margin of the mandible, the lower laminæ divided into a nearly equal double series. Nostrils oblong, large, and nearly basal. Forehead high; neck rather thick. Tail very long, of 14 feathers. Toes short.

H. glacialis, Anas glacialis, Linn., the Long-Tailed Duck. This is the Canard à Longue Queue, ou Canard de Miclon, of the French; Eis-Ente, Winter-Ente, of the Germans; Ungle, Angeltaske, Trasfoener, of the Norwegians; Oedel of the Faroe Islanders; Ha-Old, Ha-Ella, of the Icelanders; Swallow-Tailed Sheldrake, Sharp-Tailed Duck, Calao, Calaw, Coal and Candle Light, of the English; Hwyad gynffon gwennol of the Welsh; Old Wife and Swallow-Tailed Duck of the Hudson's Bay residents; South-Southerly of the United States; Aldiggee-areoo of the Esquimaux; Caccåwee of the Canadian voyagers; and Hahhaway of the Cree Indians.

The old male in winter has the summit of the head, nape, front, and lower parts of the neck, long scapulars, belly, abdomen, and lateral tail-feathers, pure white; cheeks and throat ash-colour; a great space of maroon-brown on the sides of the neck; breast, back, rump, wings, and the two long feathers of the middle of the tail, brownish; flanks ash-coloured; the black of the bill cut transversely by a red band; tarsi and toes yellow; webs blackish; iris orange. Length, comprising the long tail-feathers, 20 to 21 inches.

The old female differs much from the male. Tail short, the feathers bordered with white and the two middle ones not elongated; forehead, throat, and eyebrows, whitish-ash; nape, front, and lower part of the neck, belly, and abdomen, pure white; top of the head and great space at the sides of the neck blackish ash; breast variegated with ash-colour and brown; feathers of the back, scapulars, and wing-coverts, black in the middle, bordered and terminated with ashy-red; rest of the other parts brown; the bluish colour of the bill cut by a yellowish band; iris bright brown; feet lead-colour. Length 16 inches.

The young of the year do not differ much from the old female; the whiteness of the face is varied with numerous brown or ash-coloured spots; throat, front of the neck, and nape, ashy-brown; lower part of the neck, a large spot behind the eyes, belly, and abdomen, white; breast and thighs variegated with brown and ash-coloured spots. (Temminck.)



Bill of Long-Tailed Duck (*Heralda glacialis*).

The summer dress of the male is as follows:—The whole upper plumage, the two central pairs of tail-feathers, and the under plumage to the fore part of the belly brownish-black; the lesser quills paler. A triangular patch of the feathers between the shoulders, and the scapulars, broadly bordered with orange-brown. Sides of the head from the bill to the ears ash-gray; eye-stripe and posterior under-plumage pure white. Flanks, sides of the rump, and lateral tail-feathers, white, stained with brown; axillaries and inner wing-coverts clove-brown. Bill black, with an orange belt before the nostrils. Legs dark-brown. Specimens killed a fortnight or three weeks later in the season at Bear Lake, on their way to the breeding-places, differed in having a large white patch on the hind head and occiput, with scattered white feathers on the neck and among the scapulars; the sides under the wings pure pearl-gray, and the sides of the rump unstained white. (Richardson.)

Colonel Sabine ('Supplement to Appendix of Captain Sir W. E. Parry's First Voyage') notices a male obtained in June, corresponding precisely with the individual killed in Baffin's Bay in the summer of 1818, which furnished the description of the full breeding plumage in the 'Memoir of the Greenland Birds.' Sir John Richardson observes that Colonel Sabine describes the plumage of the specimens killed at Bear Lake as the pure breeding plumage; but individuals coloured like the one killed on the Saskatchewan are, he remarks, often seen at the breeding stations. He quotes Mr. Edwards, surgeon of the Fury ('Sir W. E. Parry's Second Voyage'), as describing the Long-Tailed Ducks killed at Melville Peninsula between the 1st and 25th of June as follows:—"They had all a dark silky chestnut-brown patch on the side of the neck; a mixture of white in the black stripe from the bill to the crown; the crown and nape either entirely white, or mixed with black; scapulars and upper tail-coverts edged with white; a broad white collar round the lower part of the neck, in some individuals tipped with black or brown; occasionally a white band on the breast. The colour of the belt on the bill varied from rose-red to violet."

A mature female, killed May 25, lat. 65° 30′, had the upper plumage and sides of the breast pale liver-brown, with dark centres; the wing-coverts, scapulars, and hinder parts, mostly edged with white. Top of the head blackish-brown, its sides anteriorly broccoli-brown; ears and base of the neck below clove-brown. A spot at the base of the bill and a stripe behind the eye white. Throat and collar ash-gray. Tail-feathers brownish-gray, edged with white, short and worn. (Richardson.)

This bird is found in the arctic seas of both worlds; an accidental visiter on the great lakes of Germany, and along the Baltic; often but never in flocks, on the maritime coasts of Holland. (Temminck.) Abundant in Sweden, Lapland, and Russia. (Gould.) Noted in the list of birds seen within the arctic circle, and as breeding in the North Georgian Islands, but not common there. ('Supplement to Appendix to Captain Parry's First Voyage.') Females taken in Duke of York's Bay. (Captain Lyon's 'Journal.') Abundant on the Arctic Sea, associating with the *Oidemiæ*, remaining in the north as long as it can find open water, and assembling in very large flocks before migrating; halts, during its progress southward, both on the shores of the Hudson's Bay and in the inland lakes, and is one of the last of the birds of passage which quits the Fur Countries. Captain Sir James Ross describes it as the most noisy and most numerous of the ducks that visit the shores of Boothia. The species is abundant in Greenland, Lapland, Russia, and Kamtchatka, and flocks pass the winter (from October to April) at the Orkney Islands. They are seldom seen in the southern parts of England, unless the weather be very severe. In October they visit the United States, and abound in Chesapeake Bay.

Long-Tailed Duck (*Harelda glacialis*), male and female.

Lively, most noisy, and gregarious, the Long-Tailed Duck, with its swallow-like appearance in flight, swims and dives with all the expertness of the Spirit-Ducks. Sir John Richardson states that in the latter end of August, when a thin crust of ice forms during the night on the Arctic Sea, the female may be often seen breaking a way with her wings for her young brood. The same author states that the eggs are pale greenish-gray, with both ends rather obtuse, 26 lines long and 18 lines wide. They are about five in number; and in Spitzbergen, Iceland, and along the grassy shores of Hudson's Bay, near the sea, this species is said to form its nest about the middle of June, lining the interior with the down of the breast. Marine productions principally, both animal and vegetable, form its food, particularly the *Zostera*, or Grass-Wrack, for which it dives like others of its congeners. "Late in the evening, or early in the morning," writes Nuttall in his 'Manual of the Ornithology of the United States and of Canada,' "towards spring more particularly, vast flocks are seen in the bays and sheltered inlets, and in calm and foggy weather we hear the loud and blended nasal call reiterated for hours from the motley multitude. There is something in the sound like the honk of the goose, and, as far as words can express a subject so uncouth, it resembles the guttural syllables ogh, ough, egh, and then ogh, ogh, ogh, ough, egh, given in a ludicrous drawling tone; but still, with all the accompaniments of scene and season, this humble harbinger of spring, obeying the feelings of nature, and pouring forth his final ditty before his departure to the distant north, conspires, with the novelty of the call, to please rather than disgust those happy few who may be willing to find 'good in everything.'"

The old birds are not considered as of much value for the table; but the young birds are tender and juicy. If, as is on good authority asserted, the down which the Long-Tailed Duck strips from its breast as a lining for the nest, is as soft and elastic as that of the Eider-Duck, it may be considered as offering no mean contribution to the comforts of man, a contribution which, however apparently hitherto neglected, deserves the attention of the intelligent and enterprising.

In addition to the genera above mentioned, *Gymnura* (*Oxyura*, Bonaparte), *Macropus*, and *Micropterus* find a place among the Sea-Ducks.

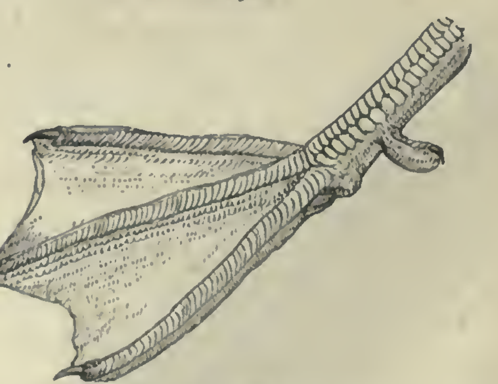
The species from which the genus *Oxyura* is established, is bred, according to Nuttall ('Manual'), in the north, and principally haunts fresh-water lakes, diving and swimming with great ease, but it is averse to rising into the air. It is small, and is said by the last-named author to be nearly allied to *Anas leucocephala*, which inhabits the saline lakes and inland seas of Siberia, Russia, and the east of Europe; and also to have an affinity to *A. Jamaicensis* of Latham. Nuttall thinks that it is perhaps identical with *A. spinosa* of Guyana, if not also with *A. Dominica* of Gmelin, a native of St. Domingo, and probably only resident there during the winter. He also observes that the name of *Oxyura* having been previously employed for a sub-genus of Creepers, it was necessary to alter it; but the student should remember that *Gymnura* had been pre-occupied by Sir Stamford Raffles for a genus of Mammifers; and that Spix has named a family of South American Monkeys *Gymnuri*. Prince C. L. Bonaparte, however, corrected himself, and changed the name to *Erismatura*. Mr. Gould gave the name of *Undina* to the genus, and figures the European species under the name of *Undina leucocephala*. The term *Macropus* has long been applied as a generic name for the Kangaroos.

Micropterus is the genus containing the well-known Race-Horse of Cook (*Micropterus brachypterus*, *Anas brachyptera* of authors). Captain Philip Parker King, R.N., who has added a second species (*Micropterus Patachonicus*), gives these short-winged but rapidly-progressing Sea-Ducks the familiar name of Steamer-Ducks or Steamers.

The sub-family *Merganinæ* (*Merginæ*, Bonap.), consists of the genus *Mergus*, Linn., the Goosanders or Mergansers of the British. Prince Bonaparte makes it include two sub-genera, *Mergus* (the Smew) and *Merganser*, Leach (the Goosander), and places the sub-family next to the *Fuligulinæ*, and immediately preceding the *Pelecanidæ*. In the second volume of Mr. Swainson's 'Classification of Birds,' the sub-family is placed after the *Fuligulinæ*, and immediately preceding the family *Colymbidæ*.

Merganser (Leach).—Bill straight, narrow, and slender, sub-cylindrical anteriorly, wide at the base, and abruptly hooked at the tip;

Bill of *Merganser*.



Foot of the same.

margins of both mandibles serrated, the serrations or teeth directed backwards. Tongue slender. Feet short, with the toes fully palmated, and placed behind the point of equilibrium.

M. castor (*Mergus Merganser* and *castor* of Linnæus), the Goosander. This species is the Sugherone of the Italians; the Meer-Rack aud See-Rack of the Germans; Wrakfogel, Kjorkfogel, Ard, and Skraka, of the 'Fauna Sueeica;' Skallesluger of the Danes; Skior-And of the Icelanders; Peksok of the Greenlanders; Seek of the Cree Indians; Hwyad ddanhe-dog of the Welsh; and Jack-Saw of the English. It is supposed to be the Κάστορος Ὄρνις of the Greeks; the *Fiber* and *Castor Ales* of the Latins; and is the Bieure of the old French.

The very old male has a tufted head (the tuft large and thick), aud part of the neck greenish-black, the reflection varying in different lights; lower part of the neck, breast, belly, abdomen, coverts of the wings and scapulars farthest from the body, tinged of a yellowish-rose-colour (which soon fades in stuffed specimens to white) on the under parts; upper part of the back and scapulars nearest to the body deep black; quills blackish; great coverts bordered with black; rest of the back and tail ash-coloured; beauty-spot on the wing white, without transverse bands; bill deep red, black above and on the terminal tail; iris reddish-brown, sometimes red; feet vermilion-red. Length 26 to 28 inches. (Temm.)

In this plumage the bird is the *Mergus Merganser* of Linnæus and others; Le Harle of Buffon and the French; the Goosander or Mersander of Latham and Pennant; Gansen-Säger and Taucher-Gans of Bechstein and the Germans; Mergo, Oca Marina e Mergo Dominicano, of the 'Stor. degl. Ucc.;' and Dubbelde Zaagbek of Sepp. and the Netherlanders.

The female has a long and looso tuft; head and part of the neck reddish-brown; throat pure white; lower part of the neck, breast, sides, and thighs whitish-ash; all the upper parts deep ash; beauty-spot of the wing white, without any transverse band; bill faded red; iris brown; feet yellowish-red; webs ashy-red. Length 24 or 25 inches.

The young males of the year are similar to the females.

The young at the age of one year are distinguished by blackish spots disposed on the white of the neck; the ruddy colour of the neck is then terminated by a deeper colour; blackish plumes begiu to show themselves on the top of the head, and white feathers appear on the coverts of the wings.

In this state the bird is the *Mergus castor* of Linnæus and others; *Mergus rubricapillus* of Gmelin; the Harle Femelle of Buffon; the Dun Diver or Sparling Fowl of Latham and others; and the Mergo Oca of the 'Stor. degl. Ucc.'

Goosander (*Mergus Merganser*, Linn.).
Lower figure, male; upper figure, female.

The food of the Goosander consists of small fish, crustaceans and mollusks. Temminck says that its nest is placed among rolled pebbles on the banks of waters, in bushes or in hollow trees, and that it lays twelve or fourteen whitish eggs, which are nearly equally pointed at each end. The flesh is very rank and bad. Graves, who tasted one, pronounces it to have been offensive in the highest degree. The old French quatrain in the 'Portraits des Oyseaux,' gives the following description of its habits and of its quality as food:—

Le Bieure scait aux estangs se plonger
Pour le poisson, auquel est dommageable.
Mais qui vouldroit festoyer un diable,
Fauldroit vn Bieure avoir pour son manger.

Mr. Gould ('Birds of Europe') states that "its nativo locality appears to be the northern regions of the continents of Europe and America, where among large and unfrequented lakes it finds an asylum and breeding-place; from these, its summer haunts, it emigrates southwards on the approach of the severities of winter, seldom appearing in our latitudes unless the season indicates an exceedingly low temperature in the arctic circle: at such times it frequents our shores and unfrozen lakes either in pairs or in small flocks of seven or eight; but the extensive inland waters of Holland and Germany appear to be its favourite resort." This species was shot at Fulham in the severe winter of 1837. It appears in Sir John Richardson's list of birds that they merely winter in Pennsylvania and migrate in summer to rear their young in the Fur Countries; the specimen described by him was killed on the Saskatchewau. It also occurs in Colonel Sabine's list of Greenland Birds. Prince Bonaparte notes it as rather rare in winter in Rome, and as not common in the same season in Philadelphia ('Specchio Comparativo'), and as occurring in Europe generally, and in America generally, in his 'Geographical and Comparative List of the Birds of Europe and North America.' It was seen in Japan by Dr. Von Siebold and M. Bürger.

Mergus.—Bill about as loug, or longer, than the head, straight, slender, rather pointed; the base large, forming an elongated and almost a cylindrical cone; point of the upper mandible curved, aud with the horny nail forming a hook; edges of both mandibles furnished with saw-like teeth, the poiuts directed backwards. Nostrils lateral, about the middle of tho beak, lougitudinally elliptic. Legs short, placed rather backwards; three toes in front, webbed, hiud toe with a lobe or membrane. Wings moderate; the first and second quill-feathers nearly equal in length.

M. albellus. The old male has a great spot of grecuish black on each side of the bill, a similar coloured but longitudinal one on the occiput; the tufted crest, neck, scapulars, small coverts of the wings, and all the lower parts, very pure white; upper part of the back, the two crescents which are directed under the sides of the breast, and the edges of the scapulars, deep black; tail ash-coloured; sides and thighs varied with ash-coloured zig-zags; bill, legs (tarsi), and toes, bluish-ash webs black; iris brown. Length 15 to 16 inches.

Mergus albellus. Upper figure, male; lower figure, female. (Gould.)

In this state the bird is *M. albellus* of Linnæus and others; Le Petit Harle Huppé ou La Piette of Buffon; the Weiser Sager of Bechstein and others; the Witte non Duiker of Sepp.; the Mergo Oca Minoro of the 'Stor. degl. Ucc.;' and the Smew or White Nun of the English ornithologists.

The female has the summit of the head, cheeks, aud occiput, reddish-brown; throat, upper part of the neck, belly, and abdomeu, white; lower part of the neck, breast, sides, and rump, bright ash; upper parts and tail deep ash; wings variegated with white, ash, and black. Length 15 inches.

Young of the year, similar to the female.

The males at the age of one year are distinguished by the small blackish feathers which form the great spot at the side of the bill; by some whitish and white feathers scattered on the head; by the upper part of the back, which is variegated with black and ash-coloured feathers; and by indications of the two black crescents ou the side of the breast. The young of both sexes have the great coverts of the wings terminated by a large white space, while the old ones have no white there except at the point.

The females and young of the year are the *Mergus minutus*, Linn.; *M. Asiaticus*, Gm.; *M. stellatus*, Brunn.; *M. Pannonicus*, Scop.; La Piette Femelle, Buff.; Le Harle Etoilé (young male), Buff.; Mergo Oca Minore (female), and Mergo Oca Cenerino (young male of the year), 'Stor. degl. Ucc.;' De Kleine Zaagbek (young of the year), Sepp.; and Red-Headed Smew (young male in moult), Penn., 'Brit. Zool.'

This species is the Kreutz-Ente of Frisch and the Germans; the Hviid Side of the Danes; Sugherone Occhialino of the Italiaus; Lleian wen of the Welsh; Smew and White Nun, Vare Widgeon, and Smec, of tho English.

The food of the Smew consists of small crustaceans, water-insects, mollusks, little fish, and water-plants. The nest, according to M. Temminck, is placed on the borders of rivers and lakes, and the number of eggs amounts to twelve; they are whitish. The bird is in no request for the table.

The countries of the arctic circle in both worlds are the habitations of the Smew. It is migratory in autumn, but especially in winter, in England, Holland, France, and as far as Italy; rather abundant in Holland on the lakes and marshes. (Temm.) It is seldom seen in Britain except in inclement winters. The species was not observed by Sir John Richardson, but it is noted by him in the tables compiled from the 'Specchio Comparativo' as one of the birds that migrate northward from or through Pennsylvania in spring, and may therefore be considered as returning to the Fur Countries to breed. Prince Bonaparte notices it as rather common in winter, particularly the young, near Rome, and as very rare and adventitious at Philadelphia. (Specchio Comparativo.') The same author, in his 'Geographical and Comparative List,' notes it as occurring in Europe generally and on the northern and central coasts of America. Dr. Von Siebold and M. Bürger found it in Japan.

M. Temminck remarks that the Harles, or birds of this sub-family, live upon the waters, where they swim, having generally the whole of the body submerged, and only the head out of the water; but this is certainly not the case with the Smew, as it swims with a very fair proportion of its body above the surface. They dive easily and often, swim with extreme agility 'entre deux eaux', and use their wings to assist them in this sort of natation. They remain long on wing, and fly very swiftly. Their walk is very vacillating and embarrassed, their legs or feet, as well as those of the Sea-Ducks, being more withdrawn within the abdomen than those of the ducks which have the posterior toe smooth. Their food consists principally of fish and amphibious animals, and of the first they make great destruction. In temperate climates they are only seen in winter; their habitual dwelling is in cold countries, where they breed. They are much wilder than the different species of ducks, and have not been domesticated. They moult once a year; but the old males, like those of the ducks, moult in the spring, whilst the old females and the young moult in the autumn. The young males, before their first or second moult, hardly differ at all from the females.

The following list of British *Anatidæ* is made up from the 'Catalogue of the Specimens of British Animals in the British Museum.' The catalogue of birds in this collection has been drawn up by Mr. George Robert Gray.

Family *Anatidæ*.

Sub-Family I. *Plectropterinæ*.

Plectropterus.

P. Gambensis, the Spur-Winged Goose.

Sub-Family II. *Anserinæ*.

Chenalopex.

C. Ægyptica, the Egyptian Goose.

Bernicla.

1. *B. leucopsis*, the Bernicle-Goose.
2. *B. Brenta*, the Brent-Goose.
3. *B. ruficollis*, the Red-Breasted Goose.
4. *B. Canadensis*, the Canada Goose.

Anser.

1. *A. ferus*, the Gray-Lag Goose.
2. *A. segetum*, the Bean-Goose.
3. *A. brachyrhynchus*, the Pink-Footed Goose.
4. *A. erythropus*, the White-Fronted Goose.
5. *A. cygnoides*, the Chinese Goose.

Sub-Family III. *Cygninæ*.

Cygnus.

1. *C. ferus*, the Whistling Swan.
2. *C. Americanus*, the American Swan.
3. *C. olor*, the Mute Swan.
4. *C. immutabilis*, the Changeless Swan.
5. *C. minor*, Bewick's Swan.

Sub-Family IV. *Anatinæ*.

Tadorna.

1. *T. vulpanser*, the Common Shieldrake.

Casarka.

1. *C. rutila*, the Ruddy Shieldrake.

Mareca.

1. *M. Penelope*, the Widgeon.
2. *M. Americana*, the American Widgeon.

Dafila.

1. *D. acuta*, the Pintail Duck.

Anas.

1. *A. Boschas*, the Wild Duck.

Querquedula.

1. *Q. crecca*, the Teal.
2. *Q. bimaculata*, the Bimaculated Duck.

Pterocyanea.

1. *P. circia*, the Garganey.

Aix.

1. *A. sponsa*, the Summer-Duck.

Chaulelasmus.

1. *C. strepera*, the Gadwall.

Spatula.

1. *S. clypeata*, the Shoveler.

Cairina.

1. *C. moschata*, the Muscovy Duck.

Sub-Family V. *Fuligulinæ*.

Branta.

1. *B. rufina*, the Red-Crested Whistling-Duck.

Fuligula.

1. *F. cristata*, the Tufted Duck.
2. *F. collaris*, the Collared Duck.
3. *F. marila*, the Scaup-Duck.

Nyroca.

1. *N. ferina*, the Pochard.
2. *N. ferinoides*, Paget's Pochard.
3. *N. leucophthalmos*, the Ferruginous Duck.

Clangula.

1. *C. glaucion*, the Golden Eye.
2. *C. histrionica*, the Harlequin-Duck.
3. *C. albeola*, the Buffel-Headed-Duck.

Harelda.

1. *H. glacialis*, the Long-Tailed Duck.

Eniconetta.

1. *E. Stelleri*, the Western Duck.

Somateria.

1. *S. mollissima*, the Eider-Duck.
2. *S. spectabilis*, the King's Duck.

Oidemia.

1. *O. fusca*, the Velvet-Scoter.
2. *O. nigra*, the Common Scoter.
3. *O. perspicellata*, the Surf-Scoter.

Sub-Family VI. *Merginæ*.

Mergus.

1. *M. castor*, the Goosander.
2. *M. serrator*, the Red-Breasted Merganser.
3. *M. cucullatus*, the Hooded Merganser.

Mergellus.

1. *M. albellus*, the Smew.

Most of the species referred to in the foregoing article may be seen living in the Gardens of the Zoological Society, Regent's Park. Some years ago an Ornithological Society was formed in London, and obtained permission to place their living collection of birds upon the waters in St. James's Park. The specimens of *Anatidæ* in this collection are very numerous and worthy the attention of the ornithological student. We are indebted to the keeper of the birds for the following list:—

The Black Swan.	Aylesbury Duck.
Bewick's Swan.	Hook-Billed Duck.
Hooper-Swan.	Muscovy Duck.
Common Swan.	Buenos Ayres Duck.
Common Goose.	Yellow-Billed Duck.
Chinese Goose.	Carolina Duck.
Egyptian Goose.	Castaneous Duck.
Brent-Goose.	Golden-Eye Duck.
Bernicle-Goose.	Pintail Duck.
Bean-Goose.	Pochard.
Canada Goose.	Gadwall.
Sandwich Island Goose.	Shieldrake.
Spur-Winged Goose.	Common Widgeon.
Goosander.	Common Teal.
Common Duck.	

There are also specimens of birds belonging to the family *Colymbidæ* in the same collection.

DUCK-WEED. [LEMNA.]

DUDLEY LIMESTONE, an equivalent term for the Wenlock Limestone of the Silurian system. [SILURIAN SYSTEM.]

DUFRENITE, a Mineral, occurring in small radiated masses. Its colour is olive or dull green. It is slightly translucent and extremely fusible. The specific gravity is 3·227. It is found at Anglar, near Limoges. The following is an analysis:—

Phosphoric Acid	24·8
Protoxide of Iron	51
Peroxide of Manganese	9
Water	15—99·8

DUFRENOYSITE, a Mineral, consisting of an arseniuret and sulphuret of lead. It occurs in dodecahedrons of a dark steel-gray colour in the Dolomite of St.-Gothard. The specific gravity is 5·55.

DUGONG [CETACEA.]

DUIKER-BOK. [ANTILOPEÆ.]

DULCAMARA. [SOLANUM.]

DULSE. [ALGÆ.]

DUMB-CANE. [AROIDEÆ; CALADIUM.]

DUNDIVER. [DUCKS.]

DUNLIN. [SCOLOPACINÆ.]

DUNNOCK. [SYLVIADÆ.]

DUODE'NUM (from a Latin word signifying twelve, because it is twelve inches in length), the first of the small intestines in immediate connection with the stomach. It commences at the pyloric end of the stomach, and terminates at the distance of twelve inches in the second portion of the small intestines called the jejunum. Though it is the straightest of the small intestines, yet the Duodenum describes in its course various turns. From the pylorus it turns backwards and upwards by the neck of the gall-bladder, with which it is in contact; it then passes obliquely downwards on the right side immediately before the great vessels which enter the liver. Opposite to the under part of the kidney it makes a turn to the left side, across the lumbar vertebræ, and is lodged in the common root of the mesocolon and mesentery, below the pancreas and behind the superior mesenteric vessels; it now makes a turn forwards, and obtains the name of jejunum.

The Duodenum is much more capacious than the jejunum or ilium, and is indeed so large that it has been regarded as a second stomach, and obtained the name of Ventriculus Succenturiatus. It is fixed much more closely to the spinal column than the other intestines, and does not, like them, float loosely in the abdomen. It is of a redder colour than the rest, has a thicker muscular coat, and a greater number of valvulæ conniventes.

At the distance of from three to four fingers' breadth from the pylorus the Duodenum is perforated by the biliary and pancreatic ducts, by which tubes the bile and the pancreatic juice flow into the intestine.

The Duodenum is probably an organ accessory to the stomach. There is evidence that it carries on the digestion commenced in the stomach. It is certain that alimentary substances which have escaped solution in the stomach are dissolved in the Duodenum.

The chyme formed from the food in the stomach and received by the Duodenum, retains the name of chyme until it reaches that portion of the Duodenum where the biliary and pancreatic ducts pierce the intestine. At this point, and by the admixture of the biliary and pancreatic juices, the chyme is changed into two portions—into a nutritious portion, which receives the name of chyle and which flows into the blood [CHYLE]; and into an excrementitious portion, which is carried along the small into the large intestines, where it receives the name of fæces, and is expelled from the body.

On the surface of the Duodenum the lacteal vessels begin to make their appearance for the absorption of the chyle. [LACTEALS.] The Duodenum is likewise provided with a great number of mucous glands, which more especially abound near the pylorus. [GLANDS.]

DURA-MATER. [BRAIN.]

DURA'MEN, the name given by physiologists to the central wood or heart-wood, in the trunk of an exogenous tree. It is the oldest part of the wood, and is filled by the secretions of the tree, so that fluid can no longer ascend through its tubes, which are choked up by the deposition of solid matter; otherwise it is of the same nature as the alburnum. It is only where plants form solid hard secretions that heart-wood is distinguishable from sap-wood: in the poplar, willow, lime, &c., no secretions of this kind are formed; the two parts of the wood are both nearly alike, and consequently the timber of such trees is uniformly perishable. Ship-carpenters call the Duramen the spine: it is always distinguishable from sap-wood by its deeper colour, and sometimes, as in the yew, the sandarach, and certain kinds of deal, the limits of the two are clearly defined. But in most cases the heart-wood and sap-wood gradually pass into each other, so that no certain line can be drawn between them. [ALBURNUM; EXOGENS; TISSUES, VEGETABLE.]

DU'RIO, a genus of Plants of which the name has been derived from Durion, a well-known fruit of the Malayan Archipelago. The specific name of *Zibethinus* has been applied to the tree which forms this genus, from the fondness of the Malayan Zibet (*Viverra Rasse*, Hors.) for this fruit.

The genus *Durio* belongs to the natural family of *Bombaceæ*, considered by some botanists to be only a tribe of *Sterculiaceæ*. It is characterised by having its five petals smaller than the five lobes of the calyx. The stamens, long and numerous, are arranged in five bundles, and have twisted anthers; the free germen is surmounted by a long filiform style and capitate stigma; the fruit, roundish and muricated, is divided internally into five cells, and easily separates when ripe into five parts; each cell contains from two to four or five seeds enveloped in soft pulp.

D. Zibethinus is a large and lofty tree, with alternate leaves, which are small in proportion to its size; in form they resemble those of the cherry, or are oblong-pointed, small and green above, like nutmeg-tree leaves, but on the under surface are covered with orbicular reddish-coloured scales, as some species of *Capparis*; the petioles are tumid, and furnished with a pit towards their base; the flowers are arranged in clusters on the trunk and older branches, where of course is also borne the fruit, as in the Jack and Cocoa trees.

The Durion is a favourite food of the natives during the time (May and June) when it is in season; but there is usually also a second crop in November. It is as remarkable for the delicacy combined with richness of its flavour, as for the intolerable offensiveness of its odour, which is compared by Rumph to that of onions in a state of putrefaction, on which account it is seldom relished by strangers, though highly esteemed by many European residents. In size it is equal to a melon, or a man's head, and sometimes compared to a rolled-up hedgehog (hence it has been called *Echinus arboreus*) in consequence of its hard and thick rind, which is yellow-coloured when ripe, being covered with firm and angular projections. From this appearance has likewise been derived its Malayan name, 'dury' in that language signifying a thorn or prickle. (Rumph.)

The seed, with its edible enveloping pulp, is about the size of a hen's egg; the latter is as white as milk, and as delicate in taste as the finest cream, and should be eaten fresh, as it soon becomes discoloured, and undergoes decomposition. Excessive indulgence in this, as in other fruits, is apt to create sickness, and therefore to its abundance has been sometimes ascribed the unhealthiness of some years; but as the crop of fruit is most abundant when the rains are very heavy and follow great heats, the sickness is probably due as much to the peculiarities of the season as to the too free use of this fruit.

The seeds of the Durion are likewise eaten when roasted, and have something of the flavour of chestnuts. The wood of the tree is valued for many economical purposes, especially when protected from moisture. The rind of this fruit is likewise turned to account by the industrious Chinese, as its ashes, when burnt, probably from containing potash, are used by them in the preparation of some dyes.

Marsden, in his account of Sumatra, quotes a celebrated writer as saying that "Nature seems to have taken a pleasure in assembling in the Malay Islands her most favourite productions." Among these may be enumerated the Mangosteen, the Jack and Bread-Fruit trees, the Lanseh, and Durion, with others which are common in other tropical parts. These it has not been possible to cultivate in the hot-houses of England, even with all the skill of its horticulturists; a circumstance which must be ascribed partly to the great size of the trees, and partly to the peculiarity in climate of 'India aquosa,' as this part of the world was called by old writers. But as it is only within a few years that moisture has been combined with heat in the present successful cultivation of Orchideous Plants, it might perhaps be possible to make some of the above fruits grow in a similar artificial climate; and, by grafting, to make them bear when only a few feet high, as has been done with the Mango in India.

DUTCH WHITE. [BARYTES.]

DUVAUA. [ANACARDIACEÆ.]

DYKE (in Geology), a fissure caused by the dislocation of strata, commonly also termed a Fault. Dykes are of frequent occurrence, and often extend several miles, penetrating generally to an unknown depth. They must have been produced by some violent disturbances, and the amount of dislocation of necessity would vary in proportion to the intensity of the disturbing force. Accordingly there are many dykes of great width and extent, which materially affect the face of the country in which they occur, while there are others so slight that it requires much care and observation to ascertain their existence. The strata are in most cases uplifted on one side of the dyke much higher (varying many fathoms) than those on the other side, and produce an apparent irregularity of strata most perplexing to the geologist. Sometimes it happens that, without any irregularity of surface, two distinct strata appear to form a continuous line, as in the Black Down Hills in Devonshire. [CHALK FORMATION.] In some cases however dislocation is found without any alteration of the level of the strata on either side, but the appearance of the strata immediately adjacent to the fault sometimes affords proof of the action of fire. [COAL FORMATION.] Dykes are of two distinct characters, depending upon the manner in which they have been filled up, and the substance of which they are composed. Dykes of the first description are those into which igneous rocks are supposed to have been injected in a state of fusion, and now appear as a consolidated mass. [BASALT.] In the second the fissures are filled with the debris, sometimes mixed with clay, of the dislocated strata through which they pass. In some cases the fissure has evidently remained unoccupied for a long period, and the filling up has proceeded gradually from the sides inwards. This is observed very evidently in the carboniferous limestones of England and Wales. Sometimes, in consequence of the great length of time intervening between the production of each coating of calcareous matter, the outside of each is covered with crystals, upon which the next layer has been formed: in the central portions of such fissures cavities are by no means uncommon.

DYNASTES, a genus of Coleopterous Insects belonging to the section *Pentamera*, sub-section *Lamellicornes*, and family *Dynastidæ* of M'Leay. The species have the body very large and thick, the outer edge of the jaws sinuated or toothed, and the lower jaws corneous and toothed. The genus *Dynastes* embraces the largest and most robust forms of the insect kingdom. They are, nevertheless, quite harmless. None of the species are found in this country, and only one in France. The largest forms are found in the tropical parts of India and South America. The habits of these insects are much the same wherever found. They bury themselves by day in holes in the ground, or in the decaying trunks of trees. At night they are seen flying about the trees. The females are more numerous than the males, and do not possess the horns, which give the males so remarkable an appearance. The more remarkable species of this genus are the Elephant and Hercules Beetles. The latter is of a glossy black colour. In the males the thorax is developed into a thick and curved horn, which is bent downwards at the tip, a similar horn projects from below which points upwards, so as to come in contact with the former. The entire length of this beetle is 6 inches.

DYNO'MENE, a genus of Brachyurous *Crustacea* belonging to the division *Notopoda*, founded by Latreille. The ocular pedicles longer than those of *Dromia*. The shell is wide, nearly heart-shaped and truncated posteriorly, hairy or bearded. The two posterior feet only dorsal, and much smaller than the others.

D. hispida, the only species known to M. Latreille, is found in the Isle of France.

Dynomene hispida.

DYSCHIRIUS. [CLIVINA.]

DYSCLASITE, a Mineral consisting of hydrous silicate of lime. It occurs in white fibrous masses, consisting of delicate fibres of a whitish or yellowish or bluish colour. It has a hardness of 4·5, and a specific gravity of from 2·28 to 2.36. It is easily gelatinised in hydrochloric acid. It is found in the trap of the Faroe Islands. A variety called *Okenite* is from Greenland.

DYSDERA, a genus of Spiders. The species have 6 eyes, placed in a curve resembling a horse-shoe open in front; the mouth-claws very large, and produced in front; the maxillæ straight, and dilated at the place of insertion of the palpi. The type of the genus is *D. erythrina*, which is not an uncommon species in Great Britain. It is mostly found under stones.

DYSLUITE, a Mineral, a variety of *Spinel*. It occurs crystallised in regular octohedrons. Its cleavage is rather imperfect, parallel with the faces of the octohedron. The colour is yellowish-brown or grayish-brown. Fracture conchoidal. Hardness 4·5. Somewhat translucent, opaque. Lustre vitreous, inclining to resinous. Specific gravity, 4·551. It is found at Sterling, New Jersey, with *Franklinite* and *Troostite*. The following is an analysis by Dr. Thomson :—

Alumina	30·490
Oxide of Zinc	16·800
Peroxide of Iron	41·934
Protoxide of Manganese	7·600
Silica	2·966
Moisture	0·400

It becomes red before the blowpipe, but loses its colour on cooling.

DYSODIL. [COAL.]

DYSOPUS. [CHEIROPTERA.]

DYTI'SCIDÆ, a tribe of Pentamerous Coleopterous Insects, founded on the genus *Dytiscus* of Linnæus. It now includes the following genera :—*Pelobius, Matus, Coptotomus, Eunectes, Agabus, Ilybius, Colymbetes, Acilius, Hydaticus, Dytiscus, Cybister, Copelatus, Anisomera, Laccophilus, Noterus, Hydrocanthus*, and *Suphis*.

The insects composing these genera are almost all oval and flattened in form. They are very variable in size, some being very minute, others several inches in length. Their four posterior extremities are longer than the anterior, flattened, and ciliated. They are all aquatic insects, and organised for swimming, though at the same time capable of flying through the air with facility. They live in fresh water, and swim with great rapidity, chasing other water-insects, and seizing them with their anterior feet. Although capable of existing a long time under water, they are obliged to ascend at intervals to the surface to breathe. This they effect by remaining quiet, when their bodies, specifically lighter than the surrounding fluid, rise to the surface obliquely, their heads downwards, so that the extremity of the abdomen, at which the stigmata of the tracheæ are situated, is exposed to the air on reaching the surface. At night they fly from one pool to another, and hence are often met with in places flooded by temporary rains. The larvæ of the *Dytiscidæ* leave the water and bury in the earth before changing into pupæ. Thus they are at first aquatic insects, next terrestrial, and in their final stage amphibious.

The typical genus *Dytiscus* has engaged the attention of Dr. Aubé, who enumerates ten European, one African, and six American species.

DZEREN. [ANTILOPEÆ.]

E

EAGLE. [FALCONIDÆ.]

EAGLE-WOOD, one of those substances of which the name, from similarity of sound in a foreign language, has been converted into another having no reference to its original signification. It is a highly fragrant wood, much esteemed by Asiatics for burning as incense, and known in Europe by its present designation ever since the Portuguese visited and imported the substance direct from the Malayan islands and the kingdom of Siam, where it has always been abundant, and long established as an article of commerce. The Malayan name is Agila, whence the wood was called Pao-d'Agila by the Portuguese, and has since been converted into Pao-d'Aguila, and Pao-d'Aquila, Bois-d'Aigle, Eagle-Wood, and Agel-Hout.

From the Malayan Agila has probably been derived the Sanscrit Agara, whence we have the Hindoo Aggur, if not from the more familiar appellation of Garoo, by which Eagle-Wood is also known in the Malayan Archipelago. In Persian works on Materia Medica in use in India, we learn from Dr. Royle ('Illustr. of Himal. Bot.' &c.) that several kinds of fragrant wood are described under the Arabic name Aod (Haud and Ud of Garcias), and that he himself obtained three kinds in the bazaars of India, called Aod-i-Hindee, Aod-i-Chinee, and Aod-i-Kimaree (evidently the Al-Cemericum of Arabian authors); and that with the above Hindoo a Greek synonym, Agallochee, is also given, and more especially applied to Aod-i-Kimaree, which is also called Aod-i-Bukhoor, Incense-Wood. As Agallochee is no doubt a corruption of the Agallochum of Dioscorides, described by him as a fragrant wood from India and Arabia, it is interesting to find that the translators from the Greek into the Arabic of the school of Baghdad settled these synonyms at a time when they must have been well acquainted, from their profession and position, with the substances to which both the Greek and Arabic names were applied. Serapion and Avicenna describe several kinds of this fragrant wood, and the latter under both Agalugen or Aghaloojee, and Aod, which in the Latin version is translated Xyloaloe, a name that was applied by the later Greek medical writers to Agallochum, whence we have lignum aloes, lign-aloe, and aloes-wood, the origin of which it is difficult, if not impossible, to ascertain, unless we suppose it to be a corruption of Agila; for the bitter, scentless, spongy-textured stems of the genus Aloe could not afford any substitute for this fragrant wood, or be thought to yield it, at least by the Arabs, who were well acquainted with and accurately describe aloes, and the place, Socotra, where the best kind is found. Though Dioscorides notices only one, which some supposed to be the Tarum of Pliny, several kinds of Agallochum are described by Serapion and Avicenna, which, as it is not possible at present to identify, it is unnecessary to notice, and therefore we shall refer only to the three kinds which have been traced to the trees yielding them, by naturalists who have visited the countries where these are indigenous.

An *Aguila brava* (wild) is mentioned by Garcias as produced near Cape Comorin, in the southern part of the Indian peninsula, and in the island of Ceylon; but the tree yielding this wood has not been ascertained. Rumphius ('Herb. Amb.' ii. p. 40), describes two kinds of *Agallochum spurium*, found in Borneo and Sumatra, one of which he calls Garo Tsjampaca, which is described as having leaves and flowers resembling those of the celebrated Champa (*Michelia champaca*), and may be a species of the same genus. A third kind of spurious Agallochum, differing much from the others as well as from the genuine, he describes in another part of his work, ii. p. 240, as the produce of his *Arbor excæcans*, so called from the acridity of its juice blinding people, and which is the *Excæcaria agallocha* of Linnæus. Considering that Rumphius, in originally describing this tree, has said 'Lignum hoc tantam cum agallocha similitudinem,' and as affording a substitute for that substance, it is not surprising that it should be frequently quoted as the tree which yields the genuine agallochum, or aloes-wood. Fée ('Hist. Nat. Pharm.') states that he had seen a genuine specimen of the wood of this tree, and that its fragrance cannot be compared with the agallochum of Loureiro. Dr. Roxburgh mentions that the wood-cutters of the delta of the Ganges, though well acquainted with the highly acrid and very dangerous milky juice of this tree (there called geria), do not mention agallochum of any kind being found in this tree.

Of the two kinds of Agallochum which are most valued, and both considered genuine, one is distinguished by the name of Calambac, and the other as the Garo of Malacca.

The first, called Calambac, and Agallochum Primarium by Rumphius, appears, as far as hitherto known, to be a native of Cochin-China only, growing on the mountains of that country iu about 13° N. lat., near the great river Lavum, which may be the Meikeng flowing between Cochin-China and the Laos. This tree was named *Aloexylum agallochum* by Loureiro, 'Fl. Cochin-Chinensis,' p. 327, and placed by him in *Decandria Monogynia*, and described as a lôfty tree with erect stem and branches, long lanceolate shining leaves, terminal bunches of flowers, with a woody falcate 1-seeded pod for its fruit, whence it is referred by De Candolle to the natural family of *Leguminosæ*. Loureiro states that the wood of this tree is white and inodorous, and that its fragrance is the result of disease, when the oily portions thicken into resin in tho central parts of the tree, and that no part of the trec is milky or poisonous, but that paper is made from its bark in Cochin-China, as in Japan from that of the mulberry.

The next kind of Agallochum is that commonly called Garos, and to which the name of Eagle-Wood is more frequently applied, and which has long been an article of export from Malacca and the kingdom of Siam. Specimens of the tree which yields this were first obtained by M. Sonnerat in his second voyage to India, from which probably have been given the figure and description by Lamarck. ('Enc. Méth.,' 1. p. 49, Illustr. t. 376.) The plant he named *Aquilaria Malaccensis*. This, the Garo de Malacca, was introduced by Dr. Roxburgh into the botanic garden of Calcutta, and was not to be distinguished from specimens of a tree called Ugoon, which is a native of the mountainous tracts east and south-east from Silhet, between 24° and 25° of N. lat., which flowers in April, and ripens its seed in August, and which he says there can be little or uo doubt furnishes the real Calambac or Agallochum of the ancients; adding, that there seems more reason to think that it was carried to China from our eastern frontier, than to suppose it was carried from Cochin-China, or any other country in the vicinity of China, where it has always been in great demand. Small quantities are sometimes imported into Calcutta by sea, from the eastward; but such is always deemed inferior to that of Silhet. ('Fl. Ind.' ii. p. 423.) As the Malacca plant had not flowered, Dr. Roxburgh was unable to decide that they were positively the same with those from Silhet, and therefore named these *Aquilaria agallocha*, as another species of the same genus. By this name it has been figured in Royle's 'Illustr.' i. 36, f. 1, from a drawing by Dr. Hamilton of a plant which he called *Agallochum Officinarum*, and which he found near Goalpara, on the eastern frontier of Bengal. This drawing is illustrated with dissections by Dr. Lindley. [AQUILARIACEÆ.]

The fragrant nature of genuine Agila or Eagle-Wood is well known, and that it has from very early periods been employed both by the natives of India and of China as incense. Mr. Finlayson, in his visit to Siam, says that the consumption of this highly odoriferous wood is very considerable in Siam, but that the greatest part is exported to China, where it is used in a very economical manner. The wood being reduced to a fiue powder, and mixed with a gummy substance, is laid over a small slip of wood, about the size of a bull-rush, so as to form a pretty thick coating. This is lighted, aud gives out a feeblo but grateful perfumo. French authors inform us that the Eagle-Wood was burned as a perfume by Napoleon in the imperial palace.

Wo cannot conclude this subject without inquiring whether the substances of which we have been treating are the Lign-Aloes of Scripture, Ahaloth, masc. Ahel, whose plural is Ahalim. It would bo impossible to do justico to the subject in a small compass, or without referring to the numerous dissertations which have been written on it; but it may be observed, that these might have been much shortened, if the authors had been naturalists, or intimately acquainted with the natural history and usages of eastern countries. Such information would at least have prevented any species of aloe being considered or figured as the far-famed and fragrant Lign-Aloe from a mere similarity in sound. In the present instance, the difficulty is increased by the supposed necessity of reconciling the different passages in which Lign-Aloes are mentioned, as in Numbers, xxiv. 6, where it is mentioned as a tree planted; but in the three other passages, Proverbs, vii. 17, Psalms, xiv. 9, and Canticles, iv. 14, it is enumerated with the most fragrant products of the east, as cinuamon, cassia, calamus, camphor, frankincense, myrrh, spikenard, and saffron. Here we may observe, that a substanco which was indigenous in a country was not likely to have been an article also of commerce from a far country in those early times; and that therefore, as it is disputed whether the word shall be translated Tents or Lign-Aloes, tho word may perhaps be used in a poetical sense, as it is thought to be by some commentators. In tho three passages above referred to, it may be noted that, except sandal-wood, thero is no other substance which could be so well enumerated with those with which it is found in connectiou as the Agila-Wood of the East, whether we consider its high price, delicate perfumo, or the long time in which it has been held in high estimation, while the similarity of its name is at the same time remarkable.
